**Simple Acute Catarrh** is usually associated with catarrhal affections of the pharynx, and is most common in children. It is characterized by acute hyperæmia and swelling of the mucous membrane with increased secretion of mucus. Difficulty of hearing is an early symptom, and in some cases there is intense ear-ache radiating over the side of the head. Noises and throbbing in the ear are seldom absent. Examination of the ear shows the external meatus clear, some redness of the membrana tympani, with bulging in some cases. If left unrelieved the membrane occasionally perforates, after which cure takes place and the aperture heals, or the disease may become chronic. The *Treatment* in mild cases consists in the application of leeches behind the ear, and hot fomentations externally. At the same time the air should be blown into the tympanum at intervals by means of Politzer's bag: the mucus will usually escape when the air regurgitates from the cavity. If there is much bulging and acute pain, relief can be obtained more surely, and the risk of permanent damage to the ear avoided by puncturing the membrane by means of a small lancet-shaped knife specially constructed for this purpose, or a cataract needle. This operation is easy of performance; the speculum having been passed, and a good view of the membrane obtained, the puncture is to be made at the lower part of the membrane behind the handle of the malleus. The mucus may then be blown out by means of air-douches from Politzer's bag, or through the Eustachian catheter. The operation is usually followed by complete relief, and the small puncture soon heals, leaving the hearing unimpaired.

**Chronic Non-Purulent Catarrh** is a very common disease and a frequent cause of deafness. Two varieties are described : the dry and moist. *Dry catarrh* is a term applied to a chronic inflammation of the mucous membrane unaccompanied by any excess of secretion. It is most commonly met with in adults, and is usually associated with a similar condition in the pharynx. It leads to thickening of the mucous membrane, and finally causes deafness from immobility of the ossicles, and from the formation of adhesions between the membrane and the promontory on the inner wall of the tympanum. In *moist catarrh* there are swelling and hyperæmia with excessive secretion. It often affects the Eustachian tube chiefly, and may lead to its contraction or closure. If this takes place, the air in the tympanum soon becomes absorbed, and the membrane becomes abnormally concave. Noises in the ears and occasional pain are common. It is most commonly associated with pharyngeal catarrh. This condition is the common cause of so-called Eustachian or throat deafness. The treatment of chronic catarrh is usually not very satisfactory. The general health must be attended to, and the catarrh of the pharynx relieved by astringent applications, as nitrate of silver, glycerine of tannin, &c. At the same time the air must be blown into the tympanum at intervals by Politzer's bag, the Eustachian catheter, or by forced expiration with the nostrils closed. By this means the strain on the membrane is relieved and the mucus allowed to escape. Astringent injections into the tympanum by means of the catheter have been used, but their beneficial effect is somewhat uncertain.

**Acute Purulent Catarrh** is commonly a sequela of scarlet fever or measles. The symptoms may be acute like those of the acute non-purulent form already described, or perforation of the membrane may occur without any acute symptoms having manifested themselves, the first symptom being the discharge from the ear. After the pus has thus found exit the opening in the membrane may close and recovery take place, but in scrofulous children the suppuration may become chronic. It is very important in all cases of scarlet fever or measles, especially in scrofulous children, to keep a careful watch on the ear, as in many cases the complete destruction of the membrana tympani and loss of the ossicles might be prevented by early incision.

**Chronic Purulent Catarrh** may arise as a sequel of acute inflammation of the middle ear, or as the result of extension from without in diffuse inflammation of the meatus. In these cases the membrana tympani is always perforated. The symptoms are merely loss or dulness of hearing, with a chronic muco-purulent discharge from the ear, often having an extremely offensive smell. The consequences of purulent catarrh are frequently serious, and sometimes fatal. If unchecked the disease may lead to necrosis of the small bones, or to their becoming ankylosed and fixed by adhesions to such an extent as to be useless. The serious complications described below are especially apt to occur if the escape of the discharge is prevented, as by a mass of granulation tissue blocking the perforation in the membrane. In some cases the disease spreads to the bone surrounding the tympanum, and may cause extensive caries or necrosis. It is especially under these circumstances that facial paralysis may result from implication of the seventh nerve, as it lies in the aqueduct of Fallopius.

In the **Treatment of Chronic Purulent Catarrh** of the middle ear, the essential objects aimed at are complete removal of the purulent secretion as soon as it forms, and prevention of its decomposition. As the secretion diminishes,

astringent applications may be used to hasten its cessation. The removal of the purulent secretion is effected chiefly by frequent syringing of the ear with some antiseptic solution, and by blowing through the cavity either by Politzer's apparatus, the catheter, or simple forced expiration. The syringe must not be used forcibly, especially if the opening in the membrane is large. Hinton recommended that an india-rubber ball syringe with a nipple-like nozzle completely filling the external meatus should be used, by means of which the fluid may be made to flow through the ear into the pharynx. This should be done with steady gentle pressure. If too much force be used it causes giddiness or faintness. The head should be held forwards, so that the fluid that enters the pharynx may pass out at the nose. Decomposition is prevented by the use of antiseptic solutions, the best being chloride of zinc (gr. j to 3j), or a concentrated solution of boric acid. After the ear has been syringed the meatus should be carefully dried with cotton-wool. In many cases great benefit is obtained from blowing into it a small quantity of iodoform. When the opening in the membrana tympani is of sufficient size the cavity of the tympanum may be cleaned out by means of a fine probe with some cotton-wool wrapped round.

Under this treatment the discharge in most cases gradually ceases, and unless it be too large, the opening in the membrane heals. In cases in which there is insufficient exit for the discharge it may be necessary to enlarge the opening in the tympanic membrane to allow of more perfect cleaning of the cavity, whilst if prominent granulations are present these may be touched with a probe coated with nitrate of silver, or with a small wool mop moistened with the strong solution of perchloride of iron.

**Complications of Chronic Suppuration in the Middle Ear.**—Chronic suppuration in the middle ear derives its chief surgical interest from the serious nature of the complications which are liable to occur, among which may be mentioned mastoid abscess, suppuration between the dura mater and the bone, meningitis, abscess of the brain, septic phlebitis of the lateral sinus, and pyæmia.

**Mastoid Abscess** results from the direct extension of the suppuration from the cavity of the tympanum into the mastoid antrum and cells. Here the discharges accumulate and decompose, and finding an imperfect escape on account of the irregularity of the cavities, the pus gradually perforates the bone and appears beneath the skin. The mastoid antrum may be regarded as the most anterior of the mastoid cells, communicating in front with the cavity of the tympanum and behind with the other cells. It may correctly be regarded as a recess of the tympanum and differs from the other cells in being present at birth, and thus it serves as the sole starting-point of mastoid abscess in children. The collection of pus is but imperfectly drained by the opening into the tympanum, for as Macewen points out, this is above the level of the floor of the antrum. The *symptoms* of mastoid abscess are fever with occasionally rigors, pain behind the ear and radiating over the side of the head, and not rarely vomiting. The discharge from the meatus often ceases or is diminished in amount; local tenderness, often with œdema and redness, is present over the mastoid process, and there may be enlargement of the mastoid lymphatic gland and of those lying below the ear.

In some cases the severity of the symptoms suggests more serious intracranial complications, and the diagnosis is often obscured by the absence of

the local signs just mentioned. In some cases the pus works its way through the outer wall of the antrum and forms a superficial abscess behind the ear, which may burst spontaneously and leave a sinus.

**Treatment.**—In a case presenting symptoms of pent-up pus in which no relief has followed the removal of any existing obstruction in the external meatus, and certainly in every instance in which the characteristic signs of mastoid abscess are present, the Surgeon should at once proceed to open up the mastoid antrum. The surrounding scalp having been shaved and rendered aseptic, an incision should be made about half an inch behind the ear, curving slightly forwards at the upper part above the attachment of the auricle, and terminating below at the tip of the mastoid process. The pinna is then pulled well forwards and the bone exposed and examined. In rare cases it may be found that an opening has already formed, which must then be enlarged with a gouge. More commonly the periosteum is loosened or raised by pus without any opening existing. To reach the mastoid antrum the bone must be cut away with a small gouge, at a point immediately above and behind the intersection of two lines—one drawn vertically through the posterior border of the auditory meatus, and the other horizontally through its upper margin (Fig. 663). This point lies in the area for which Macewen has suggested the name of the “suprameatal triangle;” it is bounded by the posterior root of the zygoma above, the upper and posterior part of the bony meatus below, and an imaginary line drawn perpendicularly upwards from the most posterior part of the meatus. After cutting away a comparatively thin layer of bone the antrum is reached, after which the remaining cells may be broken into with a strong probe. All inspissated pus and granulation tissue may then be cleaned out with a small sharp spoon. Various special instruments have been devised for cutting away the bone, such as small trephines and drills, but the operation is much more safely performed with a gouge and mallet. If the bone be cut away too far back, there is danger of wounding the lateral sinus (Fig. 663), and for this reason the instrument must never be directed backwards. After the cells are opened, it is advisable in some cases to cut away part of the bony wall of the meatus. A metal or india-rubber drainage-tube is then inserted and some antiseptic solution syringed through it daily. By the timely performance of this operation many patients may be saved from the dangers of intracranial suppuration.

Fig. 663.—Temporal Bone showing position of Lateral Sinus and the point (x) from which the Mastoid Antrum may be reached.

**Extradural Abscess.**—In this condition suppuration occurs between the dura mater and some part of the temporal bone, often as the result of extensive necrosis of the tympanum or mastoid. Barker finds that the two most common situations of extradural abscess are the neighbourhood of the petro-squamous suture and the lateral sulcus, the former especially in children.

In either situation there is great danger of septic meningitis, and when the lateral sulcus is affected there is the additional risk of septic phlebitis of the sinus. An extradural abscess may perforate the squamous bone above and behind the meatus, or discharge through the roof of the tympanum. No special *symptoms* are caused by this complication beyond those due to pent-up pus; it is, however, often associated with more serious intracranial mischief, the symptoms of which will mask those of the abscess itself. The *Treatment* consists in laying open the mastoid in the way already described, and affording drainage to any extradural collection of pus by the careful removal of bone with the gouge. The roof of the tympanum, and the superior surface of the petrous bone, may readily be explored by applying a small trephine, as suggested by Ballance, at a point a short inch above the centre of the external auditory meatus, and carefully separating the dura mater from the bone at the lower border of the opening.

**Septic Phlebitis of the Lateral Sinus** is a most serious complication of chronic suppuration in the middle ear, and is most commonly met with in adults. The inflammation usually affects that part of the vein which lies in the groove on the mastoid; it may be due, as we have already seen, to necrosis and extradural abscess in the lateral sulcus, but may occur without these, as the result of the spread of inflammation along the small veins entering the sinus from the bone. The special danger of this complication is embolic pyæmia due to the disintegration of the septic thrombus.

The *symptoms* of septic phlebitis of the lateral sinus are not always sufficiently characteristic to distinguish it from other forms of intracranial suppuration, with which, indeed, it may be associated. Amongst the most important symptoms may be mentioned irregular elevation of temperature with often-repeated rigors, vomiting, and severe pain in the temporal region. With these may be associated swelling over the mastoid, enlargement of the cervical glands, and perhaps tenderness and induration along the upper part of the internal jugular vein, due to extension of the inflammation below the jugular foramen. In addition, evidences of meningitis or pyæmia often manifest themselves, so that Macewen recognizes three types of symptoms—pulmonary, abdominal, and meningeal. The pulmonary symptoms are those due to embolism of the lungs, whilst in other cases diarrhoea is a marked feature, and the general resemblance to typhoid fever may be close.

The *Treatment* will, in the first instance, usually be exploratory, and directed to investigate the condition of the sinus in a case in which septic phlebitis is suspected. This will usually be done by carefully enlarging backwards the opening already made into the mastoid antrum (Fig. 663), but if it be done independently of this a small trephine should be applied, as suggested by Ballance, at a point one inch behind the centre of the external auditory meatus and a quarter of an inch above Reid's base line—a line drawn from the lower border of the orbit through the centre of the external auditory meatus. The opening may be carefully enlarged with bone forceps in the direction of the sinus. If it be doubtful whether the vein is thrombosed or not, an exploring needle or small trocar may be introduced, when the escape of fluid blood will clear up the doubt. If, however, the vein contains a septic thrombus, the only available treatment consists in freely opening the sinus and clearing it of the disintegrating clot, by careful flushing with 1 in 4000 mercurial solution. The risk of bleeding is small, as the coagulum extends beyond the

part in which disintegration has occurred ; in the event of hæmorrhage it may readily be arrested with antiseptic gauze plugs. This treatment of the sinus is necessarily attended with considerable risk of the entry of septic matter into the vein on the cardiac side ; a danger which may be diminished by the preliminary ligature of the internal jugular vein in the neck, as suggested by Horsley. This has been done in a considerable number of cases by Arbuthnot Lane, Ballance, Rushton Parker, and others. The vein should be exposed in the neck before the lateral sinus is opened, and divided between two ligatures, care being taken that this is done below any part of the vessel which is inflamed. This treatment has been adopted successfully in several most desperate cases, even after the development of secondary foci in the lungs and elsewhere.

**Septic Meningitis** due to middle ear disease is often associated with other complications, and as a rule must be regarded as necessarily fatal. The *Symptoms* are identical with those of the form which sometimes complicates fracture of the skull (Vol. I., p. 771). The *Treatment* will as a rule be confined to that of the mastoid or extradural suppuration to which the meningitis is directly due. In a case under the care of Barker, in University College Hospital, an abscess, apparently resulting from a localized meningitis in the Sylvian fissure, was successfully treated by drainage. The patient, who was deeply comatose and partially hemiplegic at the time of the operation, made a complete recovery. It is certainly open to question, however, in this case whether the primary seat of the suppuration was not in the substance of the temporal lobe.

**Abscess of the Brain** is a complication occasionally met with, apparently as a consequence of septic phlebitis. It is most commonly seated in the temporal lobe, but, especially when the mastoid is implicated, it may form in the cerebellum. The relative frequency of abscess below the tentorium is said to be greater in adults than in children. When the temporal lobe is affected the abscess will usually be found, according to Barker, between two vertical lines, one through the tragus and another two inches further back ; cerebellar abscess is usually found in the anterior part of the lateral lobe. The *Symptoms* of abscess of the brain are often obscured by the other conditions, such as extradural suppuration and meningitis, with which it may be associated. In an uncomplicated case the signs are the same, as those of abscess following injuries of the head (Vol. I., p. 775). The most marked are headache, vomiting, slow cerebration, gradually increasing insensibility, and optic neuritis. A very slow pulse and a temperature often below normal are very characteristic symptoms. The symptoms as a rule come on slowly and insidiously, but their onset may be marked by a severe rigor. Unless relieved by treatment, abscess of the brain is necessarily fatal, the patient either gradually becoming comatose or dying somewhat suddenly as if from apoplexy, apparently from bursting of the abscess into the ventricles.

The **Diagnosis of Abscess of the Brain** is often rendered difficult by its association with other intracranial complications such as septic thrombosis and meningitis. The diagnosis can be made with comparative certainty when a slow pulse and low temperature are present together. Optic neuritis cannot be taken as proof of the existence of abscess, nor does its absence exclude abscess if the other characteristic symptoms are present. It may occur in cases of meningitis and of phlebitis of the lateral sinus, and has indeed been met

with in cases of chronic ear disease in which no clinical evidences of intracranial complications were present. Barker has recorded two cases of this nature, in both of which there was mastoid disease, and in one pus in the lateral sulcus. In another case under the care of Sainsbury and Battle symptoms suggestive of cerebral abscess, including double optic neuritis, were completely relieved by treatment of the tympanum and mastoid cells.

In endeavouring to decide whether a suspected abscess of the brain is in the temporal lobe or in the cerebellum, it must be remembered that in either position no localizing symptoms are, as a rule, present. A large abscess in the temporal lobe may occasion weakness of the opposite side of the body from pressure on the motor cortex or internal capsule, paralysis of the third nerve, and, when the left side is affected, aphasia. In two cases of large cerebellar abscess Macewen noted a condition of extreme depression and prostration, with retraction of the head, and extremely feeble slow pulse and respiration. There was also rigidity of the masseter, and in one case paralysis of the arm and leg on the same side as the lesion.

*Treatment.*—Considering the severity of the symptoms occasioned by the accumulation of decomposing discharges in the tympanum and mastoid, it will usually be advisable to open these freely before proceeding to other measures. If the symptoms point clearly to abscess of the brain, the only chance of saving the patient is to trephine and let out the pus. This operation has now been performed in a large number of cases by Hulke, Barker, Caird, Macewen, Bergmann, and others.

The first case in which a cerebral abscess secondary to ear disease was diagnosed from localizing symptoms and operated upon during life was under the care of Macewen in 1881. The patient, who was *in extremis* at the time of the operation, died six hours afterwards.

The first successful case was that performed by A. E. Barker on a patient under the care of Gowers in 1886. The abscess contained nearly an ounce of foetid pus, yet the patient perfectly recovered without any apparent impairment of function. Barker recommends that the mastoid foramen should be examined as a preliminary step. If the vein passing through it is thrombosed, or if pus is escaping beside it, it is probable that the collection of pus is below the tentorium. If there is reason to believe the abscess to be in the temporo-sphenoidal lobe, Barker advises that the pin of the trephine be placed an inch and a quarter above a line drawn from the lower margin of the orbit through the centre of the meatus of the ear, and the same distance behind the centre of the auditory meatus (Fig. 664 D). The dura mater must be divided, any branches of the meningeal artery being ligatured and the substance of the brain examined by means of a hollow needle thrust in various directions, or better, with a special instrument devised by Horsley which has fine blades which can be slightly separated after it is pushed into the brain. If pus is found, the opening may be enlarged by means of sinus-forceps, and a drainage-tube inserted. A metal tube about the size of a No. 8 catheter was used in Barker's case and found to keep in better than the ordinary india-rubber tube.

If the abscess is in the cerebellum, Barker has found by observations on the dead body that the best point to apply the pin of the trephine is an inch and a half behind the centre of the meatus, and an inch below a line drawn from the lower border of the orbit through the centre of the meatus of the

ear (Fig. 664 C). This will avoid the lateral sinus completely. The bone is exposed by an incision carried backwards from the mastoid process along the superior curved line of the occipital bone for about two inches. The periosteum and soft parts are then stripped off with an elevator till the inferior curved line is exposed, immediately below which the opening may be made. The bone here is excessively thin, and can easily be broken through with a gouge.

In a case of cerebellar abscess successfully treated by Dean the trephine was applied at a point an inch and a quarter behind the external auditory meatus and a quarter of an inch above the base line. Through this opening the lateral sinus was first examined. By enlarging the opening upwards and forwards the temporal lobe was explored, and no pus being found the opening was next

Fig. 664. — Diagram showing positions for Application of Trephine in Temporal Abscess (D) and Cerebellar Abscess (C). A B, Reid's base line.

enlarged downwards and backwards and pus found in the cerebellum by incising the dura mater below the sinus. The same method was successfully employed in a case recorded by Winter and Deanesley.

These operations have on the whole been very successful, the most remarkable series being that recorded by Macewen. Of 9 cases of abscess in the temporal lobe operated on by that Surgeon, 8 recovered, the only fatal case being the one above mentioned, whilst 4 cases of cerebellar abscess submitted to operation were all successful.

**Pyæmia** as a result of middle ear disease needs no special description. It is especially apt to occur in cases of septic phlebitis of the lateral sinus (p. 582) but is sometimes met with independently of that condition.

**Polypus.**—Polypi of the ear, in the great majority of cases, spring from the tympanum, and project through an opening in the membrane in cases of chronic suppuration in the tympanum. They are rarely met with springing from the external meatus. They are usually firm and fleshy-looking, though sometimes soft and gelatinous, and composed simply of granulation tissue, sometimes pedunculated, but at others situated on a broad base.

They may be a source of danger by blocking the meatus and preventing the escape of discharges. The treatment should consist in removing the polypus with a wire snare or small sharp spoon. Before doing this it is

generally advisable to use antiseptic injections and iodoform for a few days previously. After the operation means must be taken to cure the purulent catarrh upon which the growth is dependent.

**Nervous Deafness** is recognized by the absence of the symptoms of any of the foregoing diseases, or of the history of their occurrence, and by the fact that a vibrating tuning-fork is either not heard at all or imperfectly heard when it is placed upon the vertex or on the mastoid. As it is not amenable to surgical treatment, it is needless to discuss here its causes or pathology.

#### DISEASES OF THE NOSE.

**EXTERNAL AFFECTIONS OF THE NOSE.**—**Acne Rosacea** is an affection of the skin of the nose, in many cases distinctly resulting from alcoholic excess, in others, especially in women, being apparently connected with chronic dyspepsia. It commences as a red spot on which dilated capillaries are visible, and extends gradually over the whole tip of the nose and often to the adjacent parts of the face. At first the sebaceous follicles are not affected, but later on they usually become enlarged, making the surface more or less tuberculated. Some thickening of the skin usually occurs at this stage. The treatment consists in correcting evil habits in drinking or eating, and attention to the digestion and general health. Locally, iodide of sulphur ointment is useful.

**"Lipoma Nasi"** is a chronic hypertrophy of the cutaneous and subcutaneous

Fig. 665.—"Lipoma Nasi" before operation.

Fig. 666.—Same Nose after Operation.

structures, forming a large reddish-blue, vascular-looking, soft, and lobulated mass, enveloping the end of the nose, and producing excessive deformity of it. There are all degrees of this disease, from mere clubbing of the end of the organ, to the formation of a set of pendulous lobular tumours attached to it. The sebaceous glands are greatly enlarged in this disease, often reaching the size of small pens. The patient's appearance may be greatly improved by the removal of these growths, as is shown in Figs. 665, 666, taken from a

patient operated on in University College Hospital. This may be done readily enough by making an incision down the mesial line to the alar cartilages, and then dissecting the hypertrophied tissue off these on each side; especial care, however, being taken in doing this not to encroach upon the nostril. This is best avoided by directing an assistant to keep his finger in it while the dissection is being carried out, so that he may warn the Surgeon of the too near approach of the knife. The surface is then left to granulate and cicatrize.

**Lupus, Squamous Carcinoma, Rodent Ulcer, and Tertiary Syphilitic Ulceration** are all common in the nose. Lupus especially may be looked upon as almost specially affecting this organ, destroying one or both alæ, the columna, or perhaps the whole of the nose. The consideration of the nature and treatment of these affections in this situation presents nothing special (*see* Chapter XXXVII., Vol. I.); but the cure of the deformities induced by them, which is full of interest to the Surgeon, will be considered in detail when we speak of the plastic operations that are practised on the face.

**Ulcers and Fissures**, of a less serious character, though very painful and

Fig. 667.—Nasal Speculum.

Fig. 668.—Fränkel's Nasal Speculum.

chronic, often occur at the angle of the ala and septum, or between the ala and the tip. Their *Treatment* consists in touching them from time to time with nitrate of silver, or in the application every night of white precipitate or citrine ointment; at the same time that the general health is attended to, and the strength restored, by the administration of tonics.

**AFFECTIONS OF THE NASAL CAVITY.—Examination of the Nasal Cavity.**—The nasal cavity may be examined from the front by means of the nasal speculum. This is introduced so as to dilate the nostril, and a strong light is then thrown in by means of the laryngoscopic mirror. The speculum shown in Fig. 668 will be found most convenient, as it does not require to be held, and thus leaves the Surgeon's hands free. The posterior nares can be examined by the laryngoscope, the mirror being held in the reversed position. The patient is placed in the same position as for examining the

larynx (see Diseases of the Larynx), but the tongue is not drawn out. The uvula is then drawn forward with a small curved spatula, or the patient may be told to bend the head slightly forwards, breathe out through the nose, and say "on" nasally as in French. The mirror is then inserted till it is close to but not touching the posterior wall of the pharynx. The handle may be slightly bent with the concavity of the curve towards the tongue. The mirror should be of small size, and should be joined to the stem at a very obtuse angle. It should be passed first on one side and then on the other of the uvula, the shank being used to depress the tongue, or if that organ is difficult to control, a tongue-depressor should be used with the left hand, whilst the mirror is held in the right. The examination is much facilitated by rendering the parts insensible with a 20 per cent. solution of cocaine applied with a brush. The posterior nares can also be examined digitally by passing the finger behind the soft palate.

**Deviation of the Septum.**—This may be the result of injury or a congenital malformation. It is seldom of any importance, but should it exist to such an extent as to obstruct one nostril it may be necessary to remedy the deformity by operation. This may be done by forcibly bending the septum into its proper position with some blunt instrument passed up the nostril. Should this be impossible, the part of the cartilage obstructing the nostril may be cut away, care being taken not to remove so much as to cause sinking in of the nose.

**Chronic Catarrh,** in the form of a thin watery mucous discharge, lasting for many months, is occasionally met with, more particularly in young women, independently of any structural disease of the mucous membrane. The *Treatment* of this affection consists in the employment of tonics and means calculated to strengthen the system generally, and the local application of astringents, such as tannin, chloride of zinc, &c. But under any plan of treatment this affection is apt to prove rebellious.

**Watery Discharge from the Nose.**—Paget has recorded a case in which a clear watery fluid of a specific gravity of 1004, containing a trace of albumen and a considerable quantity of chloride of sodium, flowed steadily at the rate of a drop every five or six seconds from the left nostril. The fluid exactly resembled cerebro-spinal fluid. Following the practice of Brodie in a similar case, Paget administered sulphate of zinc internally, and injected the nostril with a solution of the same substance, and under this treatment the discharge ceased. The flow commenced six months after a severe blow on the forehead. The patient subsequently died of meningitis, the inflammation being most marked about the under surface of the frontal lobes, but no communication was found between the nasal fossæ and the subarachnoid space. In the left antrum, however, were found two broad-based polypoid growths which Paget believes to have been the cause of the discharge.

**Ozena.**—By the term Ozena is meant a chronic muco-purulent discharge from the nose, having a peculiar and most offensive smell. It may arise in some cases without evident cause, and is then called *simple*; but more commonly it is due to *sypilitic* or *strumous* disease in the nasal fossæ, accompanied by ulceration of the mucous membrane or necrosis of the bones. The *treatment* necessarily varies with the cause of the disease, and will be discussed with the affections that give rise to it, but from whatever cause it may arise the nasal cavity must be thoroughly washed out twice a day at least to remove

the offensive discharge. This can be done efficiently by means of the "*nasal douche*." This consists of an india-rubber tube about three feet long, to one end of which is fixed a nipple-like nozzle, and to the other a metal tube bent into the shape of a siphon. It is thus used: The tube is first filled with water and the siphon end hung over the edge of a jug or tumbler containing the fluid to be injected into the nose. The patient then holds his head over a basin, and breathes through the mouth, which must be kept open. The nipple end of the tube is now placed in the nostril, and the vessel holding the fluid to be injected is raised about two feet above the patient's head. As the patient is breathing through the open mouth, the soft palate is curved backwards against the posterior wall of the pharynx, and shuts off the nasal part of that cavity; the fluid, therefore, passes out at the opposite nostril, thus washing out both nasal cavities and the part of the pharynx above the soft palate. The fluid used should contain some antiseptic, as Condyl's fluid, chloride of zinc (gr. j to 3j), a concentrated solution of boric acid, or sulphate of zinc (gr. ij to 3j). After the nose has been thoroughly cleaned, a deodorizing solution may be blown into it by a nasal apparatus, which should be fitted with nozzles adapted both for the posterior and the anterior nares. In using the former the nozzle must be passed up behind the soft palate. G. V. Poore recommends the following powder to be taken as snuff: Biborate of sodium, nitrate of bismuth, aa 3j; disulphate of quinine, gr. x; iodoform, gr. v.—The snuff may be used two or three times a day, care being taken to wash it out thoroughly each day with the nasal douche.

**Simple Ozena.**—A very foetid discharge from the nose will occasionally occur in delicate or strumous children while cutting their teeth, and may continue for several years. It may arise also after one of the acute specific fevers, especially scarlatina or measles. Sometimes it occurs at a later period, chiefly in women. The mucous membrane is swollen and red, but the disease is not necessarily attended with ulceration, although this may take place if the foul discharge is allowed to accumulate. In all cases of obstruction of one nostril with offensive discharge in children the presence of a foreign body should be suspected. The *Treatment* consists in the use of the nasal douche or spray, after which some astringent application may be applied. Glycerine of tannin will often be found of great use. It may be applied by means of a camel's-hair pencil through the nostrils, and in most cases it is necessary also to pass a long brush on a bent stem from the mouth behind the soft palate, so as to reach the upper part of the pharynx and the posterior nares. In young children the teeth and stomach must be attended to.

**Chronic Thickening of the Schneiderian Membrane or Hypertrophic Catarrh.**—The mucous membrane of the nose is not unfrequently chronically inflamed, especially in strumous children; that portion of the membrane covering the turbinate bones becoming thick, soft, and vascular, and projecting like a broad fringe from their surface. It is usually of a bright red colour, and covered with muco-pus without offensive odour. This swelling at all times produces snuffling and a peculiar intonation of voice, but increases in wet weather, and then may become so great as seriously to obstruct the breathing.

**Nasal Reflex Neuroses.**—Chronic nasal catarrh with hypertrophic changes in the mucous membrane occasionally gives rise to various reflex nervous phenomena, amongst which may be asthma, spasmodic sneezing and

cough, megrim, supra-orbital neuralgia, vascular disturbances of the face, vertigo, and it is said even epilepsy. These are said to be always accompanied by hyperemia of the excessively vascular tissue which exists in the mucous membrane of the free edges of the inferior and middle turbinate bones. A cure may be effected by the destruction of the swollen mucous membrane with the galvanic cautery, or by the application of a strong caustic, such as chromic acid. There can be little doubt that the frequency of these reflex neuroses has been greatly exaggerated by some enthusiastic specialists, particularly in Germany, but at the same time the evidence that they occasionally occur is practically conclusive. In all cases, therefore, in which the above conditions are met with, the nasal cavities should be examined, and if the mucous membrane covering the margins of the turbinate bones appears swollen or thickened, it may be cauterized with a fair hope of giving relief.

**Abscess** occasionally forms either in the mucous membrane or on the septum, and thus may lead to necrosis of the cartilages and bones, separation of these, flattening of the nose, depression of its bridge, and great deformity. These various forms of abscess, followed by necrosis, are commonly syphilitic, and result from softening gummata beneath the mucous membrane or periosteum, and are associated with ulcers and a foetid discharge, which has a tendency to cake upon the surface, forming dark and rugged crusts, constituting the condition known as *Syphilitic Ozæna*. A similar condition may be met with also without any evidence of syphilitic infection. This most commonly occurs in strumous subjects, and is usually associated with enlargement of the glands at the angle of the jaw. Such a condition would be described as *Strumous Ozæna*. Ulceration in the nasal cavity may in some cases be consequent upon the irritation of decayed teeth, producing disease of the antrum, and escape of morbid secretion from this into the cavity of the nose.

The *Treatment* of these conditions must be conducted by the use of the nasal douche or spray, followed by the application of solution of nitrate of silver, sulphate of copper or bichloride of mercury, one or two grains to the ounce. The snuff above mentioned will often be found very useful. In extreme cases it may be necessary to destroy the hypertrophied mucous membrane covering the inferior and middle spongy bones by the galvanic cautery or by the application of some caustic, chromic acid being one of the best. If this is not successful, a portion of the spongy bones may be removed so as to restore the passage through the nose. In syphilitic cases the general treatment of syphilis must be carried out, iodide of potassium or mercury being administered according to the condition of the patient. In strumous cases, codliver-oil and iodide of iron are most useful. When necrosis occurs, it must be treated as described below.

**Necrosis** not unfrequently occurs in the loose bony structures lying in the nasal fossæ or in the nasal bones themselves. In these cases the septum nasi participates in the morbid process, and commonly separates or is perforated.

Necrosis may occur in these situations either as the result of syphilis, the abuse of mercury, or from external injury. It is also met with in workers with arsenic or chromic salts. I have, however, seen cases, more particularly in women and children, which are not referable to any of these causes, or indeed to any other external exciting cause, and in which scrofula was pro-

bably the occasion of the disease. Perforation of the septum has also been observed as a congenital malformation.

The presence of the necrosis may be suspected from the great fœtor that infects the breath, of which the patient himself is unconscious ; and its existence may always be positively determined by exploration of the nasal cavities with a probe.

The *Treatment* is simple, and must be conducted on ordinary principles. If the general health be impaired, or if the disease be specific, appropriate constitutional treatment must be adopted. The fœtor may be lessened by the nasal douche and antiseptic applications. As soon as the bone is loosened, it must be extracted with polypus-forceps, coming away in soft black crumbling, offensive masses. There is often abundant hæmorrhage after this extraction, but I have only once seen serious trouble result from this cause. The patient, who was of intemperate habits, suffered from extensive destruction of the hard palate and bones of the nose. An attempt was made to remove a sequestrum, when a sudden gush of blood took place which rapidly proved fatal, partly by entering the lungs and partly from syncope. If hæmorrhage occurs, plugging will in most cases easily arrest it.

In cases of obstinate ozæna in which necrosis is suspected, or in which the sequestra cannot be removed by the nostril, Rouge, of Lausanne, recommends that the nasal cavity should be opened by an incision made from the mouth at the reflection of the mucous membrane from the gums to the upper lip. The cartilages are separated, and the septum cut through with strong scissors sufficiently to allow the upper lip and nose to be pulled upwards for a sufficient distance thoroughly to expose the nasal cavity. By removing sequestra in this way, Rouge cured several cases of most obstinate ozæna. After the operation the nose is replaced, and no scar or other deformity results.

**Calculi**, or **Rhinoliths**, are occasionally met with in the nasal fossæ, where they simulate foreign bodies, and may keep up considerable irritation and offensive discharge ; and here extraction may be practised with a pair of forceps. But sometimes they are situated under the mucous membrane. In two cases I have dissected round calcareous bodies of this kind, of about the size of cherry-stones, from under the mucous membrane of the ala of the nostril in children.

**Epistaxis**, or bleeding from the nose, is very common in children and in young people about the age of puberty, more particularly in girls, antecedently to the menstrual period ; it may either be active or passive, but is most usually dependent on congestion of the mucous membrane. In the adult it is more serious, and it may then be dependent on one of two very opposite conditions—either on a state of plethora with tendency to cerebral congestion, or on an anæmic and cachectic state, in which the blood is thin, and does not coagulate readily. In the first condition, it is often a salutary relief to the system, but when occurring in cachectic, anæmic, and especially aged people, it becomes of very serious moment ; and the loss of blood may be so considerable that, unless active means be adopted, a fatal termination may ensue. When epistaxis proves fatal, it is by its constant recurrence. In these cases, I believe, the nasal hæmorrhage is always associated with a broken-down and unhealthy state of the constitution, dependent upon chronic visceral mischief, especially granular contracted kidney and cirrhosis of the liver. The worst and most intractable cases that I have seen have been

connected with hepatic disease and jaundice. Epistaxis is in some cases associated with purpura; more rarely it occurs in patients suffering from hæmophilia. It is sometimes a prominent symptom in sarcoma of the bones of the nose.

*Treatment.*—Epistaxis must not be treated simply as a local disease of the nose. It is usually only a symptom of some constitutional condition or visceral disease that must be remedied before the hæmorrhage can be expected to cease. Hence it is of the first importance to treat on ordinary medical principles those states of plethora or cachexy with which it may be associated, or those conditions of disease of liver or of kidney that are met with in persons suffering from it.

In young people, otherwise healthy, and in slighter cases, epistaxis may commonly be arrested by the employment of ordinary domestic means, such as pinching the nostrils between the finger and thumb or the application of cold to the nape of the neck and forehead. The patient should be placed in the recumbent position with the arms raised above the head. The return of the epistaxis may be prevented by the use of purgatives, or in girls by attention to the proper regulation of the menstrual function.

In plethoric adults the flow should not be too suddenly checked, especially if the pulse be very hard and incompressible. Should it prove very abundant, dry cupping between the shoulders, and the application of an ice-bag to the forehead, with rest, will be required.

In anæmic subjects, and in old people, the hæmorrhage is often dangerous, and requires the use of active measures for its suppression. In these cases the following plan should be adopted. The head should be raised, an ice-bag applied to the forehead, complete quietude enjoined, and gallic acid in ten-grain doses, or half-drachm doses of the tincture of ergot or of tincture of hamamelis, administered at frequent intervals. Should the bleeding still be profuse and continuous, a current of iced water may be made to flow through the nose by means of the nasal douche, or the interior of the nose may be sponged out with a solution of perchloride of iron or tannin. Ergotine may be given in three-grain doses as an injection into the muscles of the back. If the nose be carefully dried with cotton-wool and examined with a speculum, it may happen that a definite bleeding point can be seen to which the actual cautery or some styptic solution can be applied. If none of these means succeed, it will become necessary to plug one or both nostrils. This may be done by carefully pushing into the nostril some strips of lint soaked in a strong solution of tannic acid. Each strip should have a string attached to it to make sure that it is not lost in the nasal cavity. A piece of dried sponge, having a quill or a piece of gum catheter passed through it for breathing purposes, may be used instead of lint. Perchloride of iron should be used only as a last resource, as it is apt to cause ulceration of the mucous membrane. Various forms of nasal tampon have been devised; the essential feature of all being a thin india-rubber bag, which can be introduced in the collapsed state into the nostril and distended with air or water. If any one of these be at hand it forms by far the best means of plugging the anterior nares.

Should the hæmorrhage still continue, the blood passing back into the throat, and perhaps being swallowed, the posterior nares require to be plugged as well. This operation should, however, be deferred until it becomes absolutely

necessary for the preservation of life. Plugs in the posterior nares behind the soft palate are a source of very great distress to most people, and in old persons will rapidly cause exhaustion by interference with the breathing and sleep. I believe that by attention to proper constitutional and by perseverance in milder local treatment plugging of the posterior nares may commonly be avoided. When absolutely required it is best done by carrying a long piece of strong whip-cord along the floor of the nose through the posterior nares into the pharynx, by means of Bellocq's sound (Fig. 669), or, if this be not at hand, by threading the cord through an elastic catheter, and carrying this into the pharynx, then seizing the cord as it appears behind the soft palate, and drawing it forwards into the mouth, at the same time that the catheter is taken out of the nostril. In this way the string will pass through the nose, round the back of the soft palate, and out of the mouth (Fig. 670). To the middle of the piece of string that hangs out between the

Fig. 669. — Bellocq's Sound.

Fig. 670. — Diagram of Plugging the Nostril by means of Bellocq's Sound.

lips, a plug of lint, about the size of the first joint of the thumb, or better still, a piece of compressed sponge, should be firmly tied; this is then drawn up into the posterior nares by pulling on the end of the ligature that hangs from the nose, being guided in its passage behind the palate by the fingers introduced into the mouth. When the bleeding has ceased, it may readily be withdrawn by means of the string that hangs out of the mouth. As the epistaxis is very apt to recur, it is a wise precaution, when the plug is removed from behind the palate, to leave a loop of string in the nose and mouth, which may be knotted and fixed by a slip of plaster behind the ear. In this way the plug may, if necessary, be readily replaced without the necessity of re-introducing the sound or catheter through the nose.

#### TUMOURS OF THE NASAL FOSSE.

**POLYPUS.**—Tumours of very different structure and composition are met with in the nostrils: and to all of those which possess the common characters of being pendulous and blocking up these passages, the term *Polypus* is given.

Thus Surgeons commonly speak of the *Benign*, the *Soft*, the *Gelatinous*, or *Mucous Polyp*, as well as the *Sarcomatous*, or *Fleshy*, and the *Malignant Polyp*. The term, however, should properly be confined to a soft and pendulous mucous growth; the fleshy and malignant polypi being mere varieties of fibrous, myeloid or other sarcomatous tumours, springing from the bones in the nasal fossæ, or from the ethmoidal and sphenoidal cells.

The true **Mucous Nasal Polypus** is a soft, moist, gelatinous tumour, of a greyish-yellow colour when lodged in the nasal fossæ; but when it descends into the anterior nares, or beyond them, and is exposed to the air, it becomes of a reddish-brown or purple tint, and somewhat shrivelled on the surface. It is usually lobulated, pedunculated, or bottle-shaped; and not very vascular except at the root, where it is permeated by thin-walled vessels that bleed freely on the slightest touch. In structure it is soft and homogeneous to the naked eye. If cut across and squeezed a large quantity of sticky fluid flows from it, and the mass becomes reduced to a small proportion of its original bulk. Mucous polypi are covered completely by mucous membrane with ciliated epithelium, the cilia of which may be seen in active movement under the microscope after removal. The mucous membrane may or may not contain glands; occasionally the surface is pitted by the orifices of glands of considerable size. The tissue which forms the bulk of the tumour is composed of delicate bands of connective tissue separated from each other by an abundant mucous fluid. Amongst the fibres are numerous cells either rounded or presenting the stellate form found in true myxomatous tissue (see *Myxoma*, Vol. I., p. 1026). The whole mass is abundantly supplied with vessels. Occasionally polypi are found growing from the lower part of the nares, covered with tessellated epithelium. The tumour may grow from any point of the surface of the turbinate and ethmoid bones, and has indeed, though very rarely, been observed to project into the nose from the frontal sinuses and antrum. Polypi most frequently grow from the middle spongy bone, sometimes from the inferior turbinate bone, and in rare cases they are said to have been seen springing from the roof of the nares, but never from the septum. They are usually numerous and of all sizes; as they increase they commonly extend forwards into the anterior nares, but, when large, they may be seen to reach into the pharynx, hanging down behind the palate.

The **Symptoms** occasioned by the presence of nasal polypi depend on the interference with respiration and speech which they occasion. Respiration through the affected nostril is impeded, the patient being unable to blow through it when directed to do so; and his speech is thick and nasal. There is snuffing with mucous discharge from the nostril; and all these symptoms are worse in damp than in dry weather. On examining the interior of the nose with the nasal speculum (Fig. 668), and then directing the patient to blow down, the lower end of the polyp may be distinctly seen, and, if large, will descend to a level with or even beyond the nasal aperture. By the introduction of a probe, the size and extent of the tumour, together with the position of its pedicle, may be readily ascertained. As it grows, it impresses changes on the shape of neighbouring bones, producing expansion and flattening of the nose; and, interfering with the flow of tears down the nasal duct, occasions a watery state of the eyes, which, together with the change of shape in the features, and the peculiar character of voice and respiration, may

enable the Surgeon at once to recognize the nature of his patient's disease. Polypi occur chiefly in young adults after the age of puberty: but they are not unfrequently met with at later periods of life.

Their **Causes** are very obscure. Most commonly they are referred either to a blow or to a prolonged catarrh. They are more common in women than in men.

**Diagnosis.**—1. Mucous nasal polypi may be distinguished from *chronic thickening of the mucous membrane covering the spongy bones*, by the absence in the latter of any pedunculated growth around which a probe can be passed, by the florid red character of the thickened membrane, and by the fact that the subjects of this thickening are almost invariably strumous children. 2. In *abscess of the septum*, the history of the case, and the fact of a polypus never being attached to this part of the nose, will establish the diagnosis. 3. *Deviation of the septum* to one side may be at first a little puzzling; but here the examination of both nostrils, and the discovery of a depression of one side of the septum corresponding to the projection on the other, will reveal the true nature of the case. 4. The *fibrous and malignant tumours* of the nostril will be found to differ sufficiently in consistence and appearance from the ordinary polypi to prevent their being confounded with them in many cases; yet in some instances much care will be required in coming to a definite opinion as to their true nature. 5. In one recorded case a *meningocele* projecting into the nasal cavity was mistaken for a polypus.

**Treatment.**—The spontaneous separation and expulsion of nasal polypi is of rare occurrence. I have, however, seen one case in which, after the assiduous use of chloride of zinc injections, a very copious discharge of large sloughy polypoid masses took place from one nostril which had been blocked up by them for many months previously, and from which they had even descended into the pharynx.

Nasal polypi may generally be most readily removed by avulsion with forceps; occasionally, but rarely, when they are very large, with a broad base, and especially when they extend into the throat, they require the application of the *écraseur*. In removing these growths by the *forceps*, instruments of good length but very slender construction should be used—those generally sold are too thick; the interior of the blades should be properly serrated, and have a longitudinal groove, so that the root of the tumour may be tightly grasped. The mucous membrane should first be rendered insensible by the application of a 20 per cent. solution of cocaine by means of a camel's hair pencil. The patient should be made to sit on a rather low chair; and, as there is generally a good deal of bleeding, a towel should be pinned over his clothes, and a basin placed before him to receive the blood. The Surgeon then, having ascertained by the introduction of a probe, or by means of the blades of the forceps, the situation of the pedicle of the polypus, grasps this firmly and removes it with a twisting movement of the hand. He proceeds in this manner, twisting off rather than pulling away polyp after polyp, until the whole of the nostril is cleared, which may be ascertained by examination, and by directing the patient to compress the sound, and to blow through the affected, side of the nose. The bleeding, which is often very free, stops on the application of cold water. It seems to be lessened by the use of cocaine. When the bleeding has ceased, the nose may be dried with cotton-wool, and the stump of the polypus, if it can be seen, may be touched with nitrate

of silver or destroyed with the galvanic cautery, to diminish the return. At about the end of a fortnight the patient should be seen again, as it not unfrequently happens that small polypi, which had been prevented from descending into the nares by the presence of the large polypus, now come down and require removal. These procedures must be had to from time to time, until all tendency to fresh formations of this kind has ceased. When the polypus is very large and hangs down into the mouth, the forceps may be guided to its base by the forefinger of the left hand from the mouth behind the soft palate.

Polypi may also be removed by the *galvanic écraseur*. To do this the patient is first rendered insensible by cocaine. A speculum is then inserted into the nostril, and a strong light thrown up the nostril. The loop of wire is then passed under the polypus and tightened up on its base. The current is then turned on, and the pedicle is rapidly cut through without pain or bleeding. Large polypi passing down into the pharynx may also be removed by the same instrument, the *écraseur* or snare. The loop of wire is passed through the nose and out of the mouth in the throat by the finger passed into the mouth. It is then tightened up and the pedicle cut through. In some instances the polypi attain a very large size, producing absorption of the nasal bones, and of the nasal process of the superior maxilla. In such cases it may be necessary, in order to extract them, to slit up the nose, and clip away with forceps the osseous surface from which they spring.

**Fibrous Polypus.—Naso-pharyngeal Fibroma.**—The term "polypus" is applied to a fibroma springing in exceedingly rare cases from the periosteum of the bones entering into the walls of the nasal cavity, commonly from the base of the skull, especially from the basilar process of the occipital bone and the under surface of the body of the sphenoid. This disease is a disease of early life, seldom commencing before the tenth year after the twentieth. As the tumour increases in size it gradually extends into the upper part of the pharynx, and extends into the posterior part of the nasal cavity. Its surface is lobulated and covered by mucous membrane; it is soft and resisting to the touch. In the earlier stages its form and size cannot be ascertained only by digital examination from the mouth, the finger being inserted behind the soft palate. In the later stages the tumour may be seen from the nostrils, and may appear below the soft palate, pushing this forward and seriously interfering with deglutition and finally with respiration. The tumours bleed freely, and may even be fatal directly from loss of blood. Microscopic examination shows that they are composed of fibrous tissue, consisting of a varying number of flattened or oat-shaped cells between the fibres. The vessels usually contain large tortuous dilated vessels, which form so prominent a feature in their structure that it has sometimes been suggested to name them *fibro-angioma*. When these vessels are opened by ulceration, they bleed exceedingly freely. In operation for removal of the growth, they bleed exceedingly freely and are unable to contract or retract owing to the density of the structure from which they lie.

The *prognosis* is extremely unfavourable. If left unrelieved they usually cause death sooner or later either by hæmorrhage or by asphyxia. In some cases by erosion of the base of the skull giving rise to brain symptoms. In some instances, however, they cease growing and undergo diminution of size.

The *Treatment* consists in their removal whenever this is possible. When the tumour is pedunculated it may be possible to pass the loop of a galvanic écraseur or of a common wire écraseur round the pedicle from the nose. This is, however, seldom practicable. Electrolysis is said to have been successfully used in the destruction of these tumours, but its efficacy is somewhat doubtful. When any cutting operation is adopted it is always safer, as great hæmorrhage may be expected, to do a preliminary tracheotomy and to plug the trachea with Trendelenburg's obturator, or to pass a large sponge into the pharynx, otherwise death may be caused by entrance of blood into the lungs. The method generally recognized as being most generally applicable at the present day, is removal by means of Paquelin's red-hot knife; but in order to do this it is necessary to expose the tumour fully, and several plans have been suggested of doing this, of which the following are the most important.

In 1862 William Lawrence exposed the nasal fossæ for the removal of polypi by carrying an incision round the nose, commencing on one side just internal to the lachrymal sac and terminating at the same point on the other side, passing below between the alæ nasi and the upper lip. The alæ nasi were then separated from the bone and the nasal process of the superior maxilla divided in the incision with cutting forceps. The septum being then divided, the nose was turned upwards. The nasal cavity is thus very fully exposed and the space obtained may in some cases be sufficient for the removal of a naso-pharyngeal tumour of considerable size.

Ollier recommends a somewhat similar operation, but carries his incision in the opposite direction, commencing at the ala on one side, passing up the side of the nose to the level of the lower margin of the orbit, then across the bridge and down the opposite side, terminating at the ala. The nasal bones and the nasal process of the superior maxilla, so far as it is concerned in the tumour, are then cut through with a fine saw and the nose turned downwards, by which the upper part of the nasal cavity is very fully exposed. In both these methods the nose is replaced after the operation and very little deformity results.

Rouge's operation (p. 591) might in some cases give sufficient access to the nasal cavity.

Maune of Avignon in 1711 attempted to reach these tumours from the mouth by dividing the soft palate. Nélaton extends the operation thus: A transverse incision is first made across the hard palate at the level of the second bicuspid teeth; from the middle of this a second incision is carried backwards, dividing the soft structures of the hard palate and the soft palate. By means of the periosteal elevator and scissors the two flaps thus formed are separated from the bone and turned downwards and outwards, out of the way. The exposed part of the hard palate is then removed with a chisel and mallet, and thus the posterior part of the nasal cavity and the upper part of the pharynx are brought very fully into view. After the removal of the tumour the flaps are united by sutures as in the operation for congenital cleft palate.

Complete removal of the superior maxilla by Syme, Flaubert, and others, has been adopted as a preliminary step to removal of the fibrous tumour when of unusual size. Langenbeck and others have performed partial excisions of the upper jaw, with replacement of the bone after the operation. These proceedings are more fully described in Chapter LVI.

All these operations are more or less difficult and dangerous, and should be undertaken unless the tumour threatens death from its size or from blood, or shows evident signs of active growth. According to Le Fort, polypi tend to cease growing with the growth of the patient, and destruction of the tumour by cauterization or electrolysis will not succeed in arresting the further progress of the growth.

**Malignant Nasal Tumours.**—There is a remarkable connexion between the ordinary benign nasal polypus and tumours of a sarcomatous or carcinomatous character, developing in the nasal cavity. I have seen several times in children and young adults tumours of the above-mentioned character developing rapidly in the orbit, the sphenoidal cells, or behind the nasal maxilla, after the extraction of perfectly and anatomically benign nasal polypi. The questions to be solved are these :—Are these tumours the result of irritation of the operation of extraction? or are they the primary growths lying concealed in the deep cavities of the face, the benign nasal polypus in reality secondary, though more apparent, and consequent on the first set up by the graver and yet latent tumour? In whatever way future surgeons may answer this, the fact remains certain, that a connexion does exist between the two forms of disease.

Tumours of rapid growth, malignant in their course (sometimes malignant polypus), either carcinoma or sarcoma, occasionally form polypi in the middle of the nasal cavity or about the posterior nares. They grow rapidly, with great expansion of the bones, much discharge, often intense pain, and often excessive hæmorrhage. They attack children and persons advanced in life. A tumour of this kind may be developed in various situations. Thus, in some cases, it extends into the pharynx, and the soft palate, giving rise to a *naso-pharyngeal tumour*; in others, a tendency to protrude through the nasal or lachrymal bones, occasioning obstruction of the nostril, divergence and protrusion of the eye-balls, disturbance of vision, and severe neuralgic pains in the head and face, as in this case a naso-orbital tumour. If the growth is a carcinoma, the bones under the angle of the jaw soon become enlarged. These growths, even when occurring in young people, speedily prove fatal. Death may occur in various ways, according to the nature of the growth and the direction of its development: by hæmorrhage; by the implication of the brain; by asphyxia; or by constitutional cachexy.

**Treatment.**—It is seldom that anything very effectual or permanent can be done by operation; and it should be borne in mind, that some malignant growths which project into the nostrils take their origin from the sphenoidal or ethmoidal cells, or even from within the cranium, and the nasal portion is only the external protrusion of a deeply-seated growth. Should the tumour be slow in its growth, with an absence of secondary deposits, the Surgeon may endeavour to extirpate it by laying open the face freely, making an incision from the inner angle of the eye to the side of the nose, and then across the cheek, dissecting up this triangular flap, cutting across the superior maxilla above the line of the alveoli, with a narrow-bladed saw and cutting-forceps, and then in a similar way in the orbit beyond and through the nasal bones, and the nasal process of the superior maxilla above the tumour, and thus extirpating the growth. In this operation there is often free bleeding, which may be arrested by the actual cautery.

the additional advantage of destroying any portions of the tumour in the irregular cavities of this region. In other cases it may be exposed the tumour sufficiently by Ollier's or Lawrence's operation. If the upper part of the pharynx is free, it should be plugged before the operation by a sponge passed behind the soft palate in the manner described (p. 593). It must not be too large, lest it push the tongue forwards against the tongue and impede respiration.

**Orbital Tumours** commence in the upper part of the nasal fossa or ethmoidal cells, perforate the thin inner wall of the orbit and extend into the interior of that cavity, displacing the eye forwards, downwards, and outwards. Vision is often but little, if at all, disturbed. The nostril on the same side is blocked up by a polypoid growth. But the outline of the maxilla and of the hard palate is normal, no projection of the bone, the deformity, in part, being perceptible. In fact, the disease and the deformity of the face which it occupies a part of the face which is above a horizontal line passing through the cheek on a level with the upper or orbital border of the maxilla. The disease always commences in the nose or in the orbit contiguous to it, and the extension into the orbit may not occur for many years. It occurs at all periods of life, from childhood to commencing old age. At first it may present the ordinary appearance of a simple nasal polypus. This, however, recurs rapidly, is again re-acted by much hæmorrhage, and then a serious implication is developed.

**Diagnosis** of the naso-orbital from the pharyngeal tumour may be made by the displacement of the eyeball and the position of the tumour behind the soft palate. In the first case; whilst, in the pharyngeal, the orbit is intact, the

the pharynx being occupied by the growth, and the superior maxilla is pushed bodily forwards or to one side. In the naso-orbital deformity is above the horizontal line of the upper edge of the maxilla; in the naso-pharyngeal, it is below this. The nature of the tumour varies. It is usually a large or small spindle-shaped, but it may be a squamous carcinoma.

**Treatment.**—The operation for the removal of naso-orbital tumour may be performed as follows: An incision should be made from the root of the nose, down along the side and round the ala, so as to open the nasal cavity. The incisions on the orbital side of this cut are then dissected down into the orbit. The blade of a cutting forceps being passed into the nose, along the side of the nasal bone, the articulation between this and the nasal bone of the superior maxilla is cut through. An oblique cut upwards should be made across the nasal process of the superior maxilla deeply into the orbit, the cut bones widely separated, and the nose turned completely over to the other side of the face. The tumour at the nasal side of the orbit may be removed, the eye being held to the outer side and protected with a retractor.

Fig. 671.—Naso Orbital Tumour.

The orbital tumour may now be enucleated with the finger and curved. The nostril is then cleared by means of a polypus-forceps. The bleeding is arrested by plugging; and, after all the morbid growth has been extirpated, the nose should be pushed back and moulded into shape. The soft parts are then brought together with a few points of suture. At similar operations, the posterior nares must be plugged to prevent the finding its way into the trachea.

Occasionally the disease has extended into the integuments at the angle of the eye. Then the operation becomes more complicated. The following cases, operated on by me at University College Hospital, are illustrations of this operation.

The first case was one of carcinoma, springing deeply from the ethmoid cells, passing out through the lachrymal bone and the orbital plate of the ethmoid into the orbit, blocking up the right nostril, and extending so far down the cheek, overlying the superior maxilla. It was growing rapidly in a woman 44 years of age, and required extensive removal of the bony structures in the situation from which it sprang.

The next case was one of a woman 64 years of age, in whom the disease had developed with great rapidity in the situation of the lachrymal sac, in the nose and orbit, and destroying the upper and inner part of the superior maxillary bone. The eye was pushed outwards, the eyelids became involved in their nasal third, and an ulcerated opening formed over the centre of the tumour. Its growth was attended by very severe tensive pain. The operation consisted in dissecting away the diseased part of the integument, in the nasal third of each eyelid, then turning down a flap from the cheek, cutting away with forceps the osseous structures, including the inner wall of the floor of the orbit, a considerable portion of the superior maxilla, and a part of the nasal bones. In order to repair the gap made by the removal of the diseased skin at the side of the nose and by the removal of so much of the eyelids, a flap of integument was dissected off the bridge of the nose and drawn over the aperture, to the edges of which and to the floor of the orbit it was fixed by metallic sutures. Good union took place, and the patient made an excellent recovery. The immediate effect of the operation in these cases was to relieve the patient of the agonizing pain, previously occasioned by the tension in the bones of the face produced by the growth of the tumour.

Busch has described a case, in which the patient, a man aged 78 years, had a malignant tumour of the size of a fist, occupying the middle of the face. The symptoms at the commencement were those of nasal polypus. In removing it was necessary to cut close to the cribriform plate of the ethmoid bone as far back as the posterior nares. A flap of skin was transplanted from the forehead, not so much to form a new nose as to cover in the cavity left. The patient was able to leave the hospital in a few weeks.

**Columnar Papilloma.**—I have once met with this form of growth in the nasal fossæ in a lady past sixty. It grew from the roof of the nasal cavity and formed a mass blocking the nostrils and projecting into each nostril laterally. Much relief was obtained for a time by removing the proximal part of the tumour by avulsion with polypus-forceps, but the growth returned. A second operation was performed, but death took place on the third day from septic meningitis. The *post-mortem* examination showed

briform plate had been absorbed by the pressure of the growth which me directly in contact with the dura mater. The cause of death was a rent in the membrane. The tumour was papillary in structure, and l with non-ciliated columnar epithelium. Sections of the growth under microscope closely resembled those of papillary growths from the rectum. fect produced by the growth on the surrounding parts seemed merely ult of pressure and not of infiltration, consequently the growth may be d rather as a papilloma than a columnar carcinoma.

FRONTAL SINUSES, though rarely, are occasionally the seat of disease. ss may form here, with much pain and expansion, and possibly caries of anterior wall, attended with the local signs of inflammation and with of concomitant inflammation of the membranes of the brain. In such stances it may be proper for the Surgeon to remove with a trephine the r wall of the sinus, and thus give exit to the retained pus. In other es the anterior wall of the sinus may be necrosed and perforated, the e being felt under a puffy tumour of the scalp. Here also the trephine ired. **Distension with serous fluid** has been described as having d in some cases. There are a few cases, recorded in surgical writings, ypi springing from these sinuses, and finding their way down into the ter producing expansion of it and much inconvenience. Here likewise, priety of trephining and so extracting the morbid mass would have to sidered.

#### DISEASES OF THE CHEEKS.

chief diseases met with in the cheeks are, Nævi (p. 69), Atheromatous Vol. I., p. 1006), Subcutaneous Tuberculous Abscesses (Vol. I., p. 1092), y Syphilitic Sores (Vol. I., p. 1128), Tertiary Syphilitic Ulcers (Vol. I., ), Lupus (Vol. II., p. 5), Squamous Carcinoma (Vol. I., p. 1069), and : Ulcer (Vol. II., p. 10). The symptoms and treatment of all these ns have already been described. On the inner surface of the cheek s cysts, which can easily be dissected out from the inside, are not un- n. Epithelioma also is not rare. Malignant tumours affecting the thickness of the cheek can seldom be operated on with any advantage.

**Salivary Fistula.**—One of the most troublesome surgical affections d in the cheek is *Salivary Fistula*, occurring in consequence of injury, , or operation, by which the parotid gland or duct has been opened, so ause a trickling of saliva through the external aperture made into it. w of saliva in these cases is always to a great extent and often entirely ittent, ceasing in the interval between meals, and becoming very abun- ring mastication.

*Treatment* is by no means satisfactory, the attempt at union of the g in the cheek being frustrated by the escape of saliva through it. If ala be very small and recent, the electric cautery may be employed with ; or the external aperture may be touched from time to time with a stick of nitrate of silver. Should these means fail, the fistula having chronic, operative measures will be required. The closure of an old fistula in the cheek is a very troublesome matter. In these cases the pears to be obstructed or partially closed ; and it is useless to attempt de the opening in the cheek until a proper aperture has been made

of silver or destroyed with the galvanic cautery, to diminish the risk of return. At about the end of a fortnight the patient should be examined again, as it not unfrequently happens that small polypi, which had been prevented from descending into the nares by the presence of the larger ones, now come down and require removal. These procedures must be had recourse to from time to time, until all tendency to fresh formations of this kind has ceased. When the polypus is very large and hangs down into the pharynx the forceps may be guided to its base by the forefinger of the left hand passed from the mouth behind the soft palate.

Polypi may also be removed by the *galvanic éraseur*. To do this the nose is first rendered insensible by cocaine. A speculum is then inserted and a strong light thrown up the nostril. The loop of wire is then passed round the polypus and tightened up on its base. The current is then turned on and the pedicle is rapidly cut through without pain or bleeding. Large polypi passing down into the pharynx may also be removed by the simple wire-*éraseur* or snare. The loop of wire is passed through the nose and expanded in the throat by the finger passed into the mouth. It is then tightened up and the pedicle cut through. In some instances the polypi attain a great size, producing absorption of the nasal bones, and of the nasal process of the superior maxilla. In such cases it may be necessary, in order to extract them, to slit up the nose, and clip away with forceps the osseous surface from which they spring.

**Fibrous Polypus.—Naso-pharyngeal Fibroma.**—The term "fibrous polypus" is applied to a fibroma springing in exceedingly rare cases from the periosteum of the bones entering into the walls of the nasal cavity, but more commonly from the base of the skull, especially from the basilar process of the occipital bone and the under surface of the body of the sphenoid. Fibrous polypus is a disease of early life, seldom commencing before the tenth year or after the twentieth. As the tumour increases in size it gradually fills the upper part of the pharynx, and extends into the posterior part of the nasal cavity. Its surface is lobulated and covered by mucous membrane; it is firm and resisting to the touch. In the earlier stages its form and size can be ascertained only by digital examination from the mouth, the finger being passed up behind the soft palate. In the later stages the tumour may be seen from the nostrils, and may appear below the soft palate, pushing this forward and seriously interfering with deglutition and finally with respiration. These tumours bleed freely, and may even be fatal directly from loss of blood. Microscopic examination shows that they are composed of fibrous tissue, with a varying number of flattened or oat-shaped cells between the fibres. They usually contain large tortuous dilated vessels, which form so prominent a feature in their structure that it has sometimes been suggested to term the growth *fibro-angioma*. When these vessels are opened by ulceration, or in an operation for removal of the growth, they bleed exceedingly freely, being unable to contract or retract owing to the density of the structure in which they lie.

The *prognosis* is extremely unfavourable. If left unrelieved these growths usually cause death sooner or later either by hæmorrhage or by asphyxia, or in some cases by erosion of the base of the skull giving rise to brain symptoms. In some instances, however, they cease growing and undergo diminution in size.

The *Treatment* consists in their removal whenever this is possible. When the tumour is pedunculated it may be possible to pass the loop of a galvanic *écraseur* or of a common wire *écraseur* round the pedicle from the nose. This is, however, seldom practicable. Electrolysis is said to have been successfully used in the destruction of these tumours, but its efficacy is somewhat doubtful. When any cutting operation is adopted it is always safer, as great hæmorrhage may be expected, to do a preliminary tracheotomy and to plug the trachea with Trendelenburg's obturator, or to pass a large sponge into the pharynx, otherwise death may be caused by entrance of blood into the lungs. The method generally recognized as being most generally applicable at the present day, is removal by means of Paquelin's red-hot knife; but in order to do this it is necessary to expose the tumour fully, and several plans have been suggested of doing this, of which the following are the most important.

In 1862 William Lawrence exposed the nasal fossæ for the removal of polypi by carrying an incision round the nose, commencing on one side just internal to the lachrymal sac and terminating at the same point on the other side, passing below between the *alæ nasi* and the upper lip. The *alæ nasi* were then separated from the bone and the nasal process of the superior maxilla divided in the incision with cutting forceps. The septum being then divided, the nose was turned upwards. The nasal cavity is thus very fully exposed and the space obtained may in some cases be sufficient for the removal of a naso-pharyngeal tumour of considerable size.

Ollier recommends a somewhat similar operation, but carries his incision in the opposite direction, commencing at the ala on one side, passing up the side of the nose to the level of the lower margin of the orbit, then across the bridge and down the opposite side, terminating at the ala. The nasal bones and the nasal process of the superior maxilla, so far as it is concerned in the tumour, are then cut through with a fine saw and the nose turned downwards, by which the upper part of the nasal cavity is very fully exposed. In both these methods the nose is replaced after the operation and very little deformity results.

Rouge's operation (p. 591) might in some cases give sufficient access to the nasal cavity.

Maune of Avignon in 1711 attempted to reach these tumours from the mouth by dividing the soft palate. Nélaton extends the operation thus: A transverse incision is first made across the hard palate at the level of the second bicuspid teeth; from the middle of this a second incision is carried backwards, dividing the soft structures of the hard palate and the soft palate. By means of the periosteal elevator and scissors the two flaps thus formed are separated from the bone and turned downwards and outwards, out of the way. The exposed part of the hard palate is then removed with a chisel and mallet, and thus the posterior part of the nasal cavity and the upper part of the pharynx are brought very fully into view. After the removal of the tumour the flaps are united by sutures as in the operation for congenital cleft palate.

Complete removal of the superior maxilla by Syme, Flaubert, and others, has been adopted as a preliminary step to removal of the fibrous tumour when of unusual size. Langenbeck and others have performed partial excisions of the upper jaw, with replacement of the bone after the operation. These proceedings are more fully described in Chapter LVI.

All these operations are more or less difficult and dangerous, and should not be undertaken unless the tumour threatens death from its size or from loss of blood, or shows evident signs of active growth. According to Le Fort, fibrous polypi tend to cease growing with the growth of the patient, and partial destruction of the tumour by canterization or electrolysis will sometimes succeed in arresting the further progress of the growth.

**Malignant Nasal Tumours.**—There is a remarkable connexion between the ordinary benign nasal polypus and tumours of a sarcomatous or carcinomatous character, developing in the nasal cavity. I have several times seen in children and young adults tumours of the above-mentioned character developing rapidly in the orbit, the sphenoidal cells, or behind the superior maxilla, after the extraction of perfectly and anatomically benign nasal polypi. The questions to be solved are these :—Are these tumours the result of the irritation of the operation of extraction? or are they the primary disease lying concealed in the deep cavities of the face, the benign nasal polypi being in reality secondary, though more apparent, and consequent on the irritation set up by the graver and yet latent tumour? In whatever way future investigators may answer this, the fact remains certain, that a connexion does exist between the two forms of disease.

Tumours of rapid growth, malignant in their course (sometimes called malignant polypus), either carcinoma or sarcoma, occasionally form primarily in the middle of the nasal cavity or about the posterior nares. They grow rapidly, with great expansion of the bones, much discharge, often extreme tensive pain, and often excessive hæmorrhage. They attack children and persons advanced in life. A tumour of this kind may be developed in different situations. Thus, in some cases, it extends into the pharynx behind the soft palate, giving rise to a *naso-pharyngeal tumour*; in others it has a tendency to protrude through the nasal or lachrymal bones, occasioning obstruction of the nostril, divergence and protrusion of the eye-ball, with disturbance of vision, and severe neuralgic pains in the head and face, forming in this case a *naso-orbital tumour*. If the growth is a carcinoma, the glands under the angle of the jaw soon become enlarged. These growths, especially when occurring in young people, speedily prove fatal. Death may occur in various ways, according to the nature of the growth and the direction of its development: by hæmorrhage; by the implication of the brain; by asphyxia; or by constitutional cachexy.

**Treatment.**—It is seldom that anything very effectual or permanent can be done by operation; and it should be borne in mind, that some of the malignant growths which project into the nostrils take their origin from the sphenoidal or ethmoidal cells, or even from within the cranium, and that the nasal portion is only the external protrusion of a deeply-seated tumour. Should the tumour be slow in its growth, with an absence of secondary deposits, the Surgeon may endeavour to extirpate it by laying open the side of the face freely, making an incision from the inner angle of the eye down the side of the nose, and then across the cheek, dissecting up this triangular flap, cutting across the superior maxilla above the line of the alveoli, with a narrow-bladed saw and cutting-forceps, and then in a similar way into the orbit beyond and through the nasal bones, and the nasal process of the superior maxilla above the tumour, and thus extirpating the growth. In this operation there is often free bleeding, which may be arrested by the actual cautery.

which has the additional advantage of destroying any portions of the tumour left behind in the irregular cavities of this region. In other cases it may be possible to expose the tumour sufficiently by Ollier's or Lawrence's operation. Whenever the upper part of the pharynx is free, it should be plugged before commencing the operation by a sponge passed behind the soft palate in the way already described (p. 593). It must not be too large, lest it push the soft palate forwards against the tongue and impede respiration.

**Naso-Orbital Tumours** commence in the upper part of the nasal fossa or in the ethmoidal cells, perforate the thin inner wall of the orbit and extend into the interior of that cavity, displacing the eye forwards, downwards, outwards. Vision is often but little, if at all, disturbed. The nostril on the affected side is blocked up by a polypoid growth. But the outline of the superior maxilla and of the hard palate is normal, no projection of the bone, in whole or in part, being perceptible. In fact, the disease and the deformity produced by it occupies a part of the face which is above a horizontal line drawn across the cheek on a level with the upper or orbital border of the superior maxilla. The disease always commences primarily in the nose or in the cavities contiguous to it, and the extension into the orbit may not occur for many months. It occurs at all periods of life, from early childhood to commencing old age. At first it may present the ordinary characters of a simple nasal polypus. This is removed, recurs rapidly, is again removed, with much hæmorrhage, and then the orbital implication is developed.

The *Diagnosis* of the naso-orbital from the naso-pharyngeal tumour may be made by the displacement of the eyeball and absence of all tumour behind the soft palate in the first case; whilst, in the naso-pharyngeal, the orbit is intact, the upper part of the pharynx being occupied by the growth, and the superior maxilla possibly pushed bodily forwards or to one side. In the naso-orbital tumour, the deformity is above the horizontal line of the upper edge of the superior maxilla; in the naso-pharyngeal, it is below this.

The nature of the tumour varies. It is usually a large or small spindle-celled sarcoma, but it may be a squamous carcinoma.

*Treatment.*—The operation for the removal of naso-orbital tumour may be done as follows: An incision should be made from the root of the nose, directly down along the side and round the ala, so as to open the nasal cavity. The soft parts on the orbital side of this cut are then dissected down into the orbit. One blade of a cutting forceps being passed into the nose, along the outer border of the nasal bone, the articulation between this and the nasal process of the superior maxilla is cut through. An oblique cut upwards should then be made across the nasal process of the superior maxilla deeply into the orbit, the cut bones widely separated, and the nose turned completely over to the sound side of the face. The tumour at the nasal side of the orbit may now be felt, the eye being held to the outer side and protected with a retractor.

Fig. 671.—Naso Orbital Tumour.

The orbital tumour may now be enucleated with the finger and curved scissors. The nostril is then cleared by means of a polypus-forceps. The bleeding should be arrested by plugging; and, after all the morbid growth has been fairly extirpated, the nose should be pushed back and moulded into shape. The soft parts are then brought together with a few points of suture. As in all similar operations, the posterior nares must be plugged to prevent the blood finding its way into the trachea.

Occasionally the disease has extended into the integuments at the inner angle of the eye. Then the operation becomes more complicated. The following cases, operated on by me at University College Hospital, are good illustrations of this operation.

The first case was one of carcinoma, springing deeply from the ethmoidal cells, passing out through the lachrymal bone and the orbital plate of the ethmoid into the orbit, blocking up the right nostril, and extending some way down the cheek, overlying the superior maxilla. It was growing rapidly in a woman 44 years of age, and required extensive removal of the bony structures in the situation from which it sprang.

The next case was one of a woman 64 years of age, in whom a sarcoma developed with great rapidity in the situation of the lachrymal sac, invading the nose and orbit, and destroying the upper and inner part of the superior maxillary bone. The eye was pushed outwards, the eyelids became implicated in their nasal third, and an ulcerated opening formed over the centre of the tumour. Its growth was attended by very severe tense pain. The operation consisted in dissecting away the diseased part of the integument, including the nasal third of each eyelid, then turning down a flap from the cheek and cutting away with forceps the osseous structures, including the inner part of the floor of the orbit, a considerable portion of the superior maxilla, and part of the nasal bones. In order to repair the gap made by the removal of diseased skin at the side of the nose and by the removal of so large a portion of the eyelids, a flap of integument was dissected off the bridge of the nose and drawn over the aperture, to the edges of which and to the eyelids it was fixed by metallic sutures. Good union took place, and the patient made an excellent recovery. The immediate effect of the operation in both these cases was to relieve the patient of the agonizing pain, previously occasioned by the tension in the bones of the face produced by the growth of the tumour.

Busch has described a case, in which the patient, a man aged 78, had a malignant tumour of the size of a fist, occupying the middle of the face. The symptoms at the commencement were those of nasal polypus. In removing it, it was necessary to cut close to the cribriform plate of the ethmoid bone, and as far back as the posterior nares. A flap of skin was transplanted from the forehead, not so much to form a new nose as to cover in the cavity left. The patient was able to leave the hospital in a few weeks.

**Columnar Papilloma.**—I have once met with this form of growth in the nasal fossæ in a lady past sixty. It grew from the roof of the nasal cavity, and formed a mass blocking the nostrils and projecting into each orbit laterally. Much relief was obtained for a time by removing the projecting part of the tumour by avulsion with polypus-forceps, but the growth soon returned. A second operation was performed, but death took place on the third day from septic meningitis. The *post-mortem* examination showed that

the cribriform plate had been absorbed by the pressure of the growth which had come directly in contact with the dura mater. The cause of death was a small rent in the membrane. The tumour was papillary in structure, and covered with non-ciliated columnar epithelium. Sections of the growth under the microscope closely resembled those of papillary growths from the rectum. The effect produced by the growth on the surrounding parts seemed merely the result of pressure and not of infiltration, consequently the growth may be regarded rather as a papilloma than a columnar carcinoma.

THE FRONTAL SINUSES, though rarely, are occasionally the seat of disease. **Abscess** may form here, with much pain and expansion, and possibly caries of their anterior wall, attended with the local signs of inflammation and with danger of concomitant inflammation of the membranes of the brain. In such circumstances it may be proper for the Surgeon to remove with a trephine the anterior wall of the sinus, and thus give exit to the retained pus. In other instances the anterior wall of the sinus may be necrosed and perforated, the aperture being felt under a puffy tumour of the scalp. Here also the trephine is required. **Distension with serous fluid** has been described as having occurred in some cases. There are a few cases, recorded in surgical writings, of **Polypi** springing from these sinuses, and finding their way down into the nose after producing expansion of it and much inconvenience. Here likewise, the propriety of trephining and so extracting the morbid mass would have to be considered.

#### DISEASES OF THE CHEEKS.

The chief diseases met with in the cheeks are, Nævi (p. 69), Atheromatous Cysts (Vol. I., p. 1006), Subcutaneous Tuberculous Abscesses (Vol. I., p. 1092), Primary Syphilitic Sores (Vol. I., p. 1128), Tertiary Syphilitic Ulcers (Vol. I., p. 1149), Lupus (Vol. II., p. 5), Squamous Carcinoma (Vol. I., p. 1069), and Rodent Ulcer (Vol. II., p. 10). The symptoms and treatment of all these affections have already been described. On the inner surface of the cheek mucous cysts, which can easily be dissected out from the inside, are not uncommon. Epithelioma also is not rare. Malignant tumours affecting the whole thickness of the cheek can seldom be operated on with any advantage.

**Salivary Fistula.**—One of the most troublesome surgical affections situated in the cheek is *Salivary Fistula*, occurring in consequence of injury, abscess, or operation, by which the parotid gland or duct has been opened, so as to cause a trickling of saliva through the external aperture made into it. The flow of saliva in these cases is always to a great extent and often entirely intermittent, ceasing in the interval between meals, and becoming very abundant during mastication.

The *Treatment* is by no means satisfactory, the attempt at union of the opening in the cheek being frustrated by the escape of saliva through it. If the fistula be very small and recent, the electric cautery may be employed with success; or the external aperture may be touched from time to time with a pointed stick of nitrate of silver. Should these means fail, the fistula having become chronic, operative measures will be required. The closure of an old salivary fistula in the cheek is a very troublesome matter. In these cases the duct appears to be obstructed or partially closed; and it is useless to attempt to occlude the opening in the cheek until a proper aperture has been made

into the mouth; the escape of a few drops of saliva through the fistulous opening rendering the attempt to close it completely nugatory. The plan of treatment which I have found to answer best is a modification of Desault's. It consists in passing a small hydrocele trochar into the fistula in the cheek, pushing this obliquely forwards and inwards into the mouth, as nearly as possible in the direction of the parotid duct, withdrawing the trochar, and then passing a horsehair seton through the cannula, so as to bring one end out of the mouth, and the other through the fistula in the cheek. The cannula is then withdrawn, and the seton tied loosely. It should be left in for about three weeks, so as to establish a sinus into the mouth. It is then to be cut and withdrawn, and the sinus in the mouth kept patent by the daily introduction of a probe, by leaving a small piece of gum catheter in it, or, if it show much disposition to close, by the introduction of a laminaria tent. In this way the saliva is diverted from the external opening and made to flow into the mouth. The external aperture in the cheek may now be closed by touching its edges with a pointed stick of nitrate of silver or the galvanic cautery; or, if large, they may be pared and stitched together.

#### DISEASES OF THE LIPS.

**Congenital Malformation of the Lips** is of common occurrence. *Congenital contraction*, or even complete closure of the orifice of the mouth, has been met with at birth; such a condition must be remedied, according to circumstances, by the skill of the Surgeon. The opposite condition is also occasionally observed, the opening of the mouth extending on one side too far into the cheek, constituting the condition known as *Macrostoma*. It must be remedied by a plastic operation. By far the most common malformation, however, is the condition termed *Hare-lip*, which will be noticed in detail in the chapter on the Plastic Surgery of the Face and Mouth.

**Hypertrophy** to a great extent occasionally occurs in either or in both lips. It is especially common in the upper lip in scrofulous children, forming the condition known as "strumous lip." It is often of an oedematous character, being kept up by the irritation of fissures or cracks; if so, these must be cured, when the size of the lip will gradually diminish. Sometimes, however, it becomes permanent, continuing after the cure of the fissure; in these circumstances it may be necessary to excise an elliptical portion of the mucous membrane of the lip in a horizontal direction, and then to bring the edges together by means of sutures.

**Ulceration** is not unfrequently met with on the prolabium, frequently of a simple character, though chronic. It is often dependent on a disordered state of the digestive organs. It will commonly yield to the application of nitrate of silver, to proper constitutional treatment having for its object the improvement of the digestion, and in very chronic cases to the administration of the preparations of arsenic.

**Primary Syphilitic Sores**, communicated by kissing, are by no means uncommon on the lips. Their peculiar character has already been described (Vol. I., p. 1128).

**Cysts and Nævi**.—The lips may be the seat of cysts and erectile tumours, requiring extirpation by the knife or ligature. In dealing with these, the Surgeon must be guided by the circumstances of the individual case; but he

should, if possible, avoid cutting through the whole thickness of the lip ; and, if compelled to do so, he must act as will be described in speaking of cancer of this region. (See p. 605.) These growths most frequently occur on the lower lip.

*Cysts* are usually small and transparent, with thin walls, containing a glairy straw-coloured fluid. These should always be dissected out ; mere excision of a portion of the wall being followed by recurrence of the disease.

*Nævi* of the lip and their treatment have already been fully described (p. 77).

**Warty Growths** are common on the lip, and are apt after existing some

Fig. 672. — Extensive Warty Epithelioma of the Lip.

Fig. 673. — Lines of Incision for Removing V-shaped Piece of Lip.

time to become carcinomatous. Sometimes crusts of epithelium, forming horn-like projections, are developed on the surface. They are best treated by early removal, no local application being of much use, and the danger of their becoming malignant being very considerable.

**Squamous Carcinoma.**—The structure of epithelioma has been so fully described in Vol. I., p. 1069, that it need not detain us here.

Epithelioma of the lip commences either as a warty growth, which gradually

Fig. 674. — Epithelioma of Lower Lip : Lines of Incision.

Fig. 675. — Lip after removal of Epithelioma.

ulcerates, or as an indurated crack or fissure, the edges of which have a tendency to spread. The submaxillary lymphatic glands tend to become early involved ; and the disease, if unrelieved by operation, will eventually prove fatal by the pain, exhaustion, and constitutional irritation thus induced. The disease almost invariably occurs in men, and in the lower lip ; I have never met with a case affecting the lower lip of a woman. It is met with after the middle period of life. Of twenty consecutive cases in which I

operated, and of which I have notes, thirteen were above sixty, and six between fifty and sixty years of age; in one case only did the disease occur under thirty. This disease is at first entirely local, often being induced by some irritation, as by a rugged broken tooth, or by smoking a clay-pipe; and when completely removed it does not, I believe, very commonly recur. At least, of the very many patients that have been operated upon at the University College Hospital, I have known but few to return with a recurrence of the disease; I cannot, therefore, but come to the conclusion that the operation for epithelioma of the lower lip frequently rids the patient permanently of his disease.

When return does take place, it is not always in the cicatrix or in the adjacent glands. I have seen recurrence at the angle of the mouth and inside the cheek of the side opposite to that on which the primary disease had declared

Fig. 676.—Extensive Epithelioma of the Lip:  
Lines of Incision.

Fig. 677.—Epithelioma of Lower Lip involving  
Jaw, successfully removed (Healed).

itself and been removed, and this not till three or four years after the operation. In these cases the tumour was probably a fresh primary growth.

When the glands are enlarged, the advisability of operating will depend upon the extent of the glandular implication. It must be remembered that the internal organs are affected in epithelioma only in exceptional cases, and thus we may hope occasionally to cure the patient permanently even after implication of the lymphatic glands. If merely the submaxillary lymphatic glands are enlarged, they should be fully exposed by a curved incision carried from near the symphysis to the level of the hyoid bone and back to the edge of the sterno-mastoid. The facial artery and vein will probably be divided, and sometimes it is necessary to remove the submaxillary gland which may be implicated by extension from the neighbouring lymphatic glands. A gland must also be sought for between the genio-hyoid muscles. If enlarged glands can be felt beneath the sterno-mastoid, it is rarely wise to operate, as these can

seldom be safely removed owing to their adhesion to the carotid sheath. If the glands are extensively adherent to the skin, no operation should be attempted.

**Operation.**—When once the true nature of the disease has been ascertained, the operation should be performed without delay ; but before it is done it is well that any very prominent or broken tooth should be removed, and the tartar cleaned away from the incisors. The operation requires to be somewhat modified, according to the situation and extent of the affection (Fig. 674). If this be tolerably limited, a V-shaped cut, extending widely round it, and carried sufficiently low to include any indurated prolongation in the lymphatics, should be made : the edges of the cut should then be brought together by two hare-lip pins with a twisted suture, as in the case of a simple hare-lip, or with silver-wire sutures. When the disease occupies a considerable longitudinal extent, but does not dip down very deeply, a slice of the lip should be shaved off, including the whole of the morbid structure ; and it is often surprising, in these circumstances, to observe how the tissues of the lip will speedily rise to their natural level, no material deformity being left (Fig. 675). In some cases the disease occupies a square surface, and then it is necessary to excise a portion of the lip ; when this is done a considerable gap is left, requiring to be filled by some plastic operation of the kind that will be considered in a subsequent chapter, which may be most conveniently done at the time when the excision is performed. When the disease occurs at the angle of the mouth, it assumes a more intractable character than when affecting the free part of the lip. The same operation—that of free excision—may be applied to it here as in the former case ; but with less prospect of success. Should the disease be as extensive as in Fig. 676, the lines of incision must be so planned as completely to surround and to isolate it.

C. Heath has very successfully extended this operation to cases in which the cancer of the lip had invaded the gum, and had involved the lower jaw, by removing a portion of the implicated bone, together with the disease in the soft parts. Fig. 677 gives a good idea of the cases to which this operation is applicable.

#### DISEASES OF THE PAROTID GLAND.

**Mumps or Parotitis** is an acute specific disease, the local manifestation of which is inflammation of the parotid and sometimes of the other salivary glands. It is common in children, though it not unfrequently occurs in adults. It is highly infectious, and frequently epidemic ; and, as in the other acute specific diseases, one attack generally protects the patient from the disease for the rest of his life. It has an incubative period of from two weeks to twenty-two days, but three weeks is the most common time. It commences usually with some febrile disturbance and malaise lasting about twenty-four hours, but this may be wanting. At the end of that time one parotid gland becomes swollen and painful ; the swelling continues to increase till about the fourth day, at which time it reaches from the zygoma to the angle of the jaw. The swollen socia parotidis can usually be clearly felt over the masseter and forms a valuable diagnostic sign, distinguishing parotitis from inflammation of the lymphatic glands behind the jaw. When the swelling is at its height, mastication is extremely painful. There is usually elevation of temperature, reaching 102° F. or 103° F. When one gland begins to subside

that on the opposite side usually begins to swell and runs the same course; but occasionally both glands swell simultaneously. Suppuration rarely, if ever, takes place, unless it be in the lymphatic glands of the neighbourhood. As the parotid affection subsides, but sometimes simultaneously with it, inflammation of the testicle in the male, or of the ovary in the female, may take place. Inflammation of the breast and labia has also been described. These so-called metastases are very rare in children. The orchitis is frequently followed by partial or complete atrophy of the testicle; but fortunately, as the disease scarcely ever affects both sides, sterility rarely results. Inflammation of the membranes of the brain has been said to have been met with as a complication of mumps.

The *Treatment* of this affection is simple. If it be severe, the application of hot fomentations and the administration of salines, and, when the affection is on the decline, frictions with camphorated oil, will hasten its resolution. The orchitis must be treated with hot fomentations, belladonna and rest.

**Parotitis after injury or Disease of the Abdomen or Pelvis.**—Inflammation of the parotid gland, frequently terminating in suppuration, has long been known to be a not uncommon complication of injuries of the abdomen and pelvis, and has usually been regarded as pyæmic. Stephen Paget has, however, shown, by a careful analysis of 101 such cases, that this explanation is not altogether satisfactory. Of the 101 cases, 10 followed injuries or diseases of the urinary tract; 18 injuries or diseases of the alimentary canal; 23 injuries or inflammation of the abdominal wall, peritoneum and pelvic cellular tissue; and 50 injuries, diseases or operations on the generative organs; 27 of these being operations on the ovary. After a very prolonged search S. Paget succeeded in finding only 13 cases of secondary parotitis arising from operation or injuries of other parts of the body, and in all of these it merely formed a part of general pyæmia. In the histories of the 101 cases the presence of septiciæmia or pyæmia is mentioned in only 15, and in 7 only of the fatal cases were secondary centres of suppuration found elsewhere. The inflammation of the parotid commences at very varying periods after the operation or injury of which it formed a complication. In 78 cases in which the fact was definitely recorded suppuration occurred in 45, the remainder undergoing resolution. As a rule the parotitis was not accompanied by very severe fever, and rigors were very rare. Of the 101, 37 died, 13 from septiciæmia or pyæmia and the rest from various causes not directly connected with the parotitis. The treatment in mild cases consists in the external application of belladonna and hot fomentations. If suppuration threatens, it should be anticipated by a free incision into the gland. The explanation of this curious association of parotitis with injuries of the abdomen and pelvis cannot be given in the present state of our knowledge.

**Tumours.**—Tumours of the parotid gland itself are not so frequent as those situated upon it or in its vicinity. The tumours met with in this region may be simple or malignant. The simple tumours most frequently present a peculiar structure rarely met with in any other part of the body. They consist of mixed cartilage, fibrous tissue, myxomatous tissue, and glandular tissue, imperfectly resembling that of a racemose gland. When small they are firm, and somewhat elastic to the feel, smooth or slightly lobulated on the surface, and freely movable on the parts beneath. As they increase in size fluctuating areas become perceptible, often projecting above the rest of the

growth. These may be actual cysts containing a glairy fluid formed by mucous softening of the cartilage, or they may be due to the presence of a mass of gelatinous tissue, presenting under the microscope the typical branched cells and mucous intercellular substance of a myxoma. These tumours grow slowly, often taking many years to reach the size of a walnut, but at any time they may take on active growth and reach a large size in a comparatively short time, becoming even as large as a cocoa-nut. The skin covering them becomes thin but not adherent, and not unfrequently a network of veins covers the mass. The simple tumours being distinctly encapsuled very rarely send any deep prolongations behind the jaw or come into relation with the large blood-vessels. The facial nerve may be adherent to the under surface, but is seldom implicated in such a way as to cause paralysis. Besides the ordinary "parotid tumour" pure cartilaginous growths are not uncommon,

Fig. 678.—Simple "Parotid Tumour."

Fig. 679.—Simple "Parotid Tumour"; Back View

and more rarely pure fibromata and myxomata are met with. Cysts, except as secondary formations in solid tumours, are very rare.

**Malignant Tumours** of the parotid are of moderately frequent occurrence. They are most commonly soft glandular carcinomata (encephaloid), but scirrhus has been met with in this situation. They originate in the gland itself and not in the structures superficial to it, as is the case with the simple growths. They present the ordinary rapid growth of such tumours; they are from the first fixed and deeply seated, and early implicate the skin.

Spindle-celled and round-celled sarcomata are occasionally met with in this region springing from the bones or fasciæ. They grow rapidly and implicate the surrounding parts. They frequently send prolongations under the ramus of the jaw and occupy the whole of the space between its angle and the mastoid process. They are often firmly bound down beneath the fascia covering the parotid and surround the large vessels at an early period of their growth. As they increase in size they implicate the styloid process and its muscles and come into relation with the internal carotid and the internal jugular vein, and may at last press upon the pharynx and project into the

faucies, as was the case with the patient from whom the annexed cut (Fig. 680) was taken. The facial nerve is, of course, surrounded by the growth and is frequently paralysed, a condition, as before stated, rarely met with as a consequence of a simple tumour. If these tumours are too deeply seated to be removed the patient eventually dies, usually in consequence of disturbance of the cerebral circulation, or of compression of the pharynx and larynx; or the skin may at last become adherent and give way, profuse hæmorrhage afterwards taking place from the ulcerating tumour.

**Diagnosis.**—It is of great importance to effect the diagnosis between the non-malignant and the malignant tumours in the parotid region. In the *simple tumours* there is always mobility; and, although the attachments may be deep, the skin is not involved to any extent. The outline of the mass is usually well defined and somewhat lobulated. The progress of the growth is very slow, often occupying many years before it attains any considerable bulk, as in the annexed cuts (Figs. 678, 679), representing a tumour of sixteen

years' standing which I excised. In the *malignant growths* there is less mobility, and the mass may be solidly fixed; its outline is ill-defined, the skin soon assumes a reddish purple colour, is brawny, and presents the usual characters indicative of a subjacent malignant growth. Soft carcinomata grow with considerable rapidity, feel soft and pulpy, and are rounded and ill-defined in their outline, especially under the ear and by the ramus of the jaw. Paralysis of the facial nerve early in the disease is indicative of a deep-seated malignant growth, but the absence of this symptom is no proof that the tumour is simple.

Fig. 680.—Tumour of Parotid, too deeply seated for Removal.

The lymphatic gland, which lies just in front of the neck of the lower jaw and those superficial to the parotid, when chronically enlarged, may often closely resemble a simple parotid tumour. Their mobility is usually less than that of the simple parotid tumour, they are slightly tender when pressed upon, and it is very seldom that a single gland is affected. It may, however, be impossible to make a certain diagnosis till the tumour is removed.

**Treatment.**—In the treatment of these tumours, extirpation is necessarily the only course that can be adopted: and this should certainly not be attempted if the disease be malignant unless at a very early stage; for, as it would be impossible to remove the deeper attachments of the growth it would speedily return. Even if the tumour be simple, care must be taken that every lobule and prolongation be extirpated: for, if any be left, however small, it will become the nucleus of a new growth. In removing tumours in this situation, the superficial incisions should be free, so that the whole mass may be fairly exposed. It is not wise to remove integument, however redundant this may appear to be, unless it has undergone incorporation with the tumour, or change of structure; and even then as little as possible should be taken away. The fibrous investments of the tumour must be fairly

opened, and the edge of the knife must then be directed against it, and the dissection carried on from below upwards, or from behind forwards, so that one division of the blood-vessels supplying it may be sufficient. After the tumour has been well loosened by the division of investing fasciæ and structures (and it is surprising how movable it often becomes after this has been done, though it may previously have appeared to be incorporated somewhat solidly with the subjacent tissues) it should be taken hold of with the hand or a large double hook, and drawn well forwards whilst the deep dissection is being carried on. In prosecuting this, the Surgeon must guard against wounding the temporo-maxillary vein, the external carotid artery and the facial nerve, which are especially exposed to injury. In some cases the division of these cannot be avoided, as they are incorporated. Hæmorrhage from the divided vein or artery will, however, be easily arrested by ligature. In most instances, however, by keeping the edge of the knife carefully against the tumour, and by drawing it well forward, so as to loosen it in its areolar bed, removal of the morbid mass may be effected without the division of any important vessel or nerve. It is of more consequence to avoid a wound of the facial nerve and its chief branches than even of the vein or artery; as incurable paralysis of the face would result from such an injury. Division of the nerve is best avoided by dissecting out the tumour by incisions parallel to its main trunk and chief branches, and especially by drawing the mass well forward, and directing the knife towards it.

In attempting the removal of a malignant tumour it must be remembered that the styloid process marks the limit beyond which no operative procedure can safely be carried. The vessels superficial to this are easily secured if divided. If, therefore, the tumour extend beyond the styloid process the operation must be abandoned.

If the tumour have been allowed to attain an enormous size, with large lobes lying behind and under the ramus of the jaw, in close relation with the pharynx, the internal carotid, and jugular vein, it will not be prudent to attempt its removal.

**Excision of the Parotid Gland** itself is occasionally spoken of, but is very rarely done. I believe that in most cases in which it is stated that complete removal of this gland has been accomplished, tumours overlying and compressing it have been mistaken for it. Godlee, in one case in University College Hospital, completely removed the gland for an infiltrating growth. The operation was tedious and difficult, and the facial nerve and carotid artery were necessarily divided. The wound healed well, but the growth returned and ultimately proved fatal. Thompson of Rome has also removed the entire gland in one case.

#### DISEASES OF THE NECK.

**Congenital Fistulæ in the Neck** are of rare occurrence. They are most common at the side of the neck but may be met with in the middle line. Those which are placed laterally arise from imperfect closure of one of the branchial clefts, and are called *Branchial Fistulæ* (see Fig. 355, Vol. I. p. 1012). Of the three cervical branchial clefts the lowest most commonly remains as a fistula, which opens in the skin near the sternal origin of the sternomastoid. It is lined with mucous membrane and discharges a small quantity

of mucous fluid. A fine probe can usually be passed a considerable distance upwards towards the hyoid bone, and, in rare cases, can be made to enter the pharynx. Sometimes the external orifice is marked by a "cervical auricle" which consists of a small prominence of skin containing cartilage in its centre. As these fistulae cause no inconvenience they are better left alone as it is usually impossible to close the whole track; obliteration of the orifice would probably be followed by the dilatation of the remainder into a cyst.

*Median cervical fistulae* are very rare. Their mode of origin probably differs, but the two structures in connexion with which they appear to arise are the "sinus precervicalis," a blind recess from the front of the pharynx connected with the development of the thymus gland, and the "thyreo-glossal duct" or "canal of His" which leads downwards from the foramen caecum of the tongue behind the hyoid bone and is concerned with the development of the thyroid body. These fistulae are not necessarily present at birth but may arise secondarily as the result of suppuration around the blind extremity of the unobliterated duct. In several cases the lower part of a persistent thyreo-hyoid duct has been dissected up to the hyoid bone and the part above this destroyed with the galvano-cautery.

**Cystic Tumours in the Neck.**—Six varieties of cysts are met with in the neck: 1, the congenital multilocular cysts or cystic hygroma; 2, unilocular serous cysts or hydrocele of the neck; 3, blood-cysts; 4, dermoid cysts; 5, bursal cysts; and 6, true hydatid cysts.

Fig. 681.—Cystic Hygroma of Neck.

1. The **Congenital Multilocular Cysts or Cystic Hygromata** are often situated in the middle line in the subcutaneous tissue in front of the trachea, where they may attain a good size. Their supposed origin and their structure have already been described (Vol. I., p. 1029). If not too large or too deeply attached they may be removed.

In many cases, however, no operative interference is possible, as in the case represented in Fig. 681, but not uncommonly the tumour gradually diminishes in size, sometimes after repeated attacks of inflammation.

2. The **Unilocular Serous Cyst or Hydrocele of the Neck** is of somewhat doubtful origin, but it is usually supposed to arise in a space left by the imperfect closure of a branchial cleft. These tumours were accurately described by Maunoir and B. Phillips. They may be congenital, but more commonly appear in children or in early adult life. The cyst is usually situated in the posterior inferior triangle, but has also been met with in front of the sterno-mastoid between that muscle and the jaw, forming a rounded tumour, smooth, tense, and elastic, and filled with a yellow or chocolate-coloured serous fluid. It may attain so large a size as to interfere with deglutition and respiration. The largest I have seen was of the size of an orange. The skin covering this tumour is not discoloured, and is in some cases of natural thickness, in others thin and expanded, so as to give a bladder-like appearance to the growth.

The *Treatment* of this tumour consists in tapping, when complete collapse

of the cyst takes place : it however soon fills again. A permanent cure may be effected by injection with iodine, or by opening the cyst, sponging it out with chloride of zinc (gr. xl. to 3j), attaching the wall to the skin by sutures and inserting a drainage-tube. It is usually impossible to dissect the cyst out owing to the depth of its attachments and the thinness of its wall.

3. **Blood-Cyst** or **Hæmatocele of the Neck**.—This may be merely one of the cysts just described into which hæmorrhage has accidentally taken place. The true blood-cysts, however, are much more serious : when punctured true blood escapes, sometimes almost arterial in tint, and even if the cyst be emptied it speedily fills again. They have been met with in close connexion with the great vessels of the neck. Their origin is not certainly known, but some have supposed them to originate from a cyst-like dilatation of one of the large veins of the neck. In others no communication has been found with any large vessels, but the lining membrane was highly vascular. The *Treatment* consists in puncturing the cyst with a fine trochar and injecting iodine or perchloride of iron. If the cyst could be partially emptied by pressure, showing communication with a large vein, this would evidently not be justifiable. Gay successfully dissected one out, which lay in close contact with the carotid sheath.

4. **Dermoid Cysts** are rare in the neck. That variety which is occasionally met with in the middle line pushing upwards beneath the tongue, will be considered later (p. 701). The other position in the neck in which these cysts occur is the anterior border of the sterno-mastoid. They are then situated deeply beneath the cervical fascia, and probably owe their origin to distension of an unobliterated portion of one of the branchial clefts with the position of which they correspond (see Vol. I., p. 1014). A dermoid cyst apparently connected with the second branchial cleft, was recently removed by Godlee in University College Hospital. The patient, a woman aged twenty-six, had noticed a swelling in the neck for ten months. The cyst lay behind the angle of the jaw on the right side of the neck, and was overlapped by the sterno-mastoid. During its removal the carotid vessels were freely exposed. The cyst contained milky fluid with abundant cholesterine ; the cyst wall was lined with a stratified epithelium covering imperfect papillæ ; no hairs or glands were present.

The only *Treatment* for these cysts consists in removing them ; a procedure which, as in the above case, may involve an extensive dissection.

5. The **Bursal Cysts** occur in the middle line about the hyoid bone and the front of the larynx. They have already been described with disease of bursæ (p. 507).

6. **True Hydatid Cysts** sometimes form in the neck. A woman was under my care in the Hospital for a hydatid tumour of the liver, which I tapped ; seven years afterwards she presented herself with a thin-walled elastic semi-transparent cyst in the posterior triangle of the neck, about the size of an orange. This was found to contain clear serous fluid, with the remains of echinococci. In another case, that of a lad aged about 18, otherwise healthy, I removed a hydatid cyst as large as a shaddock from the neck, where it was deeply seated under the trapezius, growing apparently in the substance of the complexus or splenius capitis, and lying close upon the cervical spine and the occipital bone.

**Solid Tumours of the Neck**.—Fatty tumours and the various forms of

sarcoma, may occur in the subcutaneous tissue and fascia of the neck as elsewhere, but they present nothing special. The neck is the favourite seat of lymphadenoma, the tumours in this situation often reaching an enormous size, so as to endanger life by their pressure. In the submaxillary region, tumours are occasionally met with similar in character to the parotid tumour already described. The submaxillary gland itself is rarely the seat of disease.

Tumours in these situations may occasionally attain a considerable size, and if beneath the fascia, may extend deeply. In some cases when the integuments and superficial structures covering the growth are divided, it may be isolated with sufficient facility, its fixity being in a great measure due to its being bound down by the investing fascia rather than to its having contracted deep adhesions. Occasionally a slowly-growing tumour develops deeply in the anterior triangle of the neck, lying between the sterno-mastoid, the trachea, and the pharynx, possibly even under the carotid sheath, with the artery pushed on one side, or even running over the anterior convexity of the growth. In some cases, the question of removal requires to be approached with the utmost caution. If the tumour be movable above the vessels, it may generally be taken out; if it lie below the sheath, even though not fixed to the spine, its extirpation is not practicable. Before determining upon the removal of a tumour situated in one of the triangles of the neck, it is indeed always very necessary that a diagnosis of its nature be made, and that some opinion be formed of the probable extent of its deep attachments.

The first point to ascertain is whether it be simple or malignant. If simple, it will usually have been many years in growing; it will be hard but not stony, lobulated or somewhat square-shaped; the patient's general health being good. It will generally be found to be movable, though not perhaps to any great extent, and will present no sign of incorporation with neighbouring structures. If it be superficial, the fibres of the platysma will not appear to spread over it, and the sterno-mastoid muscle may be traced to one side of or below it. In such circumstances, removal of the tumour may be undertaken with every prospect of success. But if the tumour be of stony hardness, have implicated the skin, and be immovable, the whole head being moved on any attempt at drawing it aside, if it be ill-defined under the jaw and ear, or rapidly growing, soft and pulpy to the feel, deeply-seated under the angle of the jaw, evidently below the platysma and deep fascia of the neck, and possibly beneath the sterno-mastoid, then no attempt at extirpation should be undertaken, as the mass could either not be removed with safety, or, if it were by any possibility extirpated, the already existing contamination of the neighbouring parts would certainly lead to a speedy recurrence of the disease.

In removing *submaxillary tumours*, a free superficial incision nearly parallel to the margin of the lower jaw, but below this, will usually allow ready extirpation of the mass. In these operations the facial artery is generally sufficiently under cover of the bone to escape injury, but there may be, and usually is, free venous hæmorrhage.

**Hæmatoma of the Sterno-mastoid.**—Under the name of "congenital tumour of the sterno-mastoid," a localized thickening and induration of the muscle has long been recognized. It is usually noticed soon after birth, and affects especially the lower and sternal part of the muscle, more commonly on the right side than the left. The lump in the child's neck is usually discovered accidentally, and as a rule, it disappears in the course of a few weeks

or months, but occasionally it seems to have an important relation to the subsequent development of wry-neck (see p. 529).

Many views have been expressed concerning the nature of the "congenital tumour of the sterno-mastoid," some regarding it as a gummatous infiltration due to congenital syphilis, others as inflammatory, and others again as a congenital hypertrophy. In 1838, Stromeyer, first traced the connexion between the lesion and difficult delivery, and it is now generally agreed that the swelling is the result of rupture of the muscle fibres with extravasation of blood within the sheath. This has indeed been demonstrated microscopically by Herbert Spencer. The damage to the muscle can generally be traced to traction on the head in breech presentations, or to the use of the forceps in vertex presentations. In nearly 300 autopsies made by Spencer on children which were still-born or died soon after birth hæmorrhage into the sterno-mastoid was found fifteen times. Ten of these were cases of breech or footling presentation, and in two others forceps had been used. In a case recorded by F. Taylor, the swelling was found to be due to a new growth of fibrous tissue between the bundles of muscular fibres; this had probably developed in the seat of the damage to the muscle. The child was syphilitic, and the case was also one of breech presentation at birth. No *Treatment* is required, unless any signs of wry-neck manifest themselves.

**Diffuse Cellulitis of the Neck.** **Ludwig's Angina** has been described in Vol. I. at p. 956.

#### DISEASES OF THE THYROID GLAND.

The thyroid gland is subject to various simple chronic enlargements, which commonly go by the name of *Bronchocele* or *Goître*. The gland is composed of closed vesicles, lined by a single layer of cubical epithelium, containing a clear albuminous fluid. The vesicles are held together by areolar tissue, supporting numerous vessels of considerable size. Virchow has shown that all forms of bronchocele commence by a true hypertrophy of the gland-substance, but as the enlargement progresses, one or other of the constituent elements of the gland may increase out of proportion to the others. If all the constituents continue to increase equally, the *Simple Bronchocele* results; if the contents of the vesicles accumulate, unduly distending the cavities, the disease assumes the form known as *Cystic Bronchocele*; whilst if there is a great increase of the fibrous tissue, the condition is known as *Fibrous Bronchocele*. *Pulsating Bronchocele* is usually said to arise from great dilatation of the blood-vessels of the gland; it is, however, doubtful whether this actually occurs or whether the pulsation of the goitre is not due merely to the excessive pulsation of the vessels of the neck generally. Secondary changes also may modify the structure of the tumour. Of these the most common is a substitution of a gelatinous colloid material for the albuminous fluid normally found in the vesicles of the gland. Calcification also is common both in the walls of the cysts in cystic bronchocele, and in the masses of fibrous tissue in the fibrous goitre.

The **Causes** of bronchocele have been much discussed. The most generally received belief is, that the disease is directly occasioned by some impurity in, or peculiarity of, the water that the patients drink; and it has been supposed that water coming through chalk or limestone is particularly apt to occasion bronchocele in this country, and that water resulting from

melted snow is its occasioning cause in Switzerland. But these ideas are groundless. Hard water is drunk largely in this country in districts where no bronchocele occurs, and snow-water is never used in Switzerland, spring-water of the purest kind only being drunk. It would appear that air and locality have much more to do with the occurrence of bronchocele than water. In mountainous countries the disease occurs almost entirely amongst the inhabitants of valleys, where the air is moist and stagnant; the inhabitants, especially, of valleys that run north and south, into which the sun does not penetrate readily, or for many hours in the day, which are always in the shade of neighbouring and overhanging mountains, are especially prone to it. This is well known to be the case in Switzerland, where the disease is endemic. So also in large towns, it occurs chiefly amongst the poor who live in cellars and kitchens, or in damp, ill-ventilated streets and courts. When it is met with in the richer classes, it is found mainly amongst children and young people shut up in school-rooms or condemned to a sedentary and indoor life. It is rarely, if ever, met with amongst those who lead open-air and active lives. Bad food and low living no doubt conduce to it. The tendency is probably hereditary in some cases; when associated with idiocy, constituting that wretched condition "cretinism," it undoubtedly is so. Every race of men is liable to bronchocele, and it occurs in all latitudes, from the Arctic region to the tropics. Thus Franklin found bronchocele amongst the inhabitants of the polar regions, and Mungo Park amongst those of the interior of Africa. In this country it is most common in Derbyshire, and has consequently received the name of "*Derbyshire neck*." It is most frequent amongst women.

**SYMPTOMS AND VARIETIES.—Simple Hypertrophy or Parenchymatous Goitre.**—In this form the thyroid gland is simply increased in size without any marked change in structure. It may attain a considerable bulk, forming a smooth rounded tumour, maintaining more or less accurately the form of the normal gland, though frequently the enlargement on one side is greater than on the other. It is soft and elastic to the feel, and moves up and down with the trachea during deglutition. In the majority of instances in England, the tumour is of but very moderate size, commencing at first as a mere fulness and uniform rounded enlargement of the isthmus, until perhaps, by the pressure of the growth confined between the sterno-mastoid muscle and under the deep fascia of the neck, the voice becomes croaking and harsh, and respiration is seriously affected, especially on exertion, and occasionally there may be some interference with deglutition. It is seldom that the bronchocele distorts the structures of the neck to one side; but this may happen. Thus I have seen the larynx and trachea pushed completely over to the left, forming a long convexity in that direction, whilst the carotid sheath on the right side was thrust behind the sterno-mastoid muscle.

When the tumour reaches any considerable size it presses on the veins of the neck and thus causes interference with the cerebral circulation; the face becomes turgid, the superficial veins are distended and the patient may suffer from headache, vertigo, or drowsiness.

There is a remarkable connexion between tumours of the thyroid gland of this kind, and a general anæmic condition of the system. In London nothing is more common than to find a certain degree of bronchocele in pale and bloodless women and girls; indeed, so frequent is the coincidence that it is impossible not to regard it in the light of cause and effect.

**Fibrous Bronchocele.**—This form commences as simple hypertrophy, but as the tumour increases in size it loses its soft elastic feel and becomes dense and indurated; at the same time its form often changes, becoming more irregular and lobulated. Calcification is not uncommon. The pressure-effects of the fibrous bronchocele are more severe than those of the simple form, owing to the greater density of its structure. Respiration may be greatly impeded, at first only during exertion, but, when the growth reaches a considerable size, during rest also. Occasionally the tumour may extend below under the sternum, and the pressure-signs then become more serious. In other cases the recurrent laryngeal nerve may be compressed, giving rise to the symptoms already described at page 155. Deglutition is seldom seriously interfered with.

**Cystic Bronchocele** is due to the development of cysts in the substance of the enlarged gland. These cysts may be single or multiple. When single or of large size, as in Fig. 682, they usually contain clear serous fluid. When multiple, they are filled with colloid substance, or with a fluid that presents the ordinary characters of altered blood, being dark, grumous, or like coffee-grounds. Cauliflower-like excrescences projecting into the interior are sometimes met with, and calcification of the cyst wall may occur.

**Pulsating Bronchocele** is occasionally met with. The pulsation which is excentric and distensile, is synchronous with the heart's action, and evidently due to the vascular character of the tumour itself. This form of bronchocele is sometimes conjoined with the cystic. When it is confined to one lobe only, care must be taken not to confound the beatings with those of carotid aneurism; a mistake which I have known to occur. The diagnosis of the two affections has been adverted to at p. 171.

**TREATMENT.**—The treatment of bronchocele must vary according to the size and character of the tumour, and the constitutional condition associated with it. When small, and associated with anæmia, and of comparatively recent formation, it is best treated by improving the general condition of the patient. This may be done in various ways: by the administration of good food; by change of air from a low and damp to an elevated and dry and healthy situation. This has been much insisted on by those who have studied the disease in those valleys of Switzerland in which it is endemic; and establishments have been erected several thousand feet above the level of the sea, for the cure of patients thus affected. Guggenbühl has been particularly successful in this respect. In towns, the patient, if living on the basement floor, should be moved to the upper storey, and should be encouraged in habits of outdoor occupations. Besides these hygienic measures the disease may be treated medically by the administration of iron, especially the iodide, and the external application of iodine or of iodide of lead ointment. Indeed, in the soft bronchocele occurring to anæmic females iron is of the utmost service, and acts almost as a specific.

In bronchoceles of large size, and unconnected with anæmia, the chief reliance is to be placed on the free and continuous use of *iodine* internally as well as externally. The iodide of potassium is the best form in which to give

Fig. 682. — Cyst of Thyroid, containing clear Serous Fluid.

the iodine internally. The quantity of this medicine should be gradually increased, until from 20 to 30 grains are given three times a day either alone, in milk, or in combination with some preparation of iron; the iodide is probably the best. But iron is very necessary in all the anæmic forms of the disease. Iodide of lead and compound iodine ointment may be used with advantage. It has been recommended by Mouat that the biniodide of mercury ointment (16 grs. to the ounce) should be well rubbed in for several days; and then, the tumour being covered with it, the patient should be exposed to the strong heat of a mid-day summer sun. This method of treatment, which is said to have been extremely successful in India, is seldom practicable in this country. In some instances *pressure* has been of use, especially, in conjunction with the iodide inunctions; though it is not so easy to apply this means, and no considerable degree of it can be borne, on account of the increased difficulty of respiration that is thus occasioned. When bronchocele is very large, and very chronic, its absorption cannot, I think, be expected to be brought about by these or any other means; and the question then arises as to the propriety of having recourse to operative interference.

**Injection of Tincture of Iodine** into the substance of the gland is recommended by Billroth in cases of simple hypertrophy. In fibrous bronchoceles he does not advise it, as they are often permeated by very large blood-vessels. The iodine is injected by means of a hypodermic syringe, about ten minims being thrown in at a time. The operation may be repeated twice or three times a week, according to the effect. In performing the operation care must be taken that the point of the needle is actually in the substance of the gland, and that a superficial vein be not wounded, and that no air is injected. The fluid must be injected slowly. With all these precautions, however, this mode of treatment is not free from danger from entrance of air, embolism, or acute inflammation and suppuration in the gland.

**Injection of Perchloride of Iron** by means of the syringe figured at p. 73, might be of service in some cases of very vascular and pulsating bronchocele; but it is not without the special danger of forming a plug in the circulation, and rapidly fatal embolism may follow its use. A fatal accident of this kind has in fact been recorded. In one instance of pulsating bronchocele in which I employed it, although much local inflammation and deep-seated suppuration were induced by it, the patient was in the end materially benefited.

**Ligature of the Thyroid Arteries** has been practised by some Surgeons, with, it is stated, a certain degree of success. The difficulties and danger of the operation, the uncertainty of its results, and the readiness with which the arterial supply would be forwarded to the tumour from other sources, have caused it to be but little resorted to by Surgeons of the present day. In one case of pulsating bronchocele in which I had recourse to this treatment, no benefit resulted from it.

**Excision of the Thyroid Body.**—Cases occasionally occur in which, from pressure on the trachea, œsophagus, and jugular vein, the dyspnoea becomes so severe, and the dysphagia and vertigo so serious, that there is no escape from death except by partial or complete removal of the tumour. Complete removal of the thyroid body was carried out by Roux, Warren, Greene, and others, in a few exceptional cases between 1820 and 1870, but the results were not encouraging, some of the patients having died on the table from hæmorrhage,

and others shortly after the operation from septicæmia and other causes. Since 1870 the operation has very frequently been performed by P. H. Watson Kocher, Billroth, and many others, with a large amount of success, so far as the immediate result is concerned. In 1883, however, Reverdin and Kocher observed that in a considerable number of cases the complete removal of the thyroid gland was followed by a peculiar train of symptoms terminating in many cases in death. At the time Kocher published his observations he had partially or wholly excised the thyroid body in 101 cases: of these he was able to trace the after-conditions in 28 cases of partial, and in 18 cases of total, extirpation of this organ. In none of the cases of partial excision was any deterioration of health noticeable. Of the 18 cases of total extirpation, in two only was there no change for the worse with regard to the general health, and it was most remarkable that in one of these cases a vicarious hypertrophy of a small accessory thyroid body had taken place, whilst in the other a return of the goitre had made its appearance.

In all the remaining 16 cases of total extirpation, more or less marked signs of derangement of the general health were manifest. This derangement was of a progressive character, being more noticeable in the oldest, least so in the more recent cases that had been operated on. Kocher describes the symptoms that manifest themselves as occurring in the following order. Some time after leaving the hospital a sense of fatigue, lassitude, and weariness was experienced in the limbs, with dragging pains in the arms and legs. A sensation of coldness soon was superadded, especially in the hands and feet, which parts in the winter become bluish-red and cold, chilblains making their appearance. The mental activity decreased; thought and speech became slow. The movements generally were sluggish, but there was no impairment of the mental powers. Swelling of the body, but more especially of the face, now began to take place. The eyelids became thickened and somewhat transparent, and the expression of the countenance idiotic. The hands, face, and abdomen swelled; the skin lost its elasticity and became dry; the hair fell off, and in more developed cases anæmia occurred. In young subjects the growth of the body was retarded in a very marked manner. In some cases dysphagia, headache, and giddiness were met with.

These symptoms, to which Kocher gave the name of "*cachexia strumipriva*," it will be observed, are identical with those of the disease first described by Gull as a "*cretinoid condition*," and subsequently more fully by Ord, under the name of "*myxœdema*." Ord showed that this condition is invariably associated with more or less complete atrophy of the thyroid body. Beyond this, the characteristic *post-mortem* appearance in the disease is the presence of large quantities of mucin in every tissue in the body. In 1885 Horsley showed that by removing the thyroid gland in monkeys an identical condition was invariably produced. These observations clearly prove that the thyroid gland plays some most important part in the animal economy, although its exact functions are not as yet accurately determined. They show, moreover, that complete removal of the thyroid body is not a justifiable proceeding, and that whatever mode of operating be adopted some portion of the gland substance should be left behind.

The operations which may be undertaken are partial excision of the gland, excision of the isthmus, and scooping out a portion of the substance of the tumour.

**Excision of Half the Thyroid Body** is best done by an incision in the middle line, from the upper border of the tumour to the sternal notch. From the upper extremity of this a lateral incision may be carried outwards and upwards along the upper border of the tumour, as far as may be necessary. The platysma and deep cervical fascia are then divided to the extent of the wound, and the sterno-hyoid, sterno-thyroid and omo-hyoid muscles drawn on one side or divided if necessary. Large dilated veins are usually found on the surface of the tumour, which must be carefully divided between double ligatures. The sterno-mastoid and the carotid sheath are drawn carefully outwards with copper spatulæ and the upper part of the tumour isolated by tearing through the areolar tissue surrounding it with forceps and a blunt instrument such as a director. When the superior thyroid vessels are reached, these may be secured within their sheath by passing an aneurism needle round them and tying them *en masse*. Double ligatures should be used, and the vessels divided between them; or the vessels may be picked up with forceps, divided and the two ends ligatured separately. The upper part of the enlarged lobe can now be turned downwards and the next step consists in separating the outer and lower part and ligaturing the inferior thyroid vessels, special care being taken not to injure or include the recurrent laryngeal nerve. The tumour may now be carefully raised towards the middle line until the isthmus is reached. This must be divided in the middle line, all bleeding vessels being secured as they are cut, or it may be transfixed with an aneurism needle and ligatured with stout silk. Jacobson prefers to divide the isthmus before proceeding to ligature the inferior thyroid vessels. The dangers during the operation are hæmorrhage, entrance of air into the dilated veins, wound of the internal jugular vein, to which the tumour is sometimes adherent, and injury to the recurrent laryngeal nerve. These can be avoided only by careful dissection, and by the application of double ligatures to every vessel before it is divided. If the tumour be very large, a part may be removed from the opposite side, but some portion of the gland should always be left.

**Excision of the Isthmus** of the thyroid has been recommended by Tillaux as a means of cure in certain cases of bronchocele, the effect of the operation being to lead to atrophy of the enlarged lateral lobes of the thyroid. Tillaux in Paris, and Sydney Jones and others in this country, have practised the operation successfully in several cases. The operation consists in exposing the isthmus by a median incision, passing a ligature round it at each end, tying them tightly, and then excising the intervening portion. Jones advises that the wound should be well drained. The results appear to have been very satisfactory.

**Scooping out a portion of the Thyroid Body** by means of a large sharp spoon has been practised with success by Lister and others. An incision is made near the edge of the sterno-mastoid, avoiding any large veins that may be visible. On exposing the tumour an opening is made into it by means of Paquelin's cautery. The sharp spoon is then introduced, and a considerable portion of the substance of the tumour rapidly scooped out. The hæmorrhage, which is usually very free, may be restrained by pressure, and, if necessary, the cavity must immediately be plugged with some efficient antiseptic material. The plugs may be removed in a few days, and a drainage-tube inserted.

In all operations on the thyroid body the strictest antiseptic precautions

must be taken, otherwise death from septicæmia, or from suppuration extending into the mediastinum, is very likely to occur.

**Treatment of Cystic Bronchocele.**—Cysts of the thyroid have been treated successfully by tapping them and then injecting tincture of iodine, or a solution of perchloride of iron (3ij to ʒi of water) as recommended by Morell Mackenzie. On account of the uncertainty of this method and the dangers of sloughing and suppuration with which it is attended, it has been largely abandoned in favour of laying open the cyst or completely excising it. In the former method the cyst is incised freely and its walls sutured to the skin. Any soft solid tissue which it contains may be scraped out, and if the hæmorrhage is free the cavity should be plugged with strips of antiseptic gauze. If the discharges decompose the patient runs considerable risk of pyæmia, septicæmia, or diffuse suppuration in the neck.

Charters Symonds has shown that in many cases thyroid cysts, being but loosely connected with the gland itself, can be treated by complete excision. After the cyst has been clearly exposed by an incision, preferably in the middle line, Symonds suggests that it should be punctured, when the collapsed cyst-wall can be dissected out with a blunt instrument. If the cyst lies behind one lobe of the gland this must be raised from its surface and then the cyst removed.

**Adenomata and Cysto-adenomata.**—These consist of encapsuled solid or cystic growths, which lie on the surface or in the substance of the gland proper, having, as Symonds has pointed out, the same relation to the thyroid body itself as adenomata have to the breast. The solid tumours have a structure closely resembling that of the normal thyroid gland, whilst the cystic forms arise by distension of the glandular acini. They present themselves as a localized enlargement usually of one lobe, and the *treatment* consists in shelling them out from their loose connexions with the gland itself.

**Acute Bronchocele** is of rare occurrence, but has been met with both sporadically and epidemically, and in young subjects. Acute goitre has also been recorded as occurring during pregnancy and after parturition. The whole thyroid gland undergoes rapid enlargement, attaining the size of a man's fist or larger in the course of a few days or weeks. Owing to the rapid enlargement of the thyroid body, the fascia of the neck covering it does not stretch with sufficient rapidity; and the consequence is that the subjacent parts, as the trachea, become compressed, so that intense dyspnœa sets in, and death from asphyxia may result in the course of a few days or weeks. It is difficult in these cases to know how to save the patient; for tracheotomy by the ordinary methods may be impracticable, owing to the manner in which the tumour dips down behind the sternum. In such cases, tapping the tumour in different places, and the division of the fascia of the neck covering it, may give relief, and afford time for the action of remedies. If death is imminent from asphyxia the Surgeon may endeavour to intubate the larynx with a No. 10 gum elastic catheter having an opening at the extremity, as recommended by Annandale and others. If this fail only two courses are possible: either the isthmus must be divided accurately in the middle line, Paquelin's red-hot knife being used to limit the hæmorrhage; or the larynx may be opened, the cricoid cartilage being divided, and a long cannula or a catheter passed downwards past the obstruction. The latter method has been

successfully adopted by König, who has invented a special cannula for such cases. In his case the tube had to be passed nearly five inches downwards before air entered freely through it.

**Exophthalmic Goitre or Graves's Disease** is characterized by a triple clinical combination—of anæmia, exophthalmos, and bronchocele. The consideration of this remarkable disease belongs rather to Medicine than to Surgery, but reference must be made to the fact that of late years numerous attempts have been made to treat the pulsating bronchocele by operative interference, apparently with a considerable degree of success. Excision of one lobe is the method which has chiefly been adopted. This was done in two cases by Lücke of Hamburg, in patients aged seventeen and forty-seven respectively. In both instances the operation was followed by shrinking of the remaining half of the gland and improvement in the other symptoms of the disease.

**Acute Inflammation of the Thyroid Body.—Thyroiditis.**—This is an uncommon affection, and is rarely, if ever, met with in a gland not already enlarged. It may arise sometimes without apparent cause, and is then attributed to exposure to cold, but more commonly it is the result of injury or a part of general pyæmic infection. It is characterized by acute febrile disturbance, sometimes commencing with a rigor. The gland becomes hot, tender, and rapidly swells, sometimes to such an extent as to threaten death from suffocation. The inflammation may subside in a few days or may terminate in suppuration, which is indicated by increasing redness and the presence of fluctuation. The *treatment* consists in the application of leeches and hot fomentations. If suppuration is suspected, the pus must be sought for with an aspirator. If it is found, an incision must be made and a drainage-tube inserted. To avoid hæmorrhage, the gland substance may be divided with Paquelin's cautery.

**Tubercle of the Thyroid** is very rare. Miliary tubercles have been found in the gland in cases dying of general tuberculosis, and caseous masses and chronic abscesses have been met with.

**Malignant Tumours of the Thyroid Body.**—Kauffman, in 1879, published a paper in which he recorded 30 cases, partly his own and partly collected, of malignant tumour of the thyroid body: of these 23 were carcinoma, and 7 sarcoma. In every case the malignant tumour originated in a gland already affected by chronic bronchocele. The tumours usually affected one lobe only, but in a few cases the whole gland was implicated. The cancerous tumours were characterized by rapid growth, infiltration of neighbouring structures, and early infection of the lymphatic glands and internal organs. In six cases, secondary tumours formed in the bones. The tumour was in all cases soft in consistence, and microscopic examination showed that the morbid growth commenced by proliferation of the normal cells of the gland, the new cells first filling the spaces and then burrowing into the surrounding parts in columns. The cells were in most cases polygonal, but in one the spaces were lined with cylindrical epithelium.

The sarcomata were round-celled, spindle-celled, and mixed. In one case the growth perforated the trachea, and in all secondary tumours appeared—in three cases in the lymphatic glands.

A special form of malignant tumour of the thyroid body—known as "*thyroid cancer*"—has been met with in a few recorded cases in which the secondary tumours closely resembled the normal thyroid body in structure.

These were first described by Cohnheim, and cases have been recorded by Morris, Warrington Haward, Neumann and others. In all these the lymphatic glands were affected, and pulsating growths appeared in the bones.

The thyroid body is also sometimes implicated by malignant sarcomata springing from the structures in its neighbourhood, and by epithelioma of the œsophagus or larynx. It is very rarely the seat of secondary malignant growths.

Malignant tumours of the thyroid are rarely suitable for removal by operation on account of the extent of the glandular infection and the implication of the important structures in their neighbourhood.

## CHAPTER LV.

## DISEASES OF THE JAWS AND THEIR APPENDAGES.

## DISEASES OF THE GUMS AND ALVEOLAR PROCESSES.

**Abscess of the Gums, Alveolar Abscess** or **Gumboil** is of very frequent occurrence, from the irritation of decayed teeth. The common gumboil forms at the edge of the gum and is quite superficial; it is at once relieved by puncturing it with a lancet. A more troublesome form of alveolar abscess is that which develops in connexion with the fang of a tooth, usually carious, but occasionally apparently healthy. The pus forms at the extremity of the fang, the alveolus being absorbed around it, so that a small abscess-cavity is hollowed out deep in the bone. The pus may find its way out along the tooth, pointing at the margin of the gum, but not unfrequently, especially in the molar or bicuspid teeth, it perforates the compact tissue of the jaw-bone and forms an abscess deeply seated below the reflexion of the mucous membrane from the gum to the lip or cheek. This is accompanied by considerable swelling of the face and severe pain. The nature of the swelling is recognized by its being firmly fixed to the jaw. By a free and early incision and extraction of the diseased tooth the pus may be let out into the mouth and immediate relief obtained, but not uncommonly in the lower jaw the abscess opens externally near the angle, and a troublesome sinus may be left which refuses to heal until the affected tooth is removed. In the upper jaw the pus may burst into the antrum or may burrow beneath the palate, forming an abscess in the roof of the mouth which occasionally leads to necrosis of a portion of the bone. To prevent this such abscesses should be opened early and the diseased tooth immediately extracted.

**Spongy Gums**, sometimes accompanied by ulceration, may occur as the result of scurvy, or from the administration of mercury. If the condition be due to scurvy, it is quickly relieved by attention to diet, fresh fruit and vegetables being freely supplied. The mouth may be washed at the same time with an alum gargle. Such cases are not uncommon among the female poor of large cities whose food consists chiefly of bread and tea. In mercurial salivation a strong alum gargle will be found the best remedy.

In scrofulous ill-fed children a *spongy condition of the gums with ulceration* and fœtor of the breath is sometimes met with. The ulcers are covered on the surface with a grey slough. The cause of the condition is often obscure. It must be treated by tonics, cod-liver oil and iron, and by chlorate of potash, administered internally to very young children, or used as a gargle when possible.

Inflammation of the gums during teething must be relieved by lancing.

**Simple Hypertrophy of the Gums**, in the form of pendulous fringed outgrowths overlapping the teeth, is occasionally met with in young children. The cause of the condition is uncertain, but it is remarkable that the children

in all recorded cases were deficient in intellect. In a case of this kind under my care I fully removed the growth with the scalpel and scissors. It was found to consist of the ordinary structure of the gums, with fine fibrous stroma containing much gland tissue; the papillæ on the surface were very large, and covered by unusually thick epithelium. At the time of the operation the child was  $2\frac{1}{2}$  years of age. Five years afterwards the late John Murray exhibited this patient and his younger brother and sister at the Medico-Chirurgical Society (Trans. Vol. LVI.). The growth had returned and the two younger children were similarly affected. They were all the subjects of tumours of the skin of the nature of molluscum fibrosum and peculiar enlargements of the fingers and toes, and were all of weak intellect. No cause could be found for the disease beyond the fact that the parents were first cousins. Heath recommends in such cases that the alveolar border should be removed with the growth.

**Epulis** is a tumour springing from the periosteum and edge of the alveolus,

Fig. 683.—Epulis of Lower Jaw.

Fig. 684.—Epulis of Upper Jaw, hanging down so as to overlap the Lower Jaw.

and implicating the osseous walls of the sockets; it grows up between and loosens the neighbouring teeth, which it displaces and envelopes in its structure. It is of two kinds: *simple* and *malignant*. The *Simple Epulis* is a fibrous tumour; the term *Malignant Epulis* is applied to a myeloid sarcoma springing from the alveolar border of the jaw, and it is sometimes extended to epithelioma of the gum.

**Fibrous Epulis** is most frequently met with in the lower jaw (Fig. 683). I have, however, seen several instances of its springing from the alveolar border of the upper jaw (Fig. 684). It appears to be occasioned chiefly by the irritation of decayed stumps, and hence occurs more frequently in connexion with the molar than with the incisor teeth. Although this disease has occasionally been seen in children, it seldom occurs before the adult age, and may be developed even up to an advanced period of life. It is seen as often among females as males. A fibrous epulis appears as a red, smooth, and lobulated tumour, at first hard and semi-elastic, like the ordinary structure of the gum, but after a time ulcerating on the surface, with a purulent or sanious discharge. The fibrous epulis springs from the periosteum of the alveolus or

from the periodontal membrane ; it sometimes contains spicula of bone. It is covered by a thin layer of mucous membrane.

The **Treatment** of fibrous epulis consists in the removal of the whole of the mass. If it be very small and superficial the growth alone may be removed and the surface from which it springs scraped with a gouge. By this means it may occasionally be cured, but more commonly it manifests a great tendency to reproduction. The portion of the alveolar border from which it springs must then be removed as well. If it grows from the periodontal membrane it can be removed by extracting the tooth. In all ordinary cases of epulis, the removal may be effected from the inside of the mouth without the necessity of making any incisions through the cheek. In very large masses of epulis extending towards the ramus, it may be necessary either to carry an incision from the angle of the mouth downwards and outwards, or to dissect up the cheek from the bone, and thus expose the disease fully. In performing the operation, the first thing to be done is to extract a tooth on each side of the tumour ; a cut must then be made with a saw through the alveoli of the teeth that have been removed, down to a level with the base of the growth. In doing this care must be taken not to cut too near the remaining teeth, lest the alveoli be opened and their support lost. If the tumour be large it may be necessary to saw deeply ; but the base of the lower jaw should, whenever practicable, be left intact, the whole of the substance not being sawn through, so that, though a considerable portion of bone be removed, yet the length of the jaw may be preserved. For this purpose Hey's saw should not be used, as it is a niggling instrument, difficult to manage in this situation ; but a straight and stiff-backed saw, with as deep a blade as the mouth will conveniently admit, will be found most useful (Fig. 692). The epulis, included between two vertical cuts, may now, if small, be removed with cross-cutting forceps, and the bleeding stopped by placing a plug in the wound and compressing it against the teeth of the upper jaw by means of a bandage passed under the chin. If the epulis be large, a horizontal cut should be made along the bone about midway between the alveolus and the base, by means of Hey's saw ; and, after the bone has been penetrated to a sufficient depth, the blade of the cross-cutting forceps may be fixed in this cut, and the diseased part then removed. Should the dental artery spout it should be touched with the fine point of Paquelin's cantery. The cut surface will speedily granulate ; and the cavity fills up with fibrous tissue. The operation for the removal of epulis is a very safe one. Of 28 cases collected by Hutchinson from different London hospitals, only one was fatal, from pyæmia.

**Myeloid Sarcoma of the Alveolar Border** forms a soft purplish, very vascular tumour, growing rapidly and speedily recurring after removal, unless the incisions are carried widely beyond the growth. It is sometimes spoken of as "myeloid epulis." It occurs principally, so far as my observation goes, in males advanced in life. These tumours require the same operation as the fibrous epulis ; and, as much hæmorrhage usually follows their removal, a cantery must be applied to the bleeding surface. If the tumour be very large, it may be necessary to remove a portion of the whole thickness of the bone, through an external incision, as will be described in the section on Excision of the Lower Jaw (p. 646).

**Epithelioma of the Gum** is not uncommon. It presents the ordinary

characters of squamous carcinoma. It is distinguished from myeloid sarcoma by its flat surface, its early ulceration, the everted edge of the ulcer, and its comparatively slight tendency to fungate (Fig. 685.) In the later stages the neighbouring lymphatic glands become enlarged. In the lower jaw, when the growth penetrates the compact bone, it extends widely in the cancellous tissue. In the upper jaw it may invade the antrum, and completely fill that cavity. The treatment is to remove the growth freely with a considerable portion of the bone on each side of it. In the upper jaw, if the growth fills the antrum, it may be necessary to remove the whole or a great part of the upper maxilla.

**Necrosis of the Jaw** may result from many different causes. It is frequently due to alveolar abscess, when all degrees are met with, from separation of a small sequestrum from the wall of an alveolus to extensive necrosis of the body of the jaw. It may also be the result of different varieties of ulceration in the mouth, salivation by mercury, syphilis, exposure to the fumes of phosphorus, or injury. A variety, spoken of as "exanthematous necrosis" is not very uncommon in the course of the acute specific fevers, having been seen after scarlet fever, measles, typhoid fever, and small-pox. Necrosis sometimes occurs without any assignable cause. In this way I have seen the whole of the alveolar process of the upper jaw exfoliate in a young lady, otherwise perfectly healthy; and I have several times had occasion to remove large portions of the lower jaw—in one case more than half of the bone—for necrosis that could not be referred to any of the causes mentioned above. The disease begins with deeply seated pain resembling severe toothache, which nothing will allay; the gums become swollen; the teeth are loosened, and eventually drop out. Before they do so, however, pus usually wells up through the alveoli. Abscesses form inside the mouth, and under the angles of the jaw, having sinuses through which bare bone is reached by the probe. The general health suffers greatly, doubtless in consequence of the patient swallowing some of the pus from the dead bone.

Necrosis of the jaws, arising from inhalation of the fumes of phosphorus during the manufacture of lucifer matches, first noticed by Lorinser of Vienna, has been especially described by Von Bibra and Geist, who had abundant opportunities of observing the disease at the large manufactories at Nuremberg. This **Lucifer Match disease** was some years ago very frequent, but, in consequence of the adoption of precautionary measures, is now much more rarely met with. It consists in necrosis of the jaws, and is attended with the symptoms above described, but in a more severe degree and an acute form. The affected bone undergoes a remarkable change, assuming the porous aspect and grey colour of dirty pumice-stone. Both jaws are equally liable to be affected, but commonly one only at a time is diseased; the whole of the bone may die and be separated. Thus of 51 cases observed by Von Bibra, both jaws were affected in five instances only—the upper alone in 21 cases, the lower in 25. According to Langenbeck, the local disease is preceded in many instances by general symptoms of phosphorus poisoning; and there is a considerable amount of bony deposit from periostitis, enclosing the necrosed bone. It has been believed that workmen having sound teeth are not easily if at all

Fig. 685.—Squamous Carcinoma of Upper Gum.

influenced by the fumes, and that the phosphorus acts through carious teeth ; but Langenbeck has observed that the teeth have been sound in cases of the disease. Mears of Philadelphia, who has seen a large number of cases, is also of opinion that the necrosis is due to the general and not the local effect of the poison.

The *diagnosis* of necrosis of the lower jaw is usually unattended with any difficulty, but in certain cases a sequestrum included in a thick mass of new bone may somewhat closely resemble a central tumour. In the upper jaw, especially when limited to the palatal process, it may resemble epithelioma in the raised and everted edges of the ulcer in the hard palate and the spongy feel communicated to the probe by the dead bone.

The **Treatment** of necrosis of the jaw presents nothing special. The removal of the sequestra should be effected as far as practicable through the interior of the mouth, by free incisions through the gums.

In the *upper* jaw, where the necrosis seldom extends beyond the alveolar border or the palatal process, this may always readily be done.

In the *lower* jaw, the question as to whether the dead bone should be extracted through the mouth, or by incision from without through the cheek, will be determined partly by the position of the sinuses and partly by the situation and extent of the bone affected. If the sinuses be in the cheek, or in the side of the neck, or under the angle of the jaw, it is usually an indication that, if the whole of the corresponding ramus or body of the bone be not involved, the posterior and outer parts are certainly affected ; and, in these circumstances, extraction of the sequestrum is best effected by opening up the sinuses parallel to the line of the jaw. The incisions for this purpose need not usually be very extensive.

Fig. 686.—Wood's Case of Phosphorus Necrosis of entire Lower Jaw.

If the operation be delayed, in accordance with those principles that guide us in the management of necrosed bone generally, until the sequestrum is quite loose, it may usually be readily extracted, in whole or in pieces, through an opening that will leave but a small cicatrix. By such operations as these, the whole of the lower jaw has been extracted piecemeal at intervals in a state of necrosis, first on one and then on the other side. Carnochan has removed the whole of the necrosed lower jaw at one operation, disarticulating first one and then the other condyle in the usual way.

If, however, there be no external abscess or sinus—if the gum have been loosened and perforated, with a ragged portion of sequestrum projecting through it into the cavity of the mouth, then no external incisions will be required, but the dead bone may readily be removed from within the

mouth. I have in this way taken away the whole of the ramus with its processes ; and, in a negro, the whole of the bone in a state of necrosis has thus been removed in separate pieces, by Perry, through the mouth.

**Reproduction of the Jaw after Removal.**—The amount of regeneration of bone will depend greatly upon the state of the periosteum before the removal of the sequestra. If this be healthy, and if new bone have already formed prior to operation, a very perfect reproduction may take place ; in fact, complete reproduction of the whole of the lower jaw, though in a somewhat rudimentary and imperfect form, may follow its removal from phosphorus necrosis. In the museum of the Bellevue Hospital, New York, Wood showed me two specimens, one of the necrosed lower jaw, removed by him for phosphorus disease from a girl about 19 (Fig. 686). She died of brain disease three years after operation ; and in the same collection is her cranium with a reproduced lower jaw, consisting of an entire semicircle of bone, about 5-8ths of an inch deep, with all the processes. This unique and most interesting case has already been described, and the regenerated bone figured (Vol. II., p. 292, Fig. 516). In it the periosteum must have been preserved entire, and thus led to the reproduction of the bone. Should no new bone have formed before the operation, a dense fibroid cicatricial structure will replace the lost bone.

**Actinomycosis**, which has a special tendency to affect the lower jaw, has been described in Vol. I., p. 1105.

#### DISEASES OF THE ANTRUM AND UPPER JAW.

Our present knowledge of the operative procedures necessary for the removal of disease of the jaws, is due chiefly to the labours of Gensoul, Lizars, and Liston. William Fergusson and Christopher Heath have also done much to simplify and extend this department of Surgery.

The various large and irregular cavities that lie amongst the bones of the face may become the seat of disease, primarily originating either in the mucous membrane by which they are lined, or in the osseous structures that compose their walls. In this way the frontal sinuses, the ethmoidal and sphenoidal cells, and the antrum, may either be seats of chronic inflammation of their mucous linings, with more or less profuse muco-purulent discharge ; or the mucous membrane may be affected by more serious organic disease. Thus carcinoma may develop in it, and after distending the cavity in which it originally formed, may destroy its osseous walls ; and, passing outwards into other situations about the face and the base of the skull, where it is freed from the pressure of surrounding bone, it may increase rapidly, blocking up mucous canals, as the nose and the lachrymal sac and duct, displacing the eye, and producing great disfigurement of the side of the face. These secondary outgrowths, from the rapidity of their development, and the amount of deformity and distress which they occasion, may readily be mistaken for the primary disease, the real starting point of which will often be found in a deeper locality. The bones constituting the walls of these facial cavities, or the periosteum covering them, may also be the seat of other morbid growths, more particularly of enchondroma, and myeloid, spindle-celled or round-celled sarcoma. These run a similar course to the growths originating in the mucous membranes.

**Suppuration in the Antrum.**—This is usually excited by caries of one of the teeth, the fangs of which come into close relation with the cavity, viz., the first and second molar, the bicuspid, and the canine, but in some cases it appears to arise by extension from the nose. It occasionally arises from injury. It is usually accompanied at first by deep-seated aching, throbbing, or lancinating pain in the face. This may be referred to the frontal region and thus simulate disease of the frontal sinuses. So much is this the case that it is a good rule not to operate for supposed disease of the frontal sinuses without previously exploring the antrum with a trochar. The pus as it forms in the antrum will sometimes flow into the nostril through the aperture into the middle fossa, and then may keep up constant irritation, with much fetor in the nostrils. When this takes place, as the olfactory region of the nose is healthy, the patient is conscious of an unpleasant smell, but according to

Fig. 687.

Fig. 688.

Fig. 689.

Various forms of Antrum-Perforator.

Heath this is not perceptible to other people. In ozæna, on the other hand, the patient is unconscious of the unpleasant smell which is perceived by others. In other cases, the pus drains through the socket of a tooth into the mouth; and much less commonly, its exit being prevented, it gives rise to enlargement of the cheek, the soft parts of which become brawny and inflamed, and the bones expanded, so that at last they are thinned to such an extent that, as in cystic disease of the cavity, they crackle when pressed upon. Any portion of the wall of the cavity—the orbital, buccal, palatal, or nasal—may thus be expanded and fluctuation be felt through it; and, the lachrymal duct being commonly obstructed, the eye on the affected side becomes watery. In some cases abscess of the antrum has been followed by loss of sight in the eye of the same side. Temporary blindness is not uncommon when the floor of the orbit is raised by the pus.

As an aid to the diagnosis of the presence of pus or solid tumours in the

antrum may be mentioned the method of transillumination recommended by Voltolini and Heryng. This consists in introducing an electric light into the mouth, the patient being in a darkened room. The cheeks, lips and lower margin of the orbits become illuminated of a rosy red colour, whilst if one antrum is filled with pus or an opaque tumour the illumination of the corresponding cheek and orbit is proportionately diminished. Although this method has proved of some practical utility it seems to give misleading evidence in some cases.

*Treatment.*—Although Mikulicz, Krause, and others have recommended draining the antrum from the nose, either in the position of the normal opening or by perforating the outer wall of the inferior meatus, the method of treatment usually adopted consists in draining the abscess from the mouth. Any carious tooth situated in the neighbourhood of the antrum should be extracted and then the antrum may be opened by perforating the socket. If however all the teeth appear healthy the opening into the antrum should be made above the alveolus, or through the canine fossa under the cheek, provided it be much expanded in this situation, so that its cavity can easily be reached.

The perforation into the antrum may readily be made, or the socket of the tooth enlarged, by means of one of the forms of antrum-perforator here represented (Figs. 687, 688, 689), or a carpenter's gimlet, as recommended by Fergusson. As the matter drains away, the cavity will gradually contract, and the deformity thus be removed. It is well not to attempt to perforate in the site of teeth that have been extracted for some time, as here the bone becomes unduly consolidated, and the attempt to reach the cavity is consequently likely to fail. The matter that is discharged is often very offensive, or it may be thick and pasty from the absorption of its watery parts. After the aperture has been made, the cavity should be syringed out twice daily with some antiseptic solution. The best instrument for this purpose is that recommended by Heath, consisting of a common Eustachian catheter, to which an india-rubber ball is fitted to contain the fluid to be injected.

Fig. 690.—Cystic Disease of Antrum.

**Cystic Disease of the Antrum.**—In this disease the antrum becomes slowly distended with a fluid, in some cases glairy and mucous in character, like the contents of a ranula, in others thin, brownish, and serous, containing cholesterine. It was formerly believed that this condition was, in some instances at least, due to obstruction of the aperture leading from the antrum to the nose, and hence the name “dropsy of the antrum” was applied to it; but it is now generally acknowledged that in all cases it results from the formation of a cystic tumour springing from the mucous membrane lining the cavity. In such cases the accumulation of fluid may after a time cause expansion and thinning of the osseous walls of the cavity. The cheek is rendered round and prominent—a painless indolent semi-elastic tumour forming in it and protruding it outwards, and giving rise to the egg-shell or parchment-like

crackling on pressure (Fig. 690). The floor of the orbit or the roof of the mouth may be caused to bulge, and the nasal cavity may be encroached upon.

**Treatment.**—The operation of "catheterizing the antrum," founded on an erroneous idea as to the nature of the disease, was formerly recommended. But was never attended with any benefit to the patient. The only efficient treatment consists in opening the antrum from without: this is done without incising the lips or wounding the face, by thrusting a trochar and cannula into the most thinned and expanded part of the tumour under the cheek; or, if necessary, by dissecting up the cheek from the gum, and thus making an opening into the cavity of the antrum with a strong pair of scissors or a perforator, through its most expanded part, so as to allow the discharge to escape freely. In order to prevent a re-accumulation of the fluid, it will be better to cut away a small portion of the expanded wall of the antrum, and thus to establish a permanent aperture in it, through which it must be syringed out daily with some antiseptic solution until all discharge ceases.

**Polypus of the Antrum.**—Mucous polypi are occasionally met with in the antrum, but they give rise to no symptoms unless they reach a size sufficient to cause distension of the cavity. They then most commonly cause absorption of the inner wall and project into the nasal cavity, from which they have been successfully removed with forceps.

**Dental and Dentigerous Cysts** will be most conveniently considered with other cystic affections of the lower jaw, although the former are, according to Heath, more common in the upper than in the lower jaw.

**SOLID TUMOURS** of various kinds may take their origin from the superior maxilla or its immediate neighbourhood. In most cases, by the time the case comes under observation, it is impossible to say with certainty in what part or tissue it took its origin—whether it began in the upper jaw, or spread into it from contiguous structures. The following are the chief tumours met with in this region:—

**Fibroma.**—This is not uncommon, springing from the periosteum and either filling the antrum or projecting from the alveolar border. It grows slowly, and has no tendency to infect the surrounding tissues, but when springing from the antrum it causes gradual absorption of the surrounding bone, and forces its way into the neighbouring sinuses and cavities, or projects forwards on the face, sometimes forming a tumour of considerable size.

**Enchondroma.**—Pure enchondroma is uncommon: its general mode of growth, and the appearance it gives rise to, are similar to those of fibroma.

**Osteoma.**—Bony growths are occasionally met with filling the antrum and causing a projection forwards on the cheek. They are composed of tissue having the normal structure of bone, and somewhat denser in structure than ordinary cancellous tissue. They increase slowly and painlessly. In the case of a young woman, aged 25, under the care of Heath in University College Hospital, the tumour formed a considerable projection on the face, and had been growing for ten years. Pedunculated growths have been met with springing from the outer surface of the bone, and still more rarely ivory-like tumours have been found in the same situation.

**Vascular Tumours.**—Liston removed a tumour from the maxillary region, which in section presented the appearance of erectile tissue. The specimen is now in the Museum of University College. The section closely resembles that of the corpus cavernosum penis.

**Sarcoma** of various kinds is of frequent occurrence in the upper jaw, originating in the maxilla itself, or in the surrounding bones. Spindle-celled and round-celled sarcoma, in some cases undergoing partial ossification, and in others developing into cartilage, are the varieties chiefly met with. They form soft, rapidly-growing tumours, often implicating the surrounding parts and pushing into the neighbouring cavities from an early period. They are extremely vascular, so much so that in rare cases they pulsate distinctly. When they project into the nose they form polypoid masses, bleeding readily and obstructing the fossæ. If they spring from behind the maxilla, they not unfrequently penetrate the cranial cavity, either from the orbit or by means of the foramina in the base of the skull. Myeloid sarcoma occurs in young adult life chiefly in the alveolar border of the bone. In other parts it is extremely rare.

**Carcinoma** is far from uncommon. It may, as before stated, begin in the gum or palate, or it may originate in the mucous membrane lining the antrum or nasal fossæ. It forms a soft rapidly-growing tumour, infiltrating the surrounding parts. It very early spreads into the irregular cavities in the neighbourhood of the upper jaw, and thus is very apt to recur after apparently complete removal.

When the tumour begins in the gums or palate it has the structure of a squamous carcinoma, which, from its tendency to spread into the antrum and deeper parts, has been termed "boring epithelioma." When the growth arises primarily in the antrum or nasal fossæ it is a columnar or tubular epithelioma.

**Situation and Symptoms of Tumours in the Region of the Upper Jaw.**—Sarcomatous tumours occasionally spring from the surface of the malar bone, pushing forward the cheek, spreading into the mouth, and involving, with greater or less rapidity, the soft structures of the face and occasionally the lymphatic glands under the jaw. They are usually rapid in growth, soft and elastic to the feel, irregular in outline, and only secondarily implicate the superior maxilla and the neighbouring cavities.

The various growths that are connected with, or spring from, the periosteum or mucous membrane of the antrum, gradually expand and dilate the cavity, thinning the bony walls, and giving rise to a considerable projection of one side of the face, the anterior surface of the superior maxilla being the part that usually first yields to the outward pressure. The tumour thus formed is generally smooth, round, or oval, slightly lobed perhaps, more especially if fibrous, and has in many cases a tendency to hang downwards so as to overlap the lower jaw to a certain extent. As it grows, it encroaches more or less upon the structures lying in the vicinity of the antrum. Thus, it pushes down the palate, causing swelling in the roof of the mouth; and displaces the alveolar processes and teeth, giving rise to irregularity in their outline, and tending to project into and occupy the alveoli. It may obstruct the lachrymal duct, occasioning epiphora, or encroach upon the orbit, causing impairment of vision, and displacement of the eye-ball. As the tumour enlarges, it obstructs the nasal cavity, and, extending back into the pharynx, interferes with respiration and deglutition, and sometimes occasions severe epistaxis. When it is of a malignant character, obstruction of the nasal fossa will be found to be one of its earliest signs, leading to the suspicion of nasal polypus; but the true and more serious nature of the disease will be revealed by the

crackling on pressure (Fig. 690). The floor of the orbit or the roof of the mouth may be caused to bulge, and the nasal cavity may be encroached upon.

**Treatment.**—The operation of "catheterizing the antrum," founded on an erroneous idea as to the nature of the disease, was formerly recommended, but was never attended with any benefit to the patient. The only efficient treatment consists in opening the antrum from without: this is done without incising the lips or wounding the face, by thrusting a trochar and cannula into the most thinned and expanded part of the tumour under the cheek; or, if necessary, by dissecting up the cheek from the gum, and thus making an opening into the cavity of the antrum with a strong pair of scissors or a perforator, through its most expanded part, so as to allow the discharge to escape freely. In order to prevent a re-accumulation of the fluid, it will be better to cut away a small portion of the expanded wall of the antrum, and thus to establish a permanent aperture in it, through which it must be syringed out daily with some antiseptic solution until all discharge ceases.

**Polypus of the Antrum.**—Mucous polypi are occasionally met with in the antrum, but they give rise to no symptoms unless they reach a size sufficient to cause distension of the cavity. They then most commonly cause absorption of the inner wall and project into the nasal cavity, from which they have been successfully removed with forceps.

**Dental and Dentigerous Cysts** will be most conveniently considered with other cystic affections of the lower jaw, although the former are, according to Heath, more common in the upper than in the lower jaw.

**SOLID TUMOURS** of various kinds may take their origin from the superior maxilla or its immediate neighbourhood. In most cases, by the time the case comes under observation, it is impossible to say with certainty in what part or tissue it took its origin—whether it began in the upper jaw, or spread into it from contiguous structures. The following are the chief tumours met with in this region:—

**Fibroma.**—This is not uncommon, springing from the periosteum and either filling the antrum or projecting from the alveolar border. It grows slowly, and has no tendency to infect the surrounding tissues, but when springing from the antrum it causes gradual absorption of the surrounding bone, and forces its way into the neighbouring sinuses and cavities, or projects forwards on the face, sometimes forming a tumour of considerable size.

**Enchondroma.**—Pure enchondroma is uncommon; its general mode of growth, and the appearance it gives rise to, are similar to those of fibroma.

**Osteoma.**—Bony growths are occasionally met with filling the antrum and causing a projection forwards on the cheek. They are composed of tissue having the normal structure of bone, and somewhat denser in structure than ordinary cancellous tissue. They increase slowly and painlessly. In the case of a young woman, aged 25, under the care of Heath in University College Hospital, the tumour formed a considerable projection on the face, and had been growing for ten years. Pedunculated growths have been met with springing from the outer surface of the bone, and still more rarely ivory-like tumours have been found in the same situation.

**Vascular Tumours.**—Liston removed a tumour from the maxillary region, which in section presented the appearance of erectile tissue. The specimen is now in the Museum of University College. The section closely resembles that of the corpus cavernosum penis.

**Sarcoma** of various kinds is of frequent occurrence in the upper jaw, originating in the maxilla itself, or in the surrounding bones. Spindle-celled and round-celled sarcoma, in some cases undergoing partial ossification, and in others developing into cartilage, are the varieties chiefly met with. They form soft, rapidly-growing tumours, often implicating the surrounding parts and pushing into the neighbouring cavities from an early period. They are extremely vascular, so much so that in rare cases they pulsate distinctly. When they project into the nose they form polypoid masses, bleeding readily and obstructing the fossæ. If they spring from behind the maxilla, they not unfrequently penetrate the cranial cavity, either from the orbit or by means of the foramina in the base of the skull. Myeloid sarcoma occurs in young adult life chiefly in the alveolar border of the bone. In other parts it is extremely rare.

**Carcinoma** is far from uncommon. It may, as before stated, begin in the gum or palate, or it may originate in the mucous membrane lining the antrum or nasal fossæ. It forms a soft rapidly-growing tumour, infiltrating the surrounding parts. It very early spreads into the irregular cavities in the neighbourhood of the upper jaw, and thus is very apt to recur after apparently complete removal.

When the tumour begins in the gums or palate it has the structure of a squamous carcinoma, which, from its tendency to spread into the antrum and deeper parts, has been termed "boring epithelioma." When the growth arises primarily in the antrum or nasal fossæ it is a columnar or tubular epithelioma.

**Situation and Symptoms of Tumours in the Region of the Upper Jaw.**—Sarcomatous tumours occasionally spring from the surface of the malar bone, pushing forward the cheek, spreading into the mouth, and involving, with greater or less rapidity, the soft structures of the face and occasionally the lymphatic glands under the jaw. They are usually rapid in growth, soft and elastic to the feel, irregular in outline, and only secondarily implicate the superior maxilla and the neighbouring cavities.

The various growths that are connected with, or spring from, the periosteum or mucous membrane of the antrum, gradually expand and dilate the cavity, thinning the bony walls, and giving rise to a considerable projection of one side of the face, the anterior surface of the superior maxilla being the part that usually first yields to the outward pressure. The tumour thus formed is generally smooth, round, or oval, slightly lobed perhaps, more especially if fibrous, and has in many cases a tendency to hang downwards so as to overlap the lower jaw to a certain extent. As it grows, it encroaches more or less upon the structures lying in the vicinity of the antrum. Thus, it pushes down the palate, causing swelling in the roof of the mouth; and displaces the alveolar processes and teeth, giving rise to irregularity in their outline, and tending to project into and occupy the alveoli. It may obstruct the lachrymal duct, occasioning epiphora, or encroach upon the orbit, causing impairment of vision, and displacement of the eye-ball. As the tumour enlarges, it obstructs the nasal cavity, and, extending back into the pharynx, interferes with respiration and deglutition, and sometimes occasions severe epistaxis. When it is of a malignant character, obstruction of the nasal fossa will be found to be one of its earliest signs, leading to the suspicion of nasal polypus; but the true and more serious nature of the disease will be revealed by the

integuments becoming involved, the gums implicated, and perhaps the sub-maxillary lymphatic glands enlarged.

**Diagnosis.**—In the diagnosis of these tumours of the upper jaw, there are three principal points to be attended to:—1, to distinguish the growth from fluid accumulation; 2, to determine whether it be simple or malignant; and 3, to ascertain its primary seat.

1. In making the diagnosis from *fluid accumulation in the antrum*, the history of the case, and the uniform enlargement of the cavity without localized projection beyond any part of its walls, the elasticity and even fluctuation that may, after a time, be detected, more particularly towards the outer side of the swelling and at the junction of the mucous membrane of the cheek and the gum, will enable the Surgeon to determine that it is not solid. But in many cases this is not sufficient; and it becomes necessary to make an exploratory puncture by means of the perforator, through one or other of the more thinned and expanded parts already indicated. This should never be omitted in cases of doubt: for it has happened even to so good a Surgeon as Gensoul that, after making incisions through the cheek with the view of extirpating the tumour, the bones were found to be expanded by an antral abscess.

2. In determining whether the growth be *simple or malignant*, the Surgeon will experience much difficulty, so long as it is confined to the cavity of the antrum; but when once it has perforated and passed beyond its walls, this point is easily solved. Yet, even whilst the tumour is still confined within the antrum, much light may be thrown upon its nature by attention to the rapidity of its growth; the greater this is, the more reason there is to suspect that it is malignant. Too much importance, however, must not be attached to this sign; for though, as a general rule, fibrous, cartilaginous, and bony tumours may increase less rapidly than the malignant, yet they may attain a very great bulk in a short space of time. The age of the patient is of comparatively little value in the diagnosis; I think, however, that, as a general rule, simple tumours more frequently occur in the young, whilst the malignant forms of the affection are more commonly met with at the middle or advanced periods of life. When the disease is malignant, the submaxillary lymphatic glands often become enlarged and indurated at an early period. In a case under my care, the malignant character of a tumour, whilst still in the antrum, was determined by the fact of there being a long chain of indurated lymphatic glands lying under the angle of the lower jaw. It must be remembered, however, that the sarcomata, which run an essentially malignant course, infiltrating surrounding parts and recurring in internal organs, do not as a rule affect the lymphatic glands. When once a malignant tumour has passed beyond the cavity of the antrum, and is thus relieved from the pressure of its walls, it grows with great rapidity, and where it can be felt under the skin, is perceived to be soft and elastic. Spreading extensively amongst the bones of the face and skull, it creeps through the foramina and fissures, and encroaches on the nasal cavity and orbit; its early protrusion into these cavities is especially characteristic of malignancy. It implicates the integuments of the cheek, with an inflammatory œdema, and the soft structures within the mouth, and throws out fungating masses in these several situations.

3. A point of very great importance in relation to operative interference is

to determine the *primary seat of the tumour*: whether it spring from the cavity of the antrum, from the malar bone, or from behind the superior maxilla in the pterygo-maxillary fossa. When it springs from the *interior of the antrum*, the buccal, orbital, nasal, or palatal walls of that cavity are expanded, and the line of teeth is rendered irregular. When the tumour primarily springs from the *malar bone* (Fig. 691), it pushes forward the cheek into a somewhat conical prominence, and dips down into the mouth between the gums and the soft structures of the face. It does not involve the palate, or alter the line of the teeth; but rather spreads over the bones, and involves the soft parts by continuity of tissue, without any definite anatomical disposition. As the tumour increases in size, it will implicate the anterior wall of the antrum, and project into that cavity. When the disease develops primarily *behind the superior maxilla*, between it and the great wing or the pterygoid process of the sphenoid, the upper jaw-bone is simply pushed bodily forwards, there being little if any deformity in its outline, the line of teeth not being displaced, nor the walls of the antrum expanded. Yet it must be borne in mind that the difficulty of diagnosis is greatly increased by the fact that a tumour, though not originating in the antrum, may find its way early into this cavity, or may pass into the orbit through the speno-maxillary fissure, and may make its way forwards amongst the bones of the face.

**Treatment.**—In the treatment of tumours of the upper jaw and antrum, nothing can be done except to extirpate the growth; and it is consequently of great importance to distinguish those forms of the disease in which an operation can be undertaken with safety, and with a fair chance of success, from those in which none should be performed.

The points to be considered are: 1, whether the tumour is benign or malignant; 2, if it be benign, whether it grows from the antrum or springs from behind the superior maxilla; or 3, if it is malignant, whether it has passed the boundaries of the antrum. When the tumour, springing from the antrum, is of a simple character, the disease should be removed, together with the whole of the superior maxilla; the tumour, whatever size it has attained, being generally encapsuled, and the bones expanded and absorbed around it; so that it is well bounded, and does not implicate neighbouring parts. When the tumour springs from the speno-maxillary or pterygo-maxillary fossa, pushing the bones of the side of the face forwards, an operation should not be lightly undertaken, as it is doubtful, in many cases, whether the Surgeon can interfere with any prospect of success. Should, however, the tumour be simple, the patient's health good, and an operation be deemed expedient, the tumour can be reached only by excising the upper jaw, when it may either be removed attached to that bone, or it may be extirpated from the cavity in which it lies behind it. Such an operation, implicating as it does

Fig. 691.—Malignant Disease of Malar Bone not suitable for operation.

the base of the skull, may be followed by death from shock, as I saw happen in a patient of Liston's; or, involving the internal maxillary artery, may be attended with very profuse hæmorrhage. When once a malignant growth of this part has passed beyond the osseous boundaries of the antrum, the question of removal becomes very complicated. In reference to this point, I think that it may be stated generally that, if the cheek be freely movable over the tumour, and the lymphatic glands unaffected, the operation may be undertaken. But, if it have advanced so far as to implicate the soft structures of the cheek, with enlargement of the submaxillary lymphatic glands, it is not prudent to interfere with it by operation: as infiltration will have taken place more widely than the knife can reach, and speedy recurrence must of necessity ensue. So long as it is contained within the cavity of the antrum, where indeed it is often impossible to ascertain, until after removal, the true nature of the affection, it may be excised, provided the glands in the neck be not

enlarged. If they be much implicated, even though the walls of the antrum be not perforated, it is wrong to interfere, as a cure by operative procedure must be hopeless. When both jaws are affected, as sometimes has happened, it is very rarely that any operation is possible (Fig. 692).

Fig. 692.—Malignant Tumour of the Upper Jaw, involving the whole of the Bones of the Face; not admitting of operation.

**Operations on the Upper Jaw.**—The *Operations* that have been practised for the removal of tumours springing from the upper jaw are of three kinds. They consist of—1. Scooping out of the Tumour; 2, Partial Excision of the Superior Maxilla; and 3, its Complete Removal with or without the Malar Bone.

For operations on the upper jaw, the Surgeon will require strong cutting forceps, and two or three narrow-bladed saws, with handles set at different angles, and having movable backs (Fig. 693).

1. **Scooping out the Tumour.**—The practice of scooping out tumours of the antrum, after turning up the cheek from its anterior surface, is one on the propriety of which there is a difference of opinion among Surgeons. Liston, whose experience in these diseases was in his day unrivalled, denounced all "grubbing" operations; and Syme strongly disapproved of the practice. But other Surgeons, whose views on the subject are entitled to the highest respect, advocate and practise this proceeding. For my own part, I look upon the practice as unscientific in principle and disastrous in its results. It is applicable only to the softer kinds of tumours, and these are chiefly sarcomata. Now I hold it to be generally impossible, by gouging or scraping, to extirpate these completely from any bone in which they may be developed. It is impossible in this way fairly to go beyond the limits of the disease into healthy structures. Tissues that appear and feel sound, are in reality infiltrated; hence speedy recurrence takes place. This has happened in every case in which I have seen this operation practised; and the recurrent is worse in all its features—more rapid, more luxuriant, more malignant—than the primary disease. In fact, there is no reason why, in operations on the jaws,

we should depart from that principle, which is found necessary in operations on other parts for the removal of malignant growths, of being guided in the extent of the removal by the anatomical boundaries of the part affected, and not by the apparent extent of diseased structure.

**2. Partial Excision of the Superior Maxilla.**—Although I do not consider the scooping away of the tumour from the antrum to be a proper

Fig. 693. — Saw with Movable Back, for Operations on the Jaws.

procedure, I would not advocate the removal of more of the bones of the face than is absolutely necessary for the complete extirpation of the disease, more especially when that is not malignant. The disease may be limited either to the upper or to the lower part of the superior maxilla. In these cases, the practice of Fergusson has led to great advances in our method of removing such disease with the least possible disfigurement and the least loss of bone.

With regard to the external incisions in these cases, Fergusson showed that they often need to be but very limited ; all that is necessary being a cut from the angle of the mouth upwards and outwards through the cheek, or, in other cases, a slit through the upper lip in the mesial line, the knife being carried along the side of the columna into the nostril. By these simple incisions, Fergusson has shown that sufficient relaxation of parts can be obtained for the excision of the greater part of the superior maxillary bone.

In some cases, the malar bone and floor of the orbit will be found to be sound. When this happens, they should both be left ; and with this view, after the cheek has been incised as just described, a deep horizontal groove should be made with a narrow straight-backed saw below the orbit, directly across from the nasal process of the maxillary to the edge of the malar bone. The forceps should now be applied so as to cut downwards and outwards from the end of this incision, and thus to sever the connexion between the superior maxilla and the malar bone. They are next to cut along the groove that has been traced horizontally with the saw, one blade cutting from the nares along this ; and lastly, the alveolus and hard palate have to be divided. This is best done after the extraction of one of the central incisors, by passing a narrow-bladed saw into the anterior nares and cutting down through the alveolus ;

Fig. 694. — Lines of Incision in Liston's Operation for Excision of Upper Jaw.

the remainder of the section being completed with the forceps. Or the proceeding may be reversed, and the cut made from the mouth up towards the nasal cavity. Should the disease implicate chiefly the upper orbital and nasal portions of the bone, leaving the cheek and roof of the mouth sound, another modification of the operation may be undertaken by carrying the knife from the nasal process down the side of the nose and from the nostril across the cheek, dissecting up the flap thus formed. The palpebral ligament must then be cut through, and the fat of the orbit pushed upwards and held on one side with a copper spatula, which at the same time protects the eye from injury. The nasal process of the superior maxillary bone is next cut through from the lower and inner part of the orbit into the nose; the saw is carried from the anterior nares across the superior maxilla above its alveolar process, and from the outer end of this a perpendicular cut is carried upwards into the orbit towards its outer angle so as to extend backwards into the spleno-maxillary fissure. The cutting forceps are then carried along these lines of incision so as to loosen the bone completely and the detached portion is lifted out by means of a curved periosteal elevator.

**3. Complete Excision of the Upper Jaw.**—The operation of excision of the whole of the upper jaw, together with the malar bone, for tumour of the antrum, was first proposed by Lizars in 1826; though Gensoul of Lyons was the first Surgeon by whom the operation was actually performed, in May, 1827. Since then, it has been practised repeatedly; and the names of Liston and of Fergusson are inseparably connected with it, for the skill with which they devised, and the boldness with which they carried out, the various steps of its performance.

The patient should be placed in a recumbent position with the head and shoulders well raised by pillows, opposite a good light. The Surgeon stands at first on the same side as the bone to be removed, but during the sawing he will find it convenient to stand always on the right side, returning to the left, if that be the affected side, during the final stages of the operation. Hæmorrhage during the operation is one of the chief difficulties, not only on account of the actual loss of blood that may take place, but from the risk of asphyxia from the blood finding its way into the larynx. In order to prevent this accident the throat must frequently be wiped out during the operation with sponges fixed upon proper holders. Annandale has recommended that the operation should be done with the patient's head hanging over the end of the table, so that any blood that runs backwards may accumulate in the upper part of the pharynx, whence it can be removed from time to time with a sponge. This position, however, tends to aggravate the hæmorrhage, and is not to be recommended when the tumour is very vascular. It will often be found useful to plug the posterior nares with a good-sized sponge passed behind the soft palate in the way already described, before commencing the operation. This tends to push the soft palate forwards, and may embarrass the breathing. Should this happen, a large tube of some kind, such as a lithotomy tube, may be passed between the root of the tongue and the soft palate through which respiration can be readily carried on. During the operation a good-sized sponge, attached to a piece of string, may be placed in the mouth on the side on which the operation is being performed, care being taken to leave a sufficient space for the passage of air in respiration. It must be remembered, that the patient does not require the whole mouth to

breathe through, and if it be carefully managed, a great part of the cavity may be filled with sponges during the operation. In this way, in ordinary cases, this operation may be performed without a drop of blood passing down the throat. If the tumour be very large and vascular, and much hæmorrhage is expected, it may be advisable to adopt more efficient means to prevent the risk of asphyxia. This danger may be entirely avoided by the method devised by Trendelenburg, and adopted by Langenbeck, in cases of operation about the jaws, palate, or pharynx, in which serious hæmorrhage is anticipated. The patient having been placed under the influence of chloroform, tracheotomy is performed in the usual way above the thyroid body. A trachea-tube fitted with a hollow india-rubber collar (Fig. 695, 1) is then introduced, and the inhalation of the anæsthetic vapour carried on through it by attaching, by means of an india-rubber tube, a funnel containing a sponge (Fig. 695, 2). When the Surgeon is about to commence his operation, the collar is inflated by means of the india-rubber ball attached (Fig. 695, 3); the effect

Fig. 695.—Trendelenburg's Trachea-Tampon.

3. The Inflating Bottle attached to the Collar on Trachea-tube.

being to close the trachea round the tube, and thus to cut off all possibility of blood finding its way down the larynx into the lungs. After the operation is completed, the "trachea-tampon" is removed, and an ordinary trachea-tube is substituted and retained as long as may be thought necessary. If this apparatus be not at hand, the desired result may be equally well obtained by performing a preliminary laryngotomy and then plugging the pharynx with a large sponge, which can be withdrawn as soon as the operation is over. Macewen has suggested that instead of opening the larynx or trachea a tube should be passed from the mouth through the pharynx and the glottis, the upper opening of the larynx being then plugged with a sponge. This he has successfully done in several cases. The tube should be of gum-elastic, and should correspond to about a No. 10 or 12 English catheter. It is passed by introducing the finger into the mouth and depressing the epiglottis on the tongue, and so guiding the tube over the back of the finger into the larynx. The patient's head should be thrown somewhat backwards while the tube is being passed.

In order to diminish the loss of blood as far as possible, the facial artery may be compressed during the early incisions, and all bleeding vessels must be seized in forcepressure forceps immediately they are divided.

The parts to be removed must be fairly exposed by raising a flap from the cheek. This may be fashioned in various ways (see Figs. 694, 696, 697). The following, which is the method adopted by Liston, will occasionally be found to be convenient where the tumour is very large (Fig. 696).

In the first stage, the central incisor tooth on the diseased side having been extracted, the point of a knife is entered opposite the external angular

Fig. 696.—Excision of Upper Jaw by Liston's Method.

process of the frontal bone, and carried with a semicircular sweep into the angle of the mouth. From the upper end of this incision, a cut about one inch in length may be carried along the zygoma. Another incision is made from the nasal process of the superior maxillary bone, down to the side of the nose, round the ala, which it detaches, and through the centre of the upper lip into the mouth. The flap thus formed is dissected upwards until the margin of the orbit is reached (Fig. 696); the soft parts are then carefully separated from the floor of this cavity, and drawn upwards by a curved copper spatula, which protects them and the globe of the eye.

The operation by the external flap (Fig. 697) is, however, preferable in all ordinary cases, and is thus carried out: The point of the knife is entered

opposite the inner angle of the eye, and carried down the side of the nose, round the ala, and through the centre of the upper lip. Another incision is now made in a horizontal direction below the orbit, by entering the point of the knife where the first incision commenced, and carrying it directly outwards in the line of junction of the lower eyelid with the cheek, along the edge of the orbit as far as the zygoma. The flap thus formed is thrown outwards. This line of incision has the great advantage over the one represented in Fig. 694, that the arteries and nerves of the face are cut near their terminations, and not through their larger branches.

The next step in the operation consists in the division of the bones. This is best done with a jaw-saw and strong cutting-forceps. The central incisor tooth is first extracted on the side on which the jaw is to be removed. The jaw-saw (Fig. 693) is then pushed into the nostril with its edge parallel to the hard palate. Its point must not be directed upwards for fear of injuring the cribriform plate. The saw is then carried through the alveolar border and the palate processes of the superior maxilla and palate bones, cutting through the alveolus of the incisor that has been extracted. No incision must be made with a knife through the soft structures of the hard palate, as they are divided readily and with less hæmorrhage by the saw. Care must be taken not to saw so far as to injure the soft palate. A smaller saw is then taken, and the nasal process divided at the level of the lower margin of the orbit, so that the posterior extremity of the incision shall correspond to the line of the articulation between the superior maxillary and the ethmoid bones. The saw is then carried through the malar bone in such a direction as to reach the anterior extremity of the spheno-maxillary fissure. If the tumour implicates the malar bone extensively, the zygoma must be divided and another saw-cut carried from the spheno-maxillary fissure through the frontal process of the malar bone.

Fig. 697.—Line of Incision in Excision of the Upper Jaw by External Flap.

The bone-forceps are now applied, first to the malar bone and next to the nasal process. One blade of the forceps (the flat side being directed to the sound bone) is then put into the nose, and the other in the mouth in the line of the saw-cut already made. As the blades are closed, the wedge-like action of the forceps forces the bone outwards and fractures its posterior attachments. Unless the bony structures are extensively destroyed by the tumour, the line of fracture runs across the ascending process of the palate bone and the middle part of the two pterygoid plates, the articulation between the superior maxillary and the palate bone, and that between the tuberosity of the palate bone and the pterygoid plates being too firm to yield. The jaw being now completely separated from its bony attachment, the Surgeon seizes it in the "lion-forceps" with his left hand and wrenches it downwards and outwards, while he cuts away the soft palate from the attachment to the bone, care being taken not

to cut it through vertically. If at this stage the superior maxillary nerve is seen, it must be cut through. The parts of the pterygoid muscles attached to the portions of the pterygoid plates that are removed can be torn through with a little help from the scalpel or scissors. If the bone is too much broken up by the tumour to be held by the lion-forceps, it can usually be drawn forwards with the fingers. As soon as the bone comes out, a dry sponge must be forced into the cavity to arrest hæmorrhage, while the mouth and fauces are cleared of blood, and the patient, who at this stage has often partly regained consciousness, is again brought under the influence of the anæsthetic. Hæmorrhage from the terminal branches of the internal maxillary must then be arrested by the actual cautery, or, if possible, by ligature. When all bleeding has ceased, the whole cavity must be carefully examined, and any remaining fragments of the growth must be removed either with scissors or with Paquelin's cautery. If the whole growth is undoubtedly removed, the cavity is then touched with a solution of chloride of zinc (gr. 40 to 3j), care being taken that none of the fluid passes down the throat. It should then be sprinkled with iodoform in crystals, and the cheek flap laid down. If there is any doubt about the complete removal of the growth, Heath recommends that some strips of lint spread with chloride of zinc paste should be laid in the cavity. Some pieces of dry lint may be placed over these to prevent any of the paste finding its way into the throat. The flap must be retained *in situ* by strong metallic sutures or hare-lip pins through the lip, and by finer sutures of catgut, horse-hair, or silk, along the other lines of incision. However much the skin may have been scratched and thinned, none should be removed unless it has been actually infiltrated by the tumour. The after-treatment consists in syringing the cavity out daily with Condy's fluid or sanitas and water, and sprinkling the raw surface with a little iodoform by means of a camel's-hair pencil. There is nothing so efficient as iodoform in the prevention of decomposition in these cases, and by its use the danger of septic poisoning or septic pneumonia is greatly diminished. After cicatrization is complete, the patient is fitted with a proper obturator, and the deformity resulting is far less than might have been anticipated.

**Results.**—The result of operations for the removal of the upper jaw is very satisfactory, so far as the operation itself is concerned. Though most serious, the operation is not very dangerous. Of 17 consecutive cases collected by Hutchinson as having been practised in the London hospitals, it was successful in 14; and of 16 cases (10 of total and 6 of partial removal) done by Esmarch, 13 were successful (viz., 8 of the former and 5 of the latter). So far as recurrence of the disease is concerned, all will depend on the nature of the tumour, and the extent of the operation. If the disease be malignant, speedy recurrence will certainly ensue if partial excision or scooping be practised. Nothing, indeed, can be more disastrous than the result of partial operations in these cases. Even though the whole maxilla be excised, the incisions being carried wide of the disease, recurrence is the almost invariable rule, though the more complete operation secures longer immunity. The liability to recurrence is remarkable in these cases, when we consider how isolated the upper jaw is, being bounded on three sides by the cavities of the mouth, nose, and orbit, and how completely it can be excised. It is, I believe, mainly due to two causes—early implication of the soft parts, and extension of the mischief through the fissures and sinuses behind the bone. These recurrent malignant

growths, after removal of the primary tumour, do not admit of extirpation. When the tumour is benign, the result is most satisfactory, and the cure usually complete.

**Tumours that spring from behind the Superior Maxilla** have already been referred to in speaking of naso-pharyngeal tumours (p. 596), and in discussing the diagnosis of tumours of the upper jaw (p. 632). They may grow from the sphenoid bone, or from some of the deep cavities lying between it, the palate bones, and the ethmoid, constituting various forms of naso-pharyngeal, palatine, or naso-palatine polypi. Formerly these tumours were either left untouched, or were extirpated together with the superior maxilla or after its removal. Of late years various operations have been devised without the necessity of removing that bone, which is either turned up, down, or on one side. The best operation on the whole for their removal is **Langenbeck's Osteoplastic Section of the Superior Maxilla**, with displacement of that bone. The first operation was performed in 1859. Up to 1877, Langenbeck had performed it 13 times, with 10 complete cures and 3 deaths. It has been performed in Germany also by Esmarch, Wagner, Simon, Nussbaum, and Billroth. The last two performed it for removal of the superior maxillary nerve for neuralgia. In America it has been performed twice by Cheever. In one case, it was done for removal of a tumour growing from the body of the sphenoid bone; the tumour recurred, and the operation was repeated at the end of eleven months, with perfect success. In the other case, both bones were displaced at the same operation; but the patient died on the fifth day of "prostration with excitement." In Langenbeck's first operation, the incision was made from the middle of the nasal eminence of the frontal bone towards the right, over the nasal process of the superior maxilla and downwards to the ala of the nose. The edges of the wound were dissected up so as to expose the whole nasal process and the nasal bone, the periosteum remaining untouched. The cartilaginous portion of the nose was separated from its bony attachments. The nasal bone was then cut through with bone-forceps, close to the septum, and upwards as far as the frontal bone; by a second cut the nasal process of the superior maxillary was divided into the antrum. The cut ended where the nasal process of the superior maxillary bone forms the lower border of the orbit. The upper part of the nasal process of the superior maxillary and the nasal bone were then prised up and were turned on to the forehead, being still attached by periosteum and mucous membrane. The nose was next fully opened, and the polypus was removed. The bones were then replaced and supported in position by a plug of charpie. The wound healed readily, and there was no exfoliation of bone. Langenbeck's second operation was undertaken for a tumour springing from behind the superior maxillary bone in the pterygo-maxillary fossa. Two incisions were made: the first began at the insertion of the ala nasi and ran along the lower border of the malar bone, describing an arch with the convexity downwards and terminating at the middle of the zygoma; the second began at the nasal notch of the frontal bone, and, following the lower margin of the orbit, crossed the frontal process of the superior maxillary bone, and joined the lower incision at its outer extremity. The soft parts were not dissected up. The lower incision was then carried to the bone, and the masseter dissected from its attachment to the malar bone. By depressing the lower jaw so as to remove the coronoid process out of the way, the finger

could be forced in front of the anterior border of the temporal muscle into the spheno-maxillary fossa, which was dilated by the tumour, into the nose through the spheno-palatine foramen. A narrow saw was now passed along the finger—its point being protected by the forefinger of the left hand introduced into the nostril—and a cut was made directly forwards through the ascending process of the palate bone and the body of the superior maxillary bone, across the cavity of the antrum, parallel to the hard palate and immediately above it, terminating at the anterior naris. The upper incision was now deepened, and the soft parts were raised from the floor of the orbit and from the angle between the zygoma and the malar bone; and, the saw being again introduced, a cut was made through the malar bone into the spheno-maxillary fissure, and thence across the floor of the orbit as far as the lachrymal bone. The wedge-shaped piece of the superior maxillary bone included between these cuts was now attached only by its connexions with the nasal and frontal bones, and by the soft parts covering it, which were untouched. By introducing an elevator into the cut in the malar bone, the whole piece was lifted up, bending upon its attachment to the nasal and frontal bones as upon a hinge, until it was completely turned inwards and upwards over the opposite side of the face. The tumour, which was found to have extensive connexions in the pterygo-maxillary region, was now removed. The bone was then replaced, and the wound closed. On the sixth day, the greater part of the wound was healed; on the sixteenth the wound had completely healed, and no mobility could be felt in the bone.

Ollier's and Lawrence's operations, which are adapted specially to tumours of the nasal fossæ, have already been described (see p. 597).

#### DISEASES OF THE LOWER JAW.

**Abscess in the Lower Jaw.**—Chronic abscesses, causing "expansion of the bone," have been met with in the lower jaw. They may arise in connexion with the fang of a diseased tooth, or from suppuration of a cyst. If the shell of bone surrounding the pus be very dense they may resemble solid tumours. Their treatment presents nothing peculiar.

**Acute Suppurative Periostitis** is occasionally met with in the lower jaw. It is dependent probably on carious teeth, but the immediate cause seems usually to be exposure to cold, such as riding in a train facing an open window. The disease is characterized by rapid swelling, with tension and redness of the skin. A large abscess quickly forms, surrounding the bone, usually limited to one side, about the angle. The swelling extends downwards into the neck, and tends to point externally. On opening the abscess a large part of the bone can be felt bare and denuded of its periosteum. If the pus be let out early, free drainage provided, and decomposition prevented, no necrosis may take place. It is usually necessary to make the incision externally, as the pus extends too far in the neck to allow of sufficient drainage being provided from within the mouth.

**Necrosis of the Lower Jaw** has already been described (p. 625).

**TUMOURS OF THE LOWER JAW.**—The lower jaw is a common seat of tumours. *Fibrous Epulis*, *Myeloid Sarcoma* of the alveolar border, and *Epithelioma of the Gum* implicating the bone, have already been described

with tumours of the alveolar borders and of the upper maxilla; they are, however, all more common in the lower jaw than in the upper.

**Cysts of the Lower Jaw.**—Cysts of various kinds are met with in both jaws, but they are mostly more common in the lower than the upper. In connexion with the teeth two varieties of single cysts occur—the “dental” and “dentigerous”; whilst a somewhat rare form of disease is met with, known as the “multilocular cystic tumour.”

*Dental cysts* are defined by Heath as “cysts originating in connexion with fully developed teeth.” Of these the simplest variety is the small cyst, seldom more than a quarter of an inch in diameter, which is occasionally found attached to the fang of a tooth on extraction. These cysts are developed beneath the periosteum of the fang, and hence have been termed “*periosteal cysts*.” Tomes believes that they are of inflammatory origin, and the fact that their contents have the appearance of inspissated pus bears out this view. According to Heath these periosteal cysts are most commonly connected with the incisor or canine teeth of the upper jaw. Single cysts containing a glairy or mucous fluid, in which cholesterine crystals are often seen, are also met with in both jaws. In the upper jaw they may extend into the antrum and in the lower jaw they cause a slow painless enlargement of a limited portion of the bone. At first the fluid is surrounded by a solid bony wall, through which no fluctuation can be felt, and in this stage they have been mistaken for solid tumours. As the wall becomes thinner fluctuation and eggshell crackling can be felt. The mode of origin of these cysts is not clear, and in many instances no actual connexion with the teeth can be traced. In some cases an epithelial lining has been demonstrated, and it has been suggested that they arise from remains of the epithelium of the enamel organ which have been shown by Malassez to exist in the jaw.

*Dentigerous cysts* are much more common in the lower jaw than in the upper. They arise in connexion with imperfectly developed teeth which have been retained in the jaw. In the large majority of cases one of the permanent set of teeth is missing in the position of the tumour; very rarely the cysts arise in connexion with the temporary or with supernumerary teeth. Dentigerous cysts may occur at any age, but are most common in young adults. In the upper jaw they may form cysts in the antrum; in the lower jaw they expand the bone in the manner above described. The smooth wall of the cyst is lined with epithelium, and the contents are usually clear fluid. The more or less perfectly developed tooth may lie free in the cavity; or more usually it is embedded in the wall of the cyst, sometimes in an inverted position. Less frequently several rudimentary teeth are present. The exact mode of origin of these dentigerous cysts is doubtful. Tomes believes that they arise from the excessive formation around a retained tooth of a fluid which is normally found after the complete development of the enamel, between it and the soft tissues covering it. The treatment consists in cutting away part of the wall of the cyst from within the mouth, and removing the retained teeth. The inner surface should then be scraped and treated with chloride of zinc (40 grains to the ounce) to destroy the lining. The size of the cavity which is left to granulate can often be much lessened by pressing together its expanded walls with the fingers.

*Multilocular cysts*, which have also been described under the names of cystic sarcoma, adenoma, and fibro-cystic tumours of the jaw, although

occasionally met with in the upper jaw, are infinitely more common in the lower. These tumours are of slow growth, but may reach great dimensions; they are composed of cysts varying in size, and having more or less solid matter between them. The walls of the cysts are sometimes thin and membranous, sometimes composed of tissue appearing to the naked eye as fibrous tissue, while in other cases bony lamellae enter largely into their composition, so that on pressure they occasionally communicate the semi-crepitant sensation peculiar to cystic expansions of osseous structures. The fluid contained in the cysts is viscid, and usually semi-transparent, yellowish or bloody. Most commonly these tumours run a simple course, but occasionally they have been known to recur after removal and infect surrounding parts. The origin of these cysts formed the subject of a most interesting lecture delivered by F. S. Eve at the Royal College of Surgeons. He confirmed the fact already noted by several observers that the solid part of these tumours is composed of irregular, branching columns of small round epithelial cells resembling those in the deeper layers of the epithelium of the gum, and surrounded by a fibrous stroma. In some cases the cells at the circumference are

Fig. 698.—Cystic Epithelioma (Multilocular Cystic Disease) of the Lower Jaw (110 diam.).

columnar. The cysts are formed by colloid degeneration of the epithelial cells (Fig. 698). Eve believes that he has demonstrated that the columns of cells are formed by an ingrowth of the epithelium of the gum, and that the starting point of the disease is often the irritation caused by a diseased tooth. Falkson and Bryk on the other hand believe that in some cases at least these cysts have their origin in a persistence of a portion of the epithelium forming the enamel organ of the developing teeth. They base their opinion upon the resemblance of the epithelium cells and the contents of the smaller spaces to those observed in the enamel organ. That this disease is in reality malignant is shown by several cases recorded by Heath. In one of these after operation several recurrences took place in the jaw, and finally a tumour developed in the pelvis, which was shown by Eve to contain "tortuous closely-crowded columns of small epithelial cells."

In speaking of the treatment of multilocular cystic disease, Heath says: "I should in future be guided by the age of the patient, and the amount of solid material found in the cysts. In young persons with cysts having fluid

contents and little growth in the bone, I should be still inclined to adopt palliative measures and to gouge very freely, carefully watching the case with a view to a more radical proceeding, should further development take place. In cases of much solid deposit in connexion with multilocular cysts, and still more in cases of solid tumour with one or more large cysts, there should, I think, be no doubt as to removal of one-half or more of the lower jaw, or of any portion of the upper jaw involved."

**Fibromata** and **Chondromata** are met with in the lower jaw, and spring either from the periosteum or from the centre of the bone. They resemble similar growths elsewhere, and present nothing peculiar.

**Osteomata** of both forms, the cancellous and ivory exostosis, are met with in the lower jaw ; it is in fact one of the most common seats of the latter affection.

**Odontoma.**—This is not properly a tumour of the jaw, but it is most conveniently mentioned here, as closely simulating disease of the bone. An odontoma is the result of some peculiar modification in the growth of a tooth, resulting in the formation of an irregular mass of dentinal tissues of no definite shape. Bland Sutton, who has carefully studied the structure of odontomata, recognizes three varieties—radicular, composite, and anomalous. A radicular odontoma develops from the root of the tooth after the formation of the crown is complete, and hence it contains no enamel in its composition. Outgrowths from the fangs of fully developed teeth composed of dentine and cement are not uncommon, forming the so-called "warty teeth ;" but these are seldom of sufficient size to be of any surgical interest.

A composite odontoma bears no resemblance to a tooth, but consists of a "disordered conglomeration of enamel, dentine, and cementum." According to Heath only eleven cases have been recorded, all of which, with one exception, were in the lower jaw. Half a large composite odontoma is preserved in the Museum of University College. It was removed by Heath from the lower jaw of a lady aged eighteen. Its cut surface has the appearance of marble, and it consists of several dental tissues mixed up together. Tomes has described one removed by Fergusson as being "composed of enamel, dentine, and bone derived from calcification of remnants of the dentine pulp, thrown together without any definite arrangement." The anomalous examples of odontoma, three specimens of which are described by Bland Sutton, need not be referred to here.

**Sarcomata** of various kinds form a considerable proportion of tumours of the lower jaw. Myeloid, spindle-celled, and round-celled sarcomata are all met with. The first is always central, the two last may be periosteal or central. Chondrifying or ossifying sarcomata are occasionally met with. The myeloid tumour usually runs a simple course ; the other forms are frequently malignant. The mode of growth of these tumours and the symptoms they give rise to are the same as in other parts.

**Squamous Carcinoma** has already been considered with diseases of the gums (p. 624).

**Diagnosis.**—In the lower, as in the upper jaw, it is of great importance to diagnose the simple from the malignant affections ; as in the latter form of disease an operation is sometimes not advisable, the soft tissues around the bone being implicated to such an extent as not to admit of the complete extirpation of the disease. The malignant tumours may generally be readily detected by the rapidity of their growth, by their pulpy or elastic character

and by infiltration of neighbouring parts, with early adhesion to it and occasionally by their implicating the glands below the jaw.

The **Treatment** of solid tumours of the lower jaw must be determined by their nature. The simple fibrous and bony growths can usually be removed without sacrificing any part of the jaw itself, or at the part from which the tumour actually springs. In central myeloid the most extensive operation that can be required is to remove completely the affected segment of the jaw, dividing it beyond the limits of the tumour. Even less extensive measures than this may give satisfactory results if the myeloid tumour is still small. Thus, when it affects merely the alveolar process, it may be removed with cross-cutting forceps, whilst if centrally placed in the body of the jaw, an attempt may be made to remove it and the surrounding bone with the gouge. If recurrence occurs, the affected part should be completely excised. In the treatment of subperiosteal sarcoma nothing but the removal of the bone is likely to prove successful, and, indeed, it is in these cases that excision of half the jaw is generally practised.

**Excision of the Lower Jaw.**—The operation of excision of a portion of the lower jaw for tumour of that bone was first performed by Dr. James H. P. Tennessee, in 1810, and not, as is generally but erroneously supposed, by Dupuytren. As the growths for which this operation is performed are usually situated between the symphysis and the angle of the bone, seldom extending beyond the middle line, the operation is generally limited to one side of the face. In some instances, however, the tumour may encroach so far on the other side that it may be necessary to remove more than the half of the bone; and in some cases again, though of very rare occurrence, the whole of the bone may be disarticulated.

When the tumour is of moderate size, and is situated about the middle of the symphysis and angle of the jaw, it may be reached by making an incision of sufficient length under the lower edge of the bone, and extending the anterior extremity of it well forward upon the chin, but not dividing the lower lip, if it can be avoided, nor cutting into the angle of the mouth. Then, by dissecting up the flap thus formed, and carrying the knife cautiously along the inner side of the jaw, so as to detach the mucous membrane of the mouth and the mylo-hyoid muscle to a sufficient extent. In doing this, the hæmorrhage is often very profuse: the bleeding from the facial artery is particularly so, and should be at once controlled by the application of ligatures to both ends of the divided artery, and to any other points from which the hæmorrhage is abundant. Unless this be done, the after-steps of the operation are rendered much more obscure and difficult. One of the teeth on each side of the tumour having previously been drawn, the jaw must now be divided through their alveoli into its base with a narrow strong-bone saw, and cut through with forceps, or completely divided with the saw. As soon as a piece of bone, with the attached tumour, has been removed, and all the blood-vessels have been secured, the flap of cheek should be laid down, and secured *in situ* by means of sutures. Occasionally the dental artery in the lower jaw gives trouble; the hæmorrhage from this source may be checked by tying it with the actual cautery. The patient must at first be fed with slop through a tube. At a later period, when cicatrization is well advanced, the teeth should be tied together with strong silver wire, and a silver cap should be fitted upon the teeth of the two portions of bone.

d attached by an elastic spring to another silver cap put on those upper jaw, so as to prevent the displacement that would otherwise in the smaller fragment. Union takes place after a time by fibrous which becomes sufficiently dense to make the jaw strong and useful.

In those cases in which the tumour *encroaches upon the angle and ramus* of the jaw, it is usually better to remove the bone at the articulation on the affected side; for, if the articular end including the coronoid process is removed, it will be displaced forwards and upwards by the action of the internal and external pterygoid muscles, and be a source of much inconvenience to the patient, not compensated by any corresponding utility. In such cases, the removal of one-half of the jaw will consequently be required,

Fig. 699.—Excision of Lower Jaw. Soft parts raised.

The operation may be performed in the following way. The patient's head must be allowed to fall a little backwards so that the chin may be well raised from the chest. An incision is then made, commencing near the angle of the jaw, passing along the lower border of the body of the jaw as far as possible and then upwards at the posterior border of the ramus as far as the lobule of the ear. If the tumour be very large it may be necessary to make an incision upwards towards the lip from the anterior end of that mentioned or even to divide the lip completely, but this should be avoided if possible. The facial artery and vein are wounded in the first incision and are at once secured. The flap is then raised and the mucous membrane reflected along its reflexion from the cheek. If the tumour is simple this may be partly done with a periosteal elevator, the periosteum being saved where possible. It can be safely taken from over the tumour. The knife is then carried

and by infiltration of neighbouring parts, with early adhesion to the skin, and occasionally by their implicating the glands below the jaw.

The **Treatment** of solid tumours of the lower jaw must be determined by their nature. The simple fibrous and bony growths can usually be completely removed without sacrificing any part of the jaw itself, or at the most, that part from which the tumour actually springs. In central myeloid sarcoma the most extensive operation that can be required is to remove completely the affected segment of the jaw, dividing it beyond the limits of the tumour. Even less extensive measures than this may give satisfactory results if the myeloid tumour is still small. Thus, when it affects merely the alveolus, it may be removed with cross-cutting forceps, whilst if centrally placed in the body of the jaw, an attempt may be made to remove it and the surrounding bone with the gouge. If recurrence occurs, the affected part should be completely excised. In the treatment of subperiosteal sarcoma nothing but a free removal of the bone is likely to prove successful, and, indeed, it is in these cases that excision of half the jaw is generally practised.

**Excision of the Lower Jaw.**—The operation of excision of a portion of the lower jaw for tumour of that bone was first performed by Deadrick of Tennessee, in 1810, and not, as is generally but erroneously supposed, by Dupuytren. As the growths for which this operation is performed are usually situated between the symphysis and the angle of the bone, seldom extending beyond the middle line, the operation is generally limited to one side of the face. In some instances, however, the tumour may encroach so far that it may be necessary to remove more than the half of the bone; and in other cases again, though of very rare occurrence, the whole of the bone has been disarticulated.

When the tumour is of moderate size, and is situated about *midway between the symphysis and angle* of the jaw, it may be reached by making a curved incision of sufficient length under the lower edge of the bone, and carrying the anterior extremity of it well forward upon the chin, but not dividing the lower lip, if it can be avoided, nor cutting into the angle of the mouth; then dissecting up the flap thus formed, and carrying the knife cautiously along the inner side of the jaw, so as to detach the mucous membrane of the mouth and the mylo-hyoid muscle to a sufficient extent. In doing this, the hæmorrhage is often very profuse: the bleeding from the facial artery is particularly forcible, and should be at once controlled by the application of ligatures to both ends of the divided artery, and to any other points from which it is abundant. Unless this be done, the after-steps of the operation will be rendered much more obscure and difficult. One of the teeth on each side of the tumour having previously been drawn, the jaw must now be deeply notched through their alveoli into its base with a narrow strong-backed saw, and cut through with forceps, or completely divided with the saw. After the piece of bone, with the attached tumour, has been removed, and all bleeding vessels have been secured, the flap of cheek should be laid down, and retained *in situ* by means of sutures. Occasionally the dental artery in the cut jaw gives trouble; the hæmorrhage from this source may be checked by touching it with the actual cautery. The patient must at first be fed with slops, which should be sucked in through a tube. At a later period, when cicatrization is well advanced, the teeth should be tied together with strong silver wire; or a silver cap should be fitted upon the teeth of the two portions of bone that are

left, and attached by an elastic spring to another silver cap put on those of the upper jaw, so as to prevent the displacement that would otherwise occur in the smaller fragment. Union takes place after a time by fibrous tissue, which becomes sufficiently dense to make the jaw strong and useful.

In those cases in which the tumour *encroaches upon the angle and ramus* of the jaw, it is usually better to remove the bone at the articulation on the affected side; for, if the articular end including the coronoid process be left, it will be displaced forwards and upwards by the action of the temporal and external pterygoid muscles, and be a source of much inconvenience to the patient, not compensated by any corresponding utility. In these cases, the removal of one-half of the jaw will consequently be required,

Fig. 699.—Excision of Lower Jaw. Soft parts raised.

and the operation may be performed in the following way. The patient's head must be allowed to fall a little backwards so that the chin may be well raised from the chest. An incision is then made, commencing near the symphysis, passing along the lower border of the body of the jaw as far as the angle and then upwards at the posterior border of the ramus as far as the level of the lobule of the ear. If the tumour be very large it may be necessary to make an incision upwards towards the lip from the anterior end of that just mentioned or even to divide the lip completely, but this should be avoided if possible. The facial artery and vein are wounded in the first incision and must be at once secured. The flap is then raised and the mucous membrane divided along its reflexion from the cheek. If the tumour is simple this may be partly done with a periosteal elevator, the periosteum being saved where it can be safely taken from over the tumour. The knife is then carried

behind the jaw in front of the tumour separating the mylo-hyoid and dividing the mucous membrane in the floor of the mouth, care being taken not to cut away the genio-hyoid and genio-hyo-glossus muscles, unless the situation of the tumour is such that this cannot be avoided. If these muscles are necessarily divided, a thick ligature should be passed through the end of the tongue, which must be drawn forwards by an assistant, lest it fall backwards into the pharynx and thus occasion suffocation, as has happened to Surgeons of eminence both in France and in America. The jaw having been cleared on both sides in front of the tumour, the incisor tooth must be drawn at the point where it is intended to divide the bone, and the saw (Fig. 699) applied. The section should be completed with the saw, as if the bone-forceps be used a jagged edge will probably be left. The jaw is then seized either by the fingers or in the

Fig. 700.—Excision of Lower Jaw. Disarticulation of Condyle.

lion-forceps, forcibly depressed and drawn somewhat outwards, while the cheek flap is pulled upwards so as to bring the coronoid process into view with the attachment of the temporal muscle, which must be divided. If, as sometimes happens, this cannot easily be reached, the coronoid process may be cut through with a saw and removed afterwards. As soon as the bone is freed from the temporal muscle it may be drawn more outwards and its inner side cleared from the internal pterygoid, care being taken to keep the edge of the knife turned towards the bone to avoid the submaxillary gland and the lingual nerve. Lastly, by forcibly depressing the bone the condyle is dislocated; the external pterygoid is divided by a touch of the knife, and the bone then comes away (Fig. 700). During this stage of the operation care must be taken not to divide the internal maxillary artery, which lies close to the neck of the bone between it and the internal lateral ligament. If the bone be twisted too much outwards the condyle will pass under the artery, which is then torn through

or cut. Should the artery be divided, it must be ligatured, or if it be cut very close to the main trunk it may be necessary to tie that immediately below the point at which it divides into the temporal and internal maxillary. In depressing the bone to reach the temporal muscle and the joint, care must be taken not to use too much force, lest the ramus give way, having been weakened by the disease. This accident causes a good deal of difficulty in disarticulation, which can be accomplished only by seizing the fragment left behind in necrosis-forceps, dragging it forwards and then dividing the muscle and capsule. When the operation is completed the raw surface should be sponged with a solution of chloride of zinc and sprinkled with iodoform. The flap is then brought down and secured with sutures, a drainage-tube being inserted in the most dependent angle of the wound. If the symphysis have been removed the root of the tongue must be stitched forwards and the ligature through its tip must be retained for a few days till all danger of its falling backwards into the pharynx is past, so that it may be drawn forward if necessity arises. When cicatrization is complete a dense mass of fibrous tissue is formed in the place of the jaw, and comparatively little deformity results.

**DISEASES OF THE TEMPORO-MAXILLARY ARTICULATION.**—The articulation of the jaw, though less frequently diseased than most other joints, is liable to the same affections as similar parts elsewhere. **Chronic Rheumatic Arthritis** of the temporo-maxillary articulation has already been described (p. 649). **Acute Arthritis**, terminating in destruction of the joint and fibrous or osseous ankylosis, most commonly occurs in consequence of disease of the middle ear in scarlet fever. According to A. E. Barker, who has specially called attention to this form of disease, it is met with almost exclusively in children, and is due to the persistence of a hiatus in that part of the tympanic plate forming the floor of the meatus and the roof of the articulation. This hiatus is always present in infancy, and may remain in adult life. The disease may result also from necrosis of the bone in chronic suppurative inflammation of the middle ear after fevers. The symptoms are those met with in other joints—acute pain, redness, swelling, and the formation of abscesses discharging either on the cheek or by the ear. The treatment consists in rest and opening the abscesses. **Ankylosis of the Jaw** may be fibrous or osseous. It necessarily, even if affecting one side only, prevents mastication. If fibrous, it may be treated by forcibly opening the mouth under chloroform by means of a screw-gag, or of an apparatus specially constructed for the purpose, after which a wedge may be placed between the teeth to keep them apart. This treatment is painful, and has to be repeated at intervals for some time, lest the articulation again become stiffened. It is not usually very satisfactory. Spanton has succeeded in producing a better result by dividing the fibrous bands in the articulation by means of a tenotome passed into it. In firm fibrous ankylosis in which other means have failed, or in osseous ankylosis, the only treatment likely to be followed by good results is excision of the condyle of the jaw. This is best done by an incision carried along the lower border of the zygoma from immediately in front of the ear, avoiding the temporal artery, to the malar bone. From the middle of this a short vertical incision may be carried downwards, for about three-quarters of an inch, dividing the skin and fat only. The masseter is then separated from the zygomatic arch, as far as it is exposed, by the scalpel and periosteal elevator. The neck of the bone is thus fully ex-

posed, and must be carefully cleaned with a narrow elevator, keeping close to the bone so as to avoid injuring the facial nerve or internal maxillary artery. The neck of the bone is then divided with a narrow chisel. After this, if the ankylosis is fibrous, it may be possible to lever the condyle out with an elevator; if it is osseous, a second section of the bone must be made with the chisel immediately below the zygoma. This operation has been successfully performed by Davies-Colley, Heath, and others. The result is usually very satisfactory. In a case of bilateral ankylosis in which removal of the condyles had failed to relieve the contraction, W. H. Bennett excised the angle of the jaw on each side with a satisfactory result. Humphry, of Cambridge, also successfully removed the condyle in 1856 for rheumatoid arthritis.

Mears, of Philadelphia, has successfully operated on four cases from within the mouth. He first passes a sharp bistoury between the masseter and the bone at the level of the last molar tooth, and then saws through the ramus at that point. The soft parts are next separated from the bone above the section by a periosteal elevator, and the insertion of the temporal muscle divided with a probe-pointed bistoury. The bone is then seized in the lion-forceps and an attempt made to wrench it out. If the ankylosis is bony, the neck probably fractures, and is then smoothed down, and as much as may be necessary removed with a chisel. Hæmorrhage is arrested by pressure. The internal maxillary artery is avoided by keeping the instruments close to the bone, but the inferior dental nerve and artery are necessarily divided. The facial nerve on the other hand is not in danger, nor is there any external scar. The results of his cases were most satisfactory.

**Enlargement of the Condyle of the Jaw** is a rare condition occasionally met with. There is great and irregular increase in size of the condyle, apparently due to the formation of ossifying cartilaginous outgrowths similar to those of rheumatoid arthritis. In a case of this kind recorded by Adams, other joints were similarly affected. In two other cases recorded by McCarthy and Heath, there were no signs of general articular affection. In Heath's case the chin was thrown over to the opposite side, and great deformity resulted. The diseased condyle was successfully removed. It measured one inch and three-quarters from before back, and one inch across. The improvement in the appearance and in the utility of the jaw was very marked.

**Spasmodic Closure of the Jaws.**—*Spasmodic closure* of the jaws, lasting weeks or months, and often accompanied by considerable pain, is not an uncommon result of retention of the wisdom tooth, either from faulty position, or from the second molar not allowing room for it to reach the surface. It occurs between the ages of 20 and 35, at the period at which the wisdom tooth should be cut. Chloroform must be administered, and the mouth gagged open. The second molar must then be extracted to give room for the wisdom tooth, after which the symptoms soon subside.

**Permanent Closure of the Jaws** may be due to ankylosis of the joint, as already described. It may also be the result of contraction of cicatrices, resulting from cancrum oris, or from gangrenous stomatitis following the excessive administration of mercury, or more rarely from extensive necrosis. When the mucous membrane has been destroyed by ulceration from the one alveolar border to the other, the resulting cicatrix binds the jaws so firmly together, that not only is movement impossible, but the inside of the cheek is in such close contact with the teeth, that there is scarcely room to pass a

director between them. Under these circumstances it is evident that little can be done to relieve the patient from within the mouth. Division of the cicatrix followed by forcible extension has been recommended and practised, but never with any good result. As the raw surface heals, the contraction necessarily recurs, and the last state of the patient is much the same as the first. Mears, however, states that contraction is less likely to recur if the bands are slowly divided by means of a ligature passed round them from within the mouth. If the band were very narrow, and healthy mucous membrane existed on each side, which could be drawn in by contraction of the sore in healing while the mouth was gagged open, some benefit might result, but practically such a condition is never met with. Various attempts at plastic operations, similar to those performed for faulty cicatrices in the skin, have been suggested and attempted, but no good result has been obtained. In order to relieve this distressing deformity, Esmarch, of Kiel, in 1855, suggested division of the jaw and the formation of a false joint in front of the cicatricial bands. About the same time, Rizzoli, of Bologna, made a similar suggestion. In Rizzoli's method the jaw is simply divided from within the mouth with a pair of strong cutting pliers; in Esmarch's operation a wedge-shaped piece of bone with the apex towards the alveolar border is removed with a saw from an incision made from outside at the lower border of the jaw. The performance of the operation is sufficiently easy, but considerable difficulty is found in maintaining the movement between the fragments after cicatrization is complete. The tendency to re-union by bone, or by fibrous tissue so dense as to prevent all movement, is certainly less when a considerable piece of the jaw is removed. Christopher Heath, who was one of the first to perform the operation in this country, expresses a strong preference for Esmarch's operation. In one case operated on by him by this method in 1864, the patient was found to have good use of the sound side of the jaw in 1880. The wedge of bone removed measured seven-eighths of an inch at the lower border.

## CHAPTER LVI.

## PLASTIC SURGERY OF THE FACE AND MOUTH.

By **Plastic** or **Reparative Surgery** is meant the performance of operations for the repair of deficiencies in structure, whether resulting from injury, from disease, or from malformation.

It has long been known that portions of the body may retain sufficient vitality to become again adherent, when attached only by a very narrow tongue of tissue to the part from which they have been all but separated. This has often been observed in injuries of the face and fingers, portions of which have been almost completely severed, and yet have united again on being replaced. But there is a sufficient number of cases on record to show that certain parts, when completely separated, may, after being replaced, again become adherent. The most remarkable instances of this kind are those which are related by Hoffacher, and attested by Chelius and Velpeau. Hoffacher was officially appointed to attend as Surgeon at the duels which were then, as now, frequent amongst the students at Heidelberg; and, as at these encounters swords were used, he had an opportunity of seeing a considerable number of incised wounds, and has related no fewer than sixteen cases in which portions of the nose, lips, or chin had been sliced off, and, being put on again, contracted adhesions. Amongst the most remarkable of these is one in which the end of the nose was sliced off, and fell under a chest of drawers; it was not found for some time, but, on being recovered and washed, was stitched on, and became firmly attached. In another instance, a dog that was in the room snapped up the detached portion of the organ as it fell to the ground, but the nose, being immediately taken out of the animal's mouth and put on again, became firmly fixed.

In order that union should take place between parts that have been separated completely or nearly so, and the rest of the body, it is necessary that they be soft and vascular, and more especially that their structure be of a homogeneous character such as is met with in the tissues of the face, where no very large blood-vessels, nerves, tendons, or bones are found. It is the same in plastic operations, which succeed best under similar conditions of tissue, and which are conducted on the same principle as an attempt at union in a partially severed structure.

It is principally for deformities and loss of the nose and lip that plastic operations are of much service; they may, however, occasionally be had recourse to in other situations, as about the cheeks and eyelids. Reference has already been made (Vol. I., p. 899) to the performance of plastic operations on the perinæum. In the practice of this very interesting branch of surgery, there is much opportunity for the display of manual dexterity. On this, indeed, almost the whole success of the operation depends; and a vast deal may be done in apparently the most unpromising cases by skill and patience. In these operative procedures the names of Serres, Dieffenbach,

Liston, Syme, Fergusson, Sédillot, Langenbeck, Jobert, and Wolfe deservedly take the first rank.

In performing the various plastic operations five methods have been employed. In the first, the flap of the skin that is intended to repair the lost structure is transplanted from a distant part, as the arm. This operation, introduced by the Italian Surgeon Tagliacotius in the sixteenth century, and hence commonly called by his name, has in a great measure fallen into disuse, on account of the difficulty of its execution, and the great uncertainty of obtaining a successful result. The second plan, which was first practised by G. Lawson and subsequently by Wolfe, of Glasgow, consists in the transplantation of a piece of skin of considerable size from one part of the body to another, the transplanted portion being completely separated at the time of the operation, and carefully freed from every trace of subcutaneous fat with a pair of sharp flat scissors. Thiersch's method of skin-grafting (Vol. I., p. 278), which may be regarded as a modification of this plan, is now largely employed in remedying defects about the cheeks and eyelids. The third plan consists in transplanting the reparative structure from some part in the neighbourhood of the organ to be repaired: the skin from the forehead, for instance, being used for the formation of a new nose; that from the chin for the restoration of a lost lip. This procedure, which seems first to have been adopted by the natives of India in repairing the loss of the nose, has been most commonly employed in this country in plastic operations on the face. The fourth method consists in loosening the skin by a process of subcutaneous section to some distance around the part to be repaired, and then drawing it forwards with or without incision through its substance. This gliding operation is chiefly practised for the closure of fistulous openings. The fifth method is employed in cases where an abnormal fissure exists in a part. It consists in bringing together and uniting the edges of the fissure, after having pared them evenly, so as to expose their vascular surfaces.

Union in plastic operations should take place by the first intention. Should this fail, however, the Surgeon need not despair; as the parts may unite by granulation in a very satisfactory and complete manner.

For proper union to be obtained, it is necessary that the edges be cleanly and evenly cut, so as to adjust themselves accurately to one another. This may often best be effected by making the incision in the part that is to receive the flap somewhat bevelled, thus securing a more accurate adaptation of the edges. After the flap has been formed and the part in which it is to be transplanted properly pared, the operation should be delayed a few minutes until all bleeding has ceased. This is of much importance, as the interposition of a layer of blood-clot will materially interfere with union. In bringing the parts into apposition, great care must be taken that no undue traction be exercised, lest their circulation be interfered with, and their vitality be endangered. The parts may be maintained in apposition by sutures. These should be as fine as possible, introduced with a small needle, and knotted on the sound parts. Horse-hair, fine catgut or silkworm-gut will be found the best materials where there is no strain on the sutures; should there unavoidably be some strain a deep metallic stitch should be passed to relieve the finer sutures. Occasionally hare-lip pins may advantageously be used. The use of collodion, where applicable, is of great advantage, as it not only secures adhesion, but, by excluding the air, lessens the chance of suppuration. If the

wound is large, it must not be completely covered by collodion lest discharges accumulate beneath the flap. In some parts in which the wound is moistened by the secretion of a neighbouring mucous membrane and cannot be kept dry, as in the eyelids, wet boric acid lint or boric acid ointment will be found the best application; in other parts absorbent iodoform or salicylic wool may be applied, a small piece of the "protective" oil-skin being placed next the wound to prevent it from sticking. The wool may be fixed in position by collodion.

For a plastic procedure to succeed, it is necessary that no morbid process be going on in the seat of operation; and not only that none be actually in progress, but that all have ceased for some considerable time. This is more particularly the case when the deformity has resulted from strumous or syphilitic ulceration. In such cases it is necessary to see that the constitution is sound, as well as that all local disease has been eradicated; otherwise the irritation of the operation might set it up again, and the new flap might be invaded and destroyed. From want of this precaution, I have more than once seen disappointment result. As a general rule, plastic operations practised for the repair of mutilations from injury or of congenital deficiencies, are more successful than those that are performed after disease.

No routine system of treatment should be adopted; but a few days of rest, good diet, and a dose or two of aperient medicine, may be prescribed before the operation is proceeded with. In the after-treatment of the case, a nourishing but unstimulating regimen should be observed.

**Faulty Cicatrices** about the face and neck often occasion much deformity and annoyance, and may require a plastic operation for their removal. Those resulting from burns have already been considered, as also their treatment (Vol. I., p. 399 *et seq.*). Much may be done by proper surgical means to remove the disfigurement occasioned by the puckered or discoloured scars sometimes left by strumous abscesses, or the healing of wounds with dirt or grains of gunpowder imbedded in them. This is best done by dissecting the scars out, then loosening the edges of the cut by running the point of the scalpel under the skin, so that they may be brought together without puckering, and uniting them by means of horse-hair or catgut sutures passed with a fine sewing or Hagedorn's needle.

**Burow's Operation.**—A plastic operation specially suited for the repair of deformity consequent on the removal of morbid growths from the cheeks and other parts of the face, was introduced by Burow, a Polish Surgeon, and successfully performed by Stokes (Fig. 701). The steps are as follows: The growth to be removed is included in three incisions, 1, 2, 3; and the integuments from which it springs are then carefully dissected off, leaving a raw triangle, the apex of which is on one, the base on the other side of the tumour. The incision 1, 4, 3, is then carried outwards to 5, 8, 7, so that the whole distance from 1 to 7 is exactly three times that of the base of the raw surface; a second triangle, 5, 6, 7, is then made, having its base on the outer third of this horizontal incision. The two triangles must be of equal size, and the integuments are dissected off 5, 6, 7. There are thus two raw surfaces to be covered in. This is done by dissecting up carefully the flaps 1, 5, 6, and 2, 3, 7. When this is done, the points 1 and 3, and 5 and 7, are respectively drawn together, each by one suture, and the two raw triangular surfaces are thus covered in.

Plastic operations of various kinds are frequently performed on the eyelids.

**Blepharoplasty**, or the operation by which the eyelids are repaired, is occasionally required for loss of substance—the result of wounds, cicatrices, or operations. It is less satisfactory in its results than most of the other plastic procedures about the face ; yet it may, in some cases, materially improve the patient's appearance.

When the upper eyelid requires repair, the flap is taken from the forehead ; when it is the lower lid, from the cheek or temple. This operation may be performed by the gliding method, by twisting a flap into its new situation, or by transplantation of a piece of skin. By the gliding method, a triangular flap is cut and partially detached (Fig. 702, *a*), and then drawn gently forwards until it corresponds to and fills up the gap that requires repair, when it is there fixed by a few points of suture. When the twisting method is employed, an oval flap is detached (Fig. 702, *b*), except its pedicle, and twisted down, to be planted on the raw surface.

Occasionally neither of these methods is applicable ; and then the procedure that I successfully adopted in a case of which the annexed cut (Fig. 703) is a representation, may be followed. In this case, which was that of a lady who

Fig. 701.—Lines of Incision in Burow's Operation.

Fig. 702.—Operation for Repair of Eyelid : (*a*) Gliding Method ; (*b*) Twisting Method.

had received a severe mutilation of the face by the bursting of a ginger-beer bottle, there was a deep and hard cicatrix across the lower eyelid, causing depression and eversion of its outer portion, and adhesion of the inner part to the ball of the eye. After dividing the adhesions and removing the cicatrix, I made a semilunar incision so as to dissect up the eyelid, and then fixed it by points of suture in its new situation, when it became firmly adherent (Fig. 704), and scarcely any apparent deformity was left. In another very similar case, in which a girl had been bitten through the lower eyelid by a dog, a similar operation was practised with equally good results. In both these cases the eyeball, having been injured, had become atrophied, with opacity of the cornea. But, when an artificial eye was adjusted to the shrunken globe, the appearance of the patient was most satisfactory.

Restoration of the lower eyelid in extreme ectropion by complete transplantation of a piece of skin was first performed by G. Lawson in 1870, and afterwards by Wolfe of Glasgow in 1875, since which time it has repeatedly been performed with success. The operation is thus performed : the eyelid is first freed from the abnormal situation into which it has been drawn until its free border can be brought in contact with the upper lid, to which it

is fixed by sutures. An accurate pattern of the raw surface to be covered is then taken, and a flap of skin is raised from the forearm corresponding in shape but a little larger to allow for shrinking. The under surface of the flap is then freed from every vestige of subcutaneous tissue with a pair of flat sharp scissors, so as to have a white appearance. It is then applied to the raw surface and united to the surrounding skin by fine silk sutures. A dressing of warm wet boric acid lint may then be applied and covered by gutta-percha tissue and cotton-wool. About a fortnight after the operation, after the flap has become firmly adherent, the sutures uniting the lids may be

Fig. 703.—Lower Eyelid deformed by Cicatrix.

Fig. 704.—Lower Eyelid after Operation.

removed and the eye allowed to open. In a case successfully operated on by Wolfe, the oval piece of skin transplanted measured two inches by one and a quarter. It united by first intention, without even desquamation of the cuticle taking place.

#### PLASTIC SURGERY OF THE NOSE.

**RHINOPLASTIC OPERATIONS** are undertaken for the restoration of a part of the nose which has been destroyed by injury or disease. This branch of plastic surgery has long received much attention, and has been reduced to definite rules. Either the entire nose, or a portion of it, may require restoration.

**Columna.**—When the columna and a portion of the septum are destroyed, a large gap is left at the nasal aperture; and, the nose becoming flattened in consequence of its tip falling in, great deformity necessarily results. The upper lip also, losing that amount of support which it receives from the columna, becomes pendulous, projecting, and thickened. The restoration of the columna is effected from the upper lip, which, by being reduced in size, is rendered more shapely. The operation consists in cutting through the whole lip from above downwards on each side of the mesial line, so as to leave a tongue about one-third of an inch in width. This is then turned up; and its free end being well pared, and the under surface of the tip of the nose properly freshened, it is fixed by means of a fine hare-lip pin and twisted suture, which should be left in for about four days. Union takes place in a few days; but until this is firm, the new columna must be properly supported with narrow strips of plaster fixed to the cheek on each side. No twisting of this small flap is required, as the mucous surface speedily becomes cutaneous, and *vice versa*. The division in the upper lip must be treated in the same way as an ordinary hare-lip, and unites without difficulty, lessening greatly the deformity in this part.

**Ala.**—When one ala only is deficient, the rest of the nose being sound, one

of three processes may be adopted to remedy the deformity : 1. When a small portion only of the free border of the tip has been lost (Fig. 705), an incision should be made across the nose, and the remains of the ala and a portion of the nasal integument thus marked out dissected down, and attached to the end of the organ. In this way a very excellent result may be obtained.

2. If the loss of substance be greater, a flap of skin, of the proper shape, may be raised from the cheek, applied to the previously pared edges of the part requiring it, and fixed there by a few points of fine suture.

3. If the loss of the substance of the ala be very considerable, or if it extend to a part of the body of the nose, other plans, presently to be described, are required for the repair of the deformity.

**Entire Nose.**—For the restoration of the entire nose, two procedures have been employed : viz., 1, the Tagiiaacotian Operation ; 2, the Indian Operation, variously modified.

1. The **Tagiiaacotian Operation** consists in taking the integument and areolar tissue required for the repair of the lost organ from the inside of the arm. Here a flap of sufficient extent is to be marked out and dissected up with its subjacent areolar tissue, leaving it merely attached to the limb by a root at its distal end. Some Surgeons attach the flap at once to the raw surface, but others recommend that this should not be done for at least a fortnight, during which time it should be kept upon a piece of wet lint, and allowed to thicken and granulate. The remains of the deformed nose having then been properly pared and the flap shaped, they must, after all bleeding has ceased, be properly adjusted and fixed to one another by points of suture. The arm must then be closely attached to the head, so as to be as nearly as possible immovable. At the end of about ten days, when adhesions have taken place, the connecting medium is cut across, and the part left to be supported by the vitality which it may gain from the new surface to which it is now attached. The uncertainty of maintaining the vitality in the flap, the constrained position in which it is necessary to keep the patient, and the great difficulty of guarding against movements of the arm, especially during sleep, have caused this plan of procedure to be almost universally abandoned.

Fig. 705.—Deficiency of Ala of Nose.

2. The **Indian Operation**, a knowledge of which was brought to this country by Carpue in 1814, is extremely successful in its results, though requiring a good deal of nicety for its proper execution. The operative procedures required in this method may conveniently be divided into three stages : 1, the Dissection of the Flap from the Forehead, and its Attachment to its new situation ; 2, the Separation of the Root of the Flap where it is turned down from the Forehead, and the Formation of a proper Bridge to the Nose ; 3, the Formation of the Columna Nasi.

1. **Formation and Attachment of the Flap.**—In the shaping of the flap, care must be taken that it is of sufficient size ; as during the after-part of the treatment it often has a tendency to shrink. The size adapted to the particular face may best be judged of by moulding a thin piece of gutta-percha to the nose, then flattening it out by dipping it in hot water, and using this as the guide for marking the outline of the flap upon the forehead. This should be traced with tincture of iodine, which will not be washed off so

readily as ink by the flow of blood, which is often rather free. This flap should be of the shape shown in Fig. 706, care being taken that it is rather square at the angles, and not too much rounded off. When the whole of the nose requires restoration, it is usually necessary to make the flap about two and a half to three inches in length, by about the same in width at the broadest part. It may be taken either from the middle of the forehead, or obliquely from one side; if the latter, the right side is the more convenient. It must now be dissected off the forehead; in doing this, care must be taken to cut the flap as thick as possible, especially at its root between the eyebrows. It must also be but little handled, and above all, not pinched, either with fingers or forceps. The dissection should be commenced at the root, so that the outline may not be obscured by blood; and this part should be left long, in order to admit afterwards of a very gradual and easy twist. In order to facilitate this, it is desirable also to make the incision on the right side a little lower than that on the left. After the flap has been raised throughout the

Fig. 706.—Diagram of Flap in Rhinoplastic Operation.

whole of its extent, pressure should be applied to the forehead by means of a sponge, with a view of arresting the bleeding, before the next step is taken. This consists in paring the surface and edges of the stump of the nose, and removing the integuments from it in such a way as to leave a triangular raw surface. In doing this care must be taken not to remove the parts too widely, lest the cheeks should retract, and flatten out the nose. The integuments also should be dissected away in such a manner as to form a deep groove shelving inwards, so as to receive and hold the flap more securely and with less overlapping of the edges. The operation must now be discontinued until all bleeding has ceased, and the cut surfaces have become glazed; this point is of great importance in securing direct adhesion. The bleeding having been arrested by exposure to the air, and by the torsion rather than the ligature of any spouting branch, the flap should be brought down by a twist from left to right, and attached by a few points of fine suture on each side to the edge of the incision around the nasal aperture. A pledget of soft lint, or wool greased with carbolic oil, should now be gently insinuated under the flap, the lower part of the incision on the forehead drawn together by a point of suture, but not so as to constrict the root, and the rest of the exposed surface covered with some simple dressing. The parts will then present the appearance shown in Fig. 708, taken from a patient of mine the day after the operation. Fig. 707 represents the deformity for which the operation was performed. The patient should be put to bed with a piece of cotton-wool laid over the whole of the face, so as to maintain its temperature; and, if it be winter, he must be placed in a room that is well warmed day and night.

The dressings must not be disturbed for three days; by this time, if all go well, the flap will be found somewhat tumid, warm, and sensitive, but pale in colour. The plug in the nose will now require changing, lest it be rendered

offensive by the discharges ; its withdrawal and the substitution of another must be done with the greatest gentleness, lest the adhesion of the flap be broken down. If the sutures cause no irritation, they may be left in till the fifth or sixth day, by which time adhesion will be tolerably perfect. As adhesion strengthens and the vitality of the flap improves, it must be elevated by putting underneath it a larger plug of lint ; for which, after a time, may be substituted a small gutta-percha tube moulded to the figure of the inside

Fig. 707.  
Depressed Nose.

of the nose. Edema of a somewhat solid character is apt to come on in the flap, giving it a white appearance ; but this is of little moment, and will gradually subside as the circulation through it becomes more actively established. The flap gradually becomes thicker and firmer, throwing out granulations from its under surface, which eventually becomes covered by epithelium. The wound on the forehead must be dressed like an ordinary ulcer. It usually cicatrizes with great readiness, and leaves a remarkably small scar.

Fig. 708.—New Nose, day after Operation.

2. **Separation of the Root of the Flap.**—This may be done about a month after the flap has been fashioned, when its vascularity, through its lateral adhesions, will be perfected. The division of the root is best done by passing a narrow-bladed bistoury under the twist, and cutting upwards towards the eyebrows, removing a wedge-shaped portion of the soft parts, so as to make a smooth and proper bridge.

3. **Formation of the Columna Nasi.**—The addition of the columna is now all that is wanted to make the nose complete. This must be made from the upper lip, perhaps at the same time that the bridge is fashioned ; and it may be cut and fixed in the way that has already been described at p. 656, the interior of the apex of the new nose having been well pared to receive it. The columna must be well supported by means of a narrow strip of plaster passing from one cheek to the other, and usually requires a good deal of fashioning before it is perfect ; indeed, this is the part of the operation that I have always found most troublesome.

The new nose must continue to be supported from beneath, for some months after its formation, by plugs of lint or small gutta-percha tubes, as it will evince a great tendency to contract, becoming either depressed or dumpy. The sensibility of the new nose is entirely destroyed for a time after the division of the bridge ; but this slowly returns, appearing first in the neighbourhood of the adhesions between it and the cheeks, and gradually—in several months—in its central portion.

The annexed cuts (Figs. 709, 710) give a faithful representation of a patient on whom I operated, before and after the operation.

The success of the case will depend very greatly upon the minute attention which the Surgeon bestows on the details of the operation, and on the care which he takes in the after-treatment. During the operation, the chief points to be attended to are, that the flap be made of sufficient size, that all oozing

have ceased before the cut edges are brought into contact, and that no tension or constriction be exercised. A principal source of failure in the operation is gangrene of the flap, in whole or in part, arising from the root being too narrow or too tightly twisted, or from the flap being too roughly handled in its dissection. So also, if it be cut too small and not properly supported afterwards, the result will not be very satisfactory. Other accidents occasionally happen: thus, erysipelas may destroy the vitality of the new nose, as happened in one of Liston's earlier cases; or the new nose may be destroyed by a return of the lupus which proved destructive to the old one. Hæmorrhage also may occur from underneath the flap. In the last case operated on by Liston just before his death, and which was completed by Morton at University College Hospital, hæmorrhage to the extent of more than a pint took place on the ninth day, without any evident cause, from under the flap, and could be arrested only by plugging. Further, the operation is not without its dangers.

Fig. 709.—Patient before Rhinoplasty.

Fig. 710.—Same Patient some months after Operation.

Dieffenbach lost two patients out of six on whom he operated; their constitutions having probably been in an unfavourable state.

The operation as just described will usually be attended with very satisfactory results. Of late years some modifications have been introduced into it. Thus, Langenbeck recommended that the periosteum should be dissected up from the frontal bone together with the skin-flap, in order that, by the after-development of osseous tissue, a firmer and better organ should be left. The objections to this operation are that in reflecting the pericranium the vitality of the flap is liable to be damaged; that there may be some risk of necrosis, although this is probably small; and especially that the pericranium is now known to have very little bone-producing power. Even if a bony layer were formed inside the nose, it seems to me that it would be rather a disadvantage than otherwise.

The operation practised by Ollier appears to me to be less happy than many of that excellent Surgeon's suggestions. It consists in cutting down the nasal process of the superior maxilla, and then bending it across so as to form a kind of bridge, on which to sustain the tegumento-pericranial flap deflected from the forehead. But by doing this the lateral supports

to the bridge of the new nose are removed, and necrosis of the bent or rather broken fragment of bone, which has actually occurred, is not an unlikely accident.

A slight modification of the operation, which has been adopted by several Surgeons, consists in utilizing instead of removing the integumentary covering of the stump of the nose. This is raised in one or two flaps, which being turned downwards receive the frontal flap on their raw surface. The employment of skin-grafting to expedite the healing of the wound on the forehead will naturally suggest itself to the operator.

Should the operation fail, or from any reason be not advisable, the patient may be fitted with a painted vulcanite nose, attached to spectacles, by which the deformity is most efficiently concealed.

**FISTULOUS OPENINGS THROUGH THE NASAL BONES** leading into the interior of the nose are occasionally met with. Such apertures as these are best closed by paring the edges, and then bringing forward a flap

Fig. 711.—Opening into Anterior Nares.

Fig. 712.—Opening into Anterior Nares closed by Operation.

of neighbouring skin by the gliding operation. The cuts represent a case many years since under my care, before and the day after operation, in which a large aperture into the side of the nose, resulting from necrosis of the left nasal bone consequent on scarlet fever (Fig. 711), was successfully closed by a flap of skin taken from the forehead by the twisting process (Fig. 712). The patient, who was a child at the time of the operation, was seen many years after the operation, and presented scarcely any disfigurement.

**OPERATION FOR DEPRESSED NOSE.**—Sometimes the nose is depressed in consequence of the loss of the septum, though the external parts remain entire. Dieffenbach proposed a plan for raising it by slitting it longitudinally into three pieces: dissecting the lateral slips from the osseous attachments; paring the edges to such an extent that they overlap, and stitching them together; then bringing the whole organ forwards by pushing long hare-lip pins across its base, so as to elevate and narrow its attachments, which are brought more into the mesial line. Fergusson improved this procedure by not slitting the nose down, but dissecting it away from the bones from within the nostril, and

then pushing long steel-pointed silver needles across from cheek to cheek, and twisting their ends over perforated pieces of sole-leather, through which they had previously been passed, thus bringing the whole organ bodily forwards. The columna is next fashioned in the way which has already been described; and the nose is completed.

#### PLASTIC SURGERY OF THE LIPS.

**HARE-LIP.**—By **hare-lip** is meant a congenital perpendicular fissure or fissures through the upper lip, the result of an arrest of development. Without going into the details of the development of the face, the mode of origin of hare-lip, cleft palate, and congenital transverse fissure of the cheeks, or macrostoma, may be made clear by recalling the main features of the process. The prominent part of the nose and part of the septum nasi are developed from a central process, the fronto-nasal plate, descending from the front of the cranium between the ocular vesicles. On either side of this the olfactory area appears as a depression in the epiblast, bounded by prominent lips, the mesial and lateral nasal processes. The former, which are united with the fronto-nasal process, end below in the globular processes of *His*, which coalesce in the middle line to form the intermaxillary bone with the incisor teeth, the central part of the upper lip, the columna nasi and the lower part of the septum. The lateral nasal processes form the *ala nasi*. The remainder of the face above the line of the lower jaw is developed from a lateral process on each side—the superior maxillary plate—which gradually grows forwards till it coalesces with the nasal processes. From the superior maxillary plates are developed the cheeks and the whole of the upper jaws, except the central intermaxillary bone, which, as already stated, is formed separately. The lower jaw, and the soft parts covering it, are formed from similar processes, the inferior maxillary plates advancing from each side and coalescing in the middle line. The superior and inferior maxillary plates coalesce at each side, leaving the open space of the mouth in the middle line. The lines in which these various processes unite are roughly indicated in the diagram on p. 355, Vol. I. The mode of origin of the various deformities of the face is therefore evident. If one maxillary plate fails to unite with the globular process in front, a cleft will be left through the upper lip on one side of the middle line, forming a single hare-lip. If both plates fail to unite with the globular processes a double hare-lip results, and the intermaxillary bone may be left adherent to the tip of the nose and septum nasi. If at the same time the development of the globular processes is arrested, we get the rare condition of a wide gap in the middle line with absence of the incisor portion of the superior maxilla, whilst still more rarely a median hare-lip may result from failure of the globular processes of the opposite sides to unite in the middle line. If the anterior parts unite while development is arrested posteriorly, cleft palate results, the fissure being single, and in the middle line as far as the posterior part of the premaxillary bone. If the arrest of development is more complete, the fissure may extend to the lip, deviating in front from the middle line as it passes between the main part of the superior maxillary and premaxillary bone. If both sides fail to unite completely the fissure is single behind and double in front, passing on each side of the intermaxillary bone. In some instances the cleft, instead of running forwards between the lateral incisor and canine teeth,

passes between the central and lateral incisors, in the line, which, according to Albrecht, marks the division between the two centres of ossification for each half of the premaxilla. Sometimes also the lateral incisor is absent, or an additional tooth may exist on the outer side of the cleft. In exceedingly rare cases the fissure of the hare-lip has been seen extending upwards on one side of the nose towards the eye. Macrostoma or congenital transverse fissure of the cheeks results from arrested union of the superior and inferior maxillary plates.

**Single Hare-lip** is by far the most common deformity (Fig. 713). In it the mesial side of the gap is usually rounded; the outer edge is flattened; and the frænum at the angle is long and subcutaneous. The hare-lip may be incomplete or complete, according as the lip is merely notched or divided up into the nose. In the latter form the corresponding ala nasi is usually much flattened. When **double** (Figs. 714, 715), the fissure is often deeper on one side than on the other, and usually extends into the nostril, and is associated with cleft palate; though sometimes it stops short of this. In these cases the nose is usually flattened and expanded, and between the fissures there is always a central lobule, consisting of the intermaxillary bones in a rudimentary condition; to this a triangular labial nodule is commonly attached. In many cases this is tilted on its base, so that the alveolar

Fig. 713.—Incomplete Single Hare-lip.

Fig. 714.—Ordinary Double Hare-lip.

Fig. 715.—Ordinary Double Hare-lip. Side View.

border projects forwards. Sometimes the projection is so considerable that it is attached to the tip of the nose.

The fissure, when single, may be confined to the lip; but in the majority of cases it extends to the alveolus of the upper jaw, giving rise to a deep notch between the lateral incisor and the canine tooth. When it is double, the four incisors, usually imperfectly and irregularly developed, are included in the central intermaxillary tubercle. Meckel and Nicati have described a rare form of hare-lip, in which the fissure corresponds to the line of junction between the central and lateral incisors. In many cases the fissure extends back into the palate; this more frequently happens when the hare-lip is double, and in these cases every variety of palatal deformity is met with (Fig. 716).

**Median Hare-lip** is so rare that there are very few authentic cases of it in the records of surgery. In a specimen dissected by Bland Sutton the premaxilla was absent, whilst in other cases the condition appears to have been due to want of union of the two globular processes. In Pitts's case the median cleft in the lip extended half way to the nose, and with the exception of a

central groove in the premaxilla the bones were normal. In Clutton's case the median hare-lip was associated with a complete cleft of the palate; the frenum of the lip was divided, one half passing to each side of the cleft in the premaxilla. Delahaye has recorded a case of mesial fissure of the upper lip with two lateral fissures. Median fissure of the lower lip has been recorded by Nicati and Wölfler.

**Age for Operation.**—The cure of hare-lip can be effected only by a properly conducted operation. In the performance of this, the first point that has to be determined is the age at which it should be done. On this there has been a good deal of difference of opinion. It is now, however, agreed by all Surgeons that the operation should be performed early, before dentition commences. During dentition, I think, it is better not to perform the operation; at all events not during the cutting of the incisor teeth, when there is much local excitement and general irritability of the nervous system. There

Fig. 716.—Skeleton of Jaw in Double Hare-lip, and Cleft Palate.

is no danger in operating in early infancy; on the contrary, very young children, those but a few weeks or months old, bear operations remarkably well. I have repeatedly operated at these tender ages, not only for hare-lip, but for hernia, the removal of tumours and nævi, the division of tendons, &c., and have never seen any bad result follow. Besides this, the performance of the operation is easier at a very early age than when the child has reached its first or second year; when, its intelligence being more developed, it knows what it has to suffer, and screams and struggles more than a very young infant does, whenever it sees the Surgeon, or when he makes an attempt to examine the wound or dressings. After the operation, also, the child will, when young, take the breast without difficulty. At very early ages, union of the wound takes place with great readiness and solidity; and, as no time has been given for the rest of the features to become distorted, there will not be that permanent flattening and deformity of the face which are apt to continue after the hare-lip is cured, if the operation be deferred to a more advanced age. For these various reasons I agree with Fergusson and Butcher, that the operation had best be performed, if possible, at about the sixth week after birth, or from that to the third month, which may, I think, be considered the time of election. At this time the vitality of the child is good, and the tissues are not so lacerable as at an earlier age. The operation may safely be performed at a much earlier period in single than in double hare-lip; and the greater the deformity, the more marked the intermaxillary projection, the wiser will it be to defer operation, which becomes increasingly severe with the extent of the deformity. Even in these cases, however, it should not be delayed beyond the third month, as the early removal of the intermaxillary bone, and the pressure of the united lip, tend to narrow the cleft in the palate. Should circumstances require it, however, the operation might be done at a much earlier period than that advised above. Thus, at the urgent solicitation of the parents, I have performed it within the first twenty-four hours after birth, and several times during the first week. But in these very early days of life the operation is not without danger; the vitality

of the child is often feeble, it suffers greatly from the loss of even a very small quantity of blood, and the tissues are so lacerable that there is great danger of the pins or stitches cutting out. I would therefore not advise its performance then.

It is scarcely necessary to observe that, as union by the first intention is aimed at, the operation should not be undertaken unless the health be good; and certainly not if the child, at whatever age, have but recently recovered from measles, scarlet fever, or other infantile disease.

**Operation for Hare-lip.**—In the treatment of hare-lip, there are three main objects to be kept in view: 1. The procuring of union by first intention of the cut edges of the fissure; 2. The prevention, as far as possible, of deformity during the process of union; and, 3. The avoidance of all traction on the line of incision that may interfere with these results.

The operation for **single hare-lip** is performed in the following way: The child is placed on a table facing a good light, the head and shoulders being raised on a small pillow and the arms fixed with a towel pinned around them. Chloroform should be administered. Before proceeding to pare the edges of the cleft the Surgeon should thoroughly free the lip from the bone on either side of the cleft, so that it may subsequently be more readily drawn into apposition.

Bleeding from the coronary artery of the lip may be prevented, either by an assistant or the Surgeon grasping the lip between his finger and thumb, or by compressing the lip with the little contrivance here figured, which consists of ordinary ring-forceps converted into a compressor by having an india-rubber ring slipped over the handles (Fig. 717). Putting the lip on the stretch by seizing the extreme edge of the cleft with a pair of artery-forceps, the Surgeon pares the edges of the cleft by transfixion with a fine scalpel, from above downwards, first on one side, then on the other; taking care that the incisions unite neatly above the upper angle of the fissure, which must be well cut out; and that they extend sufficiently far outwards to cut away the rounded portion of the prolabium which forms the side of the base of the fissure. The incision on each side must be curved with the concavity towards the fissure (Fig. 723), so that by bringing the two curves into a straight line a slight projection of the prolabium at the point of union shall be produced. If this be not done a notch will be left when the lip is healed. Care should be taken that enough is cut away; there is more danger usually of taking too little than too much.

The edges of the cleft are now adjusted with hare-lip pins or simple sutures; of these the latter are generally to be preferred. In either case two points require special attention: first, that the whole thickness of the pared surface, and not the skin only, be drawn together; and secondly, that the line of the red edge of the lip be accurately adjusted. If pins are used, two, or sometimes three, are required. Each should be entered about a third of an inch from the pared edge on one side, and brought out at a corresponding point on the other, the whole thickness of the lip except the mucous membrane being included.

Fig. 717.—Elastic Compressor applied over Coronary Artery.

The lower pin should be introduced first underneath the coronary artery, in such a way that its pressure may stop the bleeding from this vessel, which is often rather free. The twisted suture is then applied in the usual way (Fig. 718), first round the lower pin, and then round the upper one (separate threads, however, being used for each); and lastly, the two are united by a few cross turns, so as to press down and support the whole length of the fissure (Fig. 719). The pins are then cut short, the whole is coated with a layer of collodion, and a piece of plaster is put under the ends of the pins to

Fig. 718.—Application of Twisted Suture.

Fig. 719.—Application of Pins and Sutures in Hare-lip.

prevent excoriation of the skin. In addition to the pins and twisted suture, one or more points of interrupted suture should be passed through the mucous membrane of the lower part of the fissure, just inside the mouth. I look upon this as of great importance in preventing the notching, which is otherwise very apt to occur, in consequence of that portion of the incision between the lower pin and the edge of the lip being kept open by the child in sucking, or protruding its tongue against it. The parts may be supported by drawing the cheeks together by a piece of muslin cut so as to form a large rounded piece in each cheek connected by a narrow strip over the lip. This must be applied while the cheeks are pressed together with the fingers and sealed down with flexible collodion. American rubber-plaster may be applied in the same way, but is not so efficient. Hainsby's truss (Fig. 720) is now rarely used.

Fig. 720.—Hare-lip: Spring Cheek-compressor.

When simple sutures are used—and in ordinary cases I much prefer them to the pins—stout silver wire or silkworm gut is the best material, and does not tend to cut out. Two or three of these are usually required, the lowest being inserted beneath the coronary artery and the highest close to the upper end of the cleft, so as to draw inwards the flattened ala nasi. A few points of horsehair suture may be inserted superficially to ensure the perfect apposition

of the edges, and others in the mucous membrane, as above described.

In many cases some modification of the operation is advisable, especially when the cleft is broad and its edges of unequal length. A method which is very largely employed is carried out as follows: The longer edge of the cleft is completely freshened, the incision at its lower end sloping slightly away on to the lip. In freshening the other margin, the incision stops below at the junction of the skin and mucous membrane, so that a small flap remains attached by its lower extremity. This flap is drawn downwards, and after the introduction of the pins or sutures, it is adjusted with horsehair sutures

to the lower end of the opposite and longer raw surface. Malgaigne's method consists in leaving a similar flap attached to the lower end of each edge of the cleft, the two being drawn and sutured together after the cleft itself has been closed. In this way the presence of a notch in the edge of the lip is avoided.

It sometimes, though rarely, happens in single hare-lip that the intermaxillary portion is so large and projecting that there is difficulty in bringing the lateral segments together over it. Should this be the case, the better plan is to notch it at its alveolar border on the side that is not fissured, and then to break it back so as to remove all projection.

When the fissure does not extend through the lip the operation recommended by Nélaton will be found to give most excellent results. The mode of performing it is fully explained by the accompanying figures (Figs. 721 and 722).

*After-Treatment.*—After the operation the lips often come in close contact, and care must be taken to clear the nostrils from clots of blood, otherwise

Figs. 721 and 722.—Nélaton's Operation for partial Hare-lip.

the child may be suffocated, especially if the effects of the chloroform have not fully passed off.

If pins have been used these should be removed, at the end of from 72 to 96 hours, according to the age of the child. The pin must be gently twisted out in such a way that the cut end does not tear the aperture in the lip. The threads, matted together with exudation and a little blood, form a good crust, which may be left on for two or three days longer, and then allowed to separate of itself; the less any crusts that form over the line of incision are interfered with, the better will the result usually be.

If simple sutures have been used the deep ones should be removed on the fourth day, but the finer ones may be left in for a day or two longer. The lip must then be supported by the collodion and muslin or by a strip of American rubber for about a fortnight after the operation, so as to prevent stretching of the cicatrix and notching of its lower part.

**Double Hare-lip.**—The operation for double hare-lip is performed on the same principle as that for the single form of the disease, the difference in the operations consisting chiefly in dealing with the median portion of the lip and the intermaxillary bone (Fig. 723). The management of the intermaxillary process must vary according to its size and degree of projection.

If the premaxilla and prolabium be well developed and not projecting they should certainly not be removed. The prolabium is first separated from the bone and its edges pared in a somewhat convex manner, the two raw surfaces being made to meet in a point below.

A small flap is now separated from the lateral edges of the lip, and is left attached below as in single hare-lip. After the lateral parts of the lip have

been attached to the prolabium with pins or sutures, these two flaps are drawn downwards and adjusted with fine stitches partly to the pointed lower end of the prolabium and partly to each other.

In cases of the opposite extreme in which the premaxilla is small and rudimentary, or fixed to the tip of the nose, as in Fig. 724, it should be removed with bone-forceps, as it would prevent the lateral segments of the lip from coming into proper apposition. A dental artery deep in the bone may bleed freely, and require to be touched with a cautery.

Fig. 723. — Operation for Double Hare-lip, Right Side of Lip drawn down by Spring hook. Forceps; long narrow Knife entered at angle; dotted line shows direction of the incisions.

In intermediate cases, where the premaxilla is well developed but projecting, it has been recommended to bend or break it back by strong forceps covered with vulcanized india-rubber. Fergusson, however, pointed out that if this be done the incisor teeth contained in the intermaxillary portion will, if they develop at all, project backwards into the roof of the mouth, as the bone is not pushed into its normal situation, but rather rotated on its transverse axis, the slender neck attaching it to the vomer being bent upon itself. He was of opinion therefore that in all cases it is better to remove the bone than to attempt to force or bend it into a new position. In cases such as that represented in Figs. 724 and 725 I have performed the following operation with great success:—

1. The triangular flap of skin covering the intermaxillary portion is dissected up as thick as possible.
2. The intermaxillary process is then cut away at its root, which is small and pedunculated, with a pair of scissors.
3. The edges of the lateral fissures are then pared in the usual way.
4. The free lower margins of the pared edges are brought together by one hare-lip pin and twisted suture.
5. The leaf-

Fig. 724. — Double Hare-lip; Intermaxillary Portion fixed to Nose.

Fig. 725. — Double Hare-lip; Projecting Intermaxillary portion.

shaped flap is then laid down in the triangular hollow left above the pin, and retained there by one or two points of silver suture on each side, the gap being thus completely filled up by it.

On the whole, however, removal of the premaxilla must not be looked upon as an unimportant detail of the operation, but rather as a serious step to be

avoided if possible. In many cases the premaxilla can be pushed back into position by firm pressure or by seizing it with strong forceps with guarded blades, and it may be found advisable to fix it by a suture to the edges of the interval in the alveolus. Rather than completely remove it Fergusson's plan will often be found useful—viz., to make a small incision through the mucous membrane and with a small gouge to remove the incisor teeth and bone, leaving only a shell of periosteum and mucous membrane which can readily be pushed back into position, and will help to support and hold forward the lip. This part of the operation may conveniently be performed a week or so before the lip itself is repaired.

The operation for hare-lip occasionally fails. This may happen either in consequence of the child's health being in so unsatisfactory a state as to prevent union by the first intention ; or in consequence of the pins or sutures having been taken out too early, before firm cohesion has been effected. In such circumstances as these, an attempt might be made to unite the granulating edges by the re-introduction of the pins or sutures, and by firmly fixing the lip by means of collodion or plaster applied as above described. Such attempts, however, rarely succeed ; should they not do so, it will usually be found most prudent to wait at least a month before taking any further steps, and then to pare the edges afresh and repeat the original operation.

**Congenital Transverse Fissures of the Cheeks**, extending from the angle of the mouth to the anterior border of the masseter or up towards the malar bone, are occasionally met with. Their mode of origin has already been referred to (p. 662). In these malformations, which are of extremely rare occurrence, the ear on the affected side is imperfectly developed. As has been observed by Fergusson, the tragus is detached from the auricle, and is fixed to the cheek, where it forms a small lobulated appendage. The external ear generally is malformed, the helix being twisted and curled inwards. These malformations require to be treated on exactly the same principles, and with the same attention to details, as hare-lip ; union between the pared edges being effected by means of deep sutures of silver-wire or silk-worm gut and superficial ones of horsehair.

**Cheiloplasty**.—Simple plastic operations are commonly practised on the lower lip for the removal of epithelioma, by cutting out a V-shaped piece of the lip, including the whole diseased structure, and then bringing together the opposite sides of the incision by sutures or hare-lip pins. These operations have already been described and figured at p. 603, *et seq.* We shall consider here those cases in which it becomes necessary to repair more extensive loss of substance in the labial structures. The plan originally introduced by Chopart consisted, when it was the lower lip that was affected, in carrying an incision on each side of the diseased portion of the lip vertically downwards below the jaw, for a greater or less distance according to the amount to be removed, if necessary, even as far as the hyoid bone. The diseased part of the lip was then removed by a transverse incision below it. The square flap marked out by the two vertical incisions was next detached from above downwards. It was then brought up, and fixed to the pared edges of the remaining portion of the lip by points of suture ; the head being kept properly inclined, in order to prevent undue tension. After sufficient union had taken place to preserve the vitality of the flap, its lower attachments were divided. This operation was not very satisfactory in its results, as the new flap was apt to become

œdematous and inverted at the edge, or the flow of saliva interfered with proper union, and it is not now practised. In those cases in which the greater portion of the lower lip has been excised for cancerous disease affecting its upper margin, a better procedure for the restoration of the deformity consists in a modification of the plan recommended by Serres; and from this I have derived excellent results, as in the case which is here represented (Fig. 726). The object of the operation is to raise the lower lip to a level with the incisor teeth. An incision, about three-quarters of an inch in length, is made directly outwards from the angle of the mouth, on each side, into the cheek; from the extremity of this a cut is carried obliquely downwards on to the upper margin

Fig. 726.—Lines of Incision in Cheiloplasty.

Fig. 727.—Incisions and Sutures in Cheiloplasty.

of the lower lip, so as to excise the included triangular piece; the lower lip is then dissected away from the jaw, from the inside of the mouth, and a V-shaped piece is taken out of its centre. By means of a hare-lip pin on each side, and a point of suture, the incisions in the angle of the mouth are brought accurately together; and in the same way the vertical one, in the centre, is united (Fig. 727). In this way the whole of the lower lip is raised, and brought more forwards. If care have been taken in removing the cancer from the edge of the lip, to leave the mucous membrane rather long (which may always be done, when the skin is affected to a greater extent than it), a

Fig. 728.

Fig. 729.

Fig. 730.

Buchanan's Operation for the Restoration of the Lower Lip.

good prolabium may be formed, and the restoration effected with but little deformity.

Buchanan, of Glasgow, as far back as 1841, published an account of a method for restoring the lower lip, which gives very satisfactory results. The accompanying figures illustrate the kind of case in which Buchanan's operation is applicable, the lines of incision required, and the appearance presented by the chin and lip after the disease has been removed and the flaps brought into proper apposition.

The steps of the operation are simple. The diseased part of the lower lip is first removed by an elliptical incision (Fig. 728, A B A). An incision, B C, is then carried downwards and outwards on each side of the chin; and another

incision, C D, upwards and outwards parallel to, and corresponding in length to, A B. The flaps formed by these incisions are represented in Fig. 729. They are detached from their subjacent connexions; and the whole is raised upwards, so that the curved incision, A B, comes into a horizontal line, and is made to constitute the margin of the new lip; the secondary incisions, B C, coming together in a vertical direction, in which they are retained by twisted and interrupted sutures (Fig. 730). The raw surfaces from which the flaps are raised are left to heal by granulation, and this forms an objection to the operation, as the contraction of the sores tends to draw the new lip downwards. Syme therefore recommended a somewhat different mode of operating. Instead of the incisions C D being made, those marked B C are carried onwards for some distance in a direction curving downwards and outwards, so that they

Fig. 731.—Syme's method of restoring the Lower Lip. Lines of Incision.

Fig. 732.—Syme's method of restoring the Lower Lip. Operation completed.

terminate below the angles of the jaw (Fig. 731). The flaps so formed are raised and united in the middle line, as in Eucharan's operation, the  $\Lambda$ -shaped portion of skin above the chin serving to maintain them in position and prevent their sliding downwards (Fig. 732). The long curved incisions enable this to be done by merely stretching the convex edges of the flaps, without sufficiently displacing them to prevent their readily meeting the concave edges of intervening skin, and being united to them by sutures. No surface is therefore left to granulate, and the whole wound heals by the first intention. In performing this operation it is essential to success that the incisions should be sufficiently free, so that the flaps may be brought into position without tension. If the chin be removed as well as the lower lip, it becomes very difficult to restore the loss, as there is no fixed point below to support the new lip, which consequently tends to sink downwards.

#### PLASTIC SURGERY OF THE PALATE.

Various degrees of congenital deformity may occur in the palate and uvula: thus the uvula alone may be bifid; or the cleft may extend through the greater part or the whole of the soft palate; or the hard palate may be divided as well (Fig. 733); and, lastly, the separation may extend forwards to the integuments of the face, producing single or double hare-lip (Fig. 716). The soft palate and uvula are not unfrequently cleft without the hard palate being divided; and, in some very rare cases, the lip and the hard palate are fissured

without the soft being cleft. The mode of origin of these deformities already been described (p. 662).

These malformations necessarily give rise to great inconvenience, interfering with deglutition, and rendering speech nasal and imperfect. In the swallowing of fluids, there is a tendency to regurgitation through the cleft, though this is occasionally prevented by the approximation of the edges of the fissure in the soft palate.

An infant born with a complete cleft of the hard and soft palate is necessarily unable to suck, and unless carefully fed by hand will soon starve. Must be fed solely on milk, the mother's milk being the best, which should be drawn periodically and administered to the child. The feeding may be done by a properly constructed bottle, from which the milk will flow slowly by the necessity of sucking on the part of the child; this must be fitted with an india-rubber tube, which must be pushed well to the back of the pharynx where the milk is given. In the absence of a bottle the child may be fed by means of a tea-spoon.

Operations for the cure of cleft palate were formerly deferred until the patient had attained the age to understand the necessity of remaining quiet during the operation, and was able to control his movements, as success depended in a great measure on his remaining perfectly steady during the necessary manipulations, and upon his assisting the Surgeon by opening his mouth, and not coughing during the introduction of instruments. Chloroform was never administered, for fear that suffocation might be caused by the blood from the operation, which is abundant, entering the air-passages. It was, however, Thomas Smith demonstrated that with proper care anæsthetics may be safely administered, and at the same time he introduced the most ingenious gag, by means of which the patient's mouth can be kept widely open without the Surgeon being interfered with either by the assistants or the instrument itself. By the help of this gag, and the administration of chloroform, the operation can now be performed at any age, as the bleeding is always very free, it is advisable not to attempt it in young children. If the cleft implicates the soft palate only, it may be closed at the age of three if the health is good and other conditions favorable. The operation has been successfully performed as early as the first year, and the advantage of having it done before the child has learned to speak justifies early operation in suitable cases. If the hard palate is involved, it is better to wait till the sixth or seventh year.

Fig. 733.—Fissure of Hard and Soft Palate.

**Operations for Cleft Palate.**—*Staphylorrhaphy*, or the operation for the cure of a cleft in the soft palate, may be said to have been first established by a definite surgical proceeding by Roux, whilst *uranoplasty*, or the cure of a cleft of the hard palate, was first performed by Warren, of Boston, brought before the profession in this country by Avery and Pollock. Changes and improvements in these operations have been made by Dieffenbach, Liston, Fergusson, Pollock, T. Smith, and others.

**on Soft Palate.**—The patient is placed in a recumbent position in good light, and with the head and shoulders raised to a convenient pillow. The Surgeon stands on the right side, the anæsthetist on the left, and an assistant at the end of the table steadies the patient's head. Some prefer to have the head hanging downwards over the end of the table in order to prevent blood entering the larynx; the position is inconvenient, but seems to increase the amount of hæmorrhage.

Chloroform will be found the most convenient anæsthetic, as it gives rise to little of mucus. It may be given by means of Junker's apparatus, a small india-rubber tube passed into the pharynx through one nostril. The apparatus represented in the accompanying drawing (Fig. 734) is a modification of that devised by Wood. It can be adjusted to fit any patient by more or less separating the two halves. A small-sized Langenbeck's gag often answers admirably (Fig. 746). The first step in the operation consists in opening of the fissure by means of a narrow sharp-pointed knife like a scalpel, with a long handle. This is best done by seizing the lower end of

the instrument on one side in a pair of toothed forceps, and putting the corresponding half on the other side on the stretch. The cut may be made either from above downwards or from below upwards, first on one side and then on the other, but whatever plan is adopted great care must be taken not to leave a flap of mucous membrane behind in union. A sponge pressed into the wound quickly arrests the bleeding, and the vessels are cleared of blood and the edges of the flaps by means of sponges on holders. When the hæmorrhaging is arrested, the Surgeon

Fig. 734.—Wood's modification of Smith's Gag.

proceeds to the next step, that of closing the wound by sutures. The best material

is in most cases fine silver wire or silkworm gut. Cat-gut is not used readily and is apt to yield before union is complete. Silk, formerly used, cannot be retained beyond a few days, as it excites inflammation when soaked in decomposing fluids. Horse-hair will be used in uniting the uvula, but is not strong enough for the other parts of the palate. Wire stitches are usually introduced by Smith's tubular needle, specially constructed for the purpose, from which the wire is protruded at the lower end. In the absence of this apparatus they may be passed as follows: A common nævus needle is threaded with fine silk; this is passed through the right side of the cleft and drawn through to the other side. A similar loop is then passed on the left side. The right needle is then passed through the left, which is withdrawn, carrying the first needle through the left side of the palate. There is thus a double thread of silk across the cleft, having two free ends on the right side and two on the left. A fine hook is then made with a pair of dissecting forceps and the wire; this is hooked into the loop, which is then withdrawn, carrying the second wire with it across the cleft. This proceeding, though it seems complicated in a written description, can be carried out with great ease; and the needle being passed on both sides from before back-

wards, the sutures can be inserted more accurately and evenly than when on one side it is passed from behind. The stitches should be about one-sixth of an inch apart, and must all be introduced before any are tightened. The next step in the operation will depend upon the amount of tension that is present when the edges are drawn together by pulling gently on the middle stitch. If the edges come readily together without any strain, all the stitches may be at once tightened by tying them if the wire be sufficiently pliant, or by twisting them with a pair of torsion forceps, or a special wire twister constructed for this purpose. In the majority of cases, however, it will be necessary to make a lateral incision on each side to relieve tension. This is done by puncturing the palate with a fine sharp-pointed knife to the inner side of the hamular process, avoiding the situation of the posterior palatine artery. Pollock recommends that by raising the handle of the knife while the palate is put on the stretch, the fibres of the levator palati be divided without greatly increasing the puncture in the anterior surface of the palate. It will be found better, however, as a rule, to follow the plan employed by Sédillot (Figs. 735, 736, 737), and after puncturing the palate with a sharp

Fig. 735.

Fig. 736.

Fig. 737.

Sédillot's Operation for Staphyloorrhaphy.

knife, to introduce a narrow blunt-pointed knife, and to make a slit of sufficient length completely to remove all tension. An incision of equal length must be made in the opposite half of the palate, and the sutures may then be tightened. The lateral incisions always heal without difficulty, even if they gape widely at the time of the operation. If necessary, tension may be further relieved by snipping the anterior and posterior pillars of the fauces, after making them prominent by pulling on the palate. Fergusson recommended the division of the muscles from behind without perforating the palate. This is more difficult of performance, and gives less perfect relief of tension; in fact it was intended rather to give rest by paralysing the muscles than to relieve the strain on the stitches. He considered the levator palati and the palato-pharyngeus to be the two muscles exerting the most disturbing influence on the wound. The former he divided by passing a lancet-ended knife bent nearly at a right angle with its handle, through the fissure behind the velum, midway between its attachment to the hard palate and the free margin, and about halfway between the velum and the end of the Eustachian tube, and cutting deeply in that situation. The posterior pillar of the fauces was divided simply by making it tense by pulling on the soft palate and then snipping it

through with scissors. Fergusson divided these muscles as a preliminary step before paring the edges in all cases.

The chances of success depend very much upon the absence of tension. The stitches should simply hold the parts in contact, not drag them together. It is safer, therefore, to adopt Sédillot's plan as being more efficient as well as easier of performance.

**Operation on Hard Palate.**—It was formerly advised by some Surgeons, not to undertake the closure of the hard and soft palate at the same time, but it is now generally recognized that nothing is gained by dividing the operation into two parts.

If the arch of the palate be very high, there may be sufficient tissue to meet in the middle line when separated from the bone and allowed to hang down; it is better, however, not to trust to this, but to make an incision on each side. The operation is performed in the following way in a case of complete cleft of the hard palate :—An incision is made from near the canine tooth parallel to the alveolar margin and about a third of inch, or less, internal to it, reaching backwards to a little beyond the last molar. When the cleft is narrow or the arch high, a smaller incision than this will suffice; it may be lengthened afterwards if necessary to relieve tension. A second incision is then made along the edge of the cleft at the junction of the nasal and palatal mucous membranes. This incision must be carried backwards into the soft palate, from which a strip of mucous membrane must be removed, as in the operation for closure of clefts implicating that part only. The soft structures covering the hard palate are next raised from the bones with a curved periosteal elevator, shaped somewhat like an aneurism needle. In fact, if the proper instrument be not at hand, a strong aneurism needle will answer the purpose admirably. The periosteum should be raised with the flap as completely as possible. Langenbeck pointed out that, if this be done, not only are the flaps thicker and stronger, but they may eventually throw out bone, and thus more efficiently close the gap in the hard palate. In raising the flaps, it will be found most convenient to introduce the elevator into the lateral incision and work inwards towards the cleft. Care must be taken to avoid those points anteriorly and, if possible posteriorly, where the blood-vessels and nerves enter. Another point of equal importance, as pointed out by Thomas Smith, is to separate the attachment of the soft palate to the hard with a sharp instrument. This is best done with curved scissors one blade of which is introduced between the soft structures of the hard palate and the bone, and the other blade through the cleft above the soft palate. If an attempt be made to tear this through with the elevator, the parts will be so bruised that union by first intention will not take place even if sloughing be avoided. When these structures have been well loosened on each side, the covering of the palate will be found to hang down as a curtain from the vault of the mouth—the two parts coming into apposition along the mesial line, or possibly overlapping. The edges are then brought into apposition by means of wire sutures introduced as before described and without any dragging. On this point great care is necessary. In cases in which the flaps do not meet readily, one or more deep sutures of thicker wire may be inserted further from the edges, so as to relieve the strain on the finer stitches; or, if necessary, the lateral incisions may be continued back some way into the soft palate. Care must be taken also that the edges of the flap are not inverted so that

the mucous surfaces are in contact. To prevent this it may be necessary to draw them down with a sharp hook while the sutures are being tightened. The hæmorrhage during the operation is usually rather free, but may be arrested by a few minutes' pressure on the bleeding point with a piece of dry sponge.

Fergusson suggested a modification of the operation, in which an incision was made on each side of the fissure, and the bone divided longitudinally with a chisel, the two edges being then forced into contact. Although in his own hands some satisfactory results were obtained by this method, further experience has led to the abandonment of this operation as being in no way superior to that already described, and being somewhat liable to be followed by necrosis of the divided bone.

When the cleft is wide, and, as usually happens, the septum nasi is adherent to one edge, T. Smith recommends that the incision instead of being made at the junction of the nasal and palatal mucous membranes should be carried some distance up the septum, from which the mucous membrane can be detached with a sharply curved raspatory.

Davies-Colley has devised a flap method which he recommends as being useful when the operation for cleft of the hard palate is undertaken in infants, and also if the ordinary method has failed, or if the cleft is too wide to allow its employment. In the first stage a long flap of the muco-periosteum is raised from the wider side of the palate or that to which the septum nasi is attached. The anterior extremity of the flap reaches forwards nearly to the incisor teeth; the outer border runs backwards close to the alveolus, and the inner border an eighth of an inch from the margin of the cleft to a point just behind the posterior border of the hard palate. The flap is turned backwards with a knife or raspatory. Secondly, an incision is made on the other side of the palate parallel to and at least a sixth of an inch external to the cleft. In front this incision is turned into the cleft at its anterior extremity and behind at the edge of the hard palate. With a raspatory this narrow flap of muco-periosteum is raised as far as the edge of the cleft. Thirdly, the flap last mentioned is turned inwards and its edge fixed by two catgut sutures to the narrow strip of mucous membrane which remains on the other side of the cleft. Lastly, the apex of the long triangular flap is drawn across the cleft and the anterior part of its inner margin is attached with two or three silver sutures to the outer edge of the raw surface on the opposite side of the palate. The soft palate is repaired subsequently. Some modifications of the operation as above described have been introduced by Davies-Colley, but the principle remains the same, viz., to close the cleft by carrying a flap of muco-periosteum across it from one side to the other.

**After-Treatment.**—After the operation the patient must be put to bed, and every care taken to avoid any movement of the palate. He should be restricted to fluid but nourishing food for a few days, and should be directed to swallow this with as little effort as possible, and indeed should not be allowed anything solid until complete union has taken place. Speaking must be strictly forbidden until union is complete. *The stitches should not be taken out for at least three weeks or a month.* If there is any tension they will probably cut their way out; if there is none, being of silver wire, they excite no irritation, and, moreover, they serve the important purpose of supporting the scar in the middle line while the lateral wounds are healing. It is a good

rule not to even look into the patient's mouth for the first week after the operation. Should there be any aperture left in the palate, where union has not taken place, this may be closed by touching it with a point of nitrate of silver, or the thermo-cautery.

Secondary hæmorrhage of a somewhat serious character has been known to occur after this operation. In one case of this kind, Howard Marsh successfully arrested the bleeding by plugging the posterior palatine canal with a piece of wood.

The voice in these cases does not usually recover its natural tone, although in some cases it may. The nasal or "Punch-like" voice that is often left after operations, appears to arise from two causes. The first is the mere habit of faulty articulation, and this can be corrected by careful instruction in elocution. The second, which is much more difficult to deal with, arises from a mechanical condition, and is dependent on the contraction upwards of the palate along the line of the cicatrix, so that the velum becomes unable to shut off the posterior nares from the pharynx.

Success will very much depend on the proper selection of cases. Fergusson considered that about one-half of the fissures of the hard palate admit of operation. If the cleft be very wide, a well-constructed obturator will probably give more relief to the patient than any operative procedure. In fact, at the present time Dental Surgeons have brought the obturators for cleft palate to such perfection that it is a question whether any adult who is in a position to pay the necessarily heavy cost of such an instrument, should be advised to submit to operative interference.

**Perforation of the Hard Palate.**—Perforations of the hard palate, consequent on necrosis of the bones, the result of syphilis or injury, are not amenable to surgical treatment. In such cases, a well fitting obturator will most effectually remedy the inconvenience.

## CHAPTER LVII.

## DISEASES OF THE MOUTH AND THROAT.

## DISEASES OF THE TONGUE.

**Tongue-Tie.**—Infants and even adults are said to be *longue-tied*, when the *frænum linguae* is shorter than usual, causing the end of the tongue to be slightly bifid, depressed, and fixed, so that it cannot be protruded beyond the incisors. If this malformation be considerable, suckling and distinct articulation may be interfered with; and then division of the fold becomes necessary, which may readily be done by snipping it across with a pair of round-ended scissors; the risk of wounding the ranine arteries being avoided by keeping the point of the scissors downwards towards the floor of the mouth.

**Hypertrophy and Prolapsus of the Tongue or Macro-glossia** is occasionally met with, either as a congenital or an acquired condition. Of 113

cases collected by A. E. Barker, in only 39 was it apparently acquired, and in most of these it appeared at a very early age. In this condition, the tongue lolls out of the mouth with constant dribbling of saliva, is greatly swollen, of a purplish colour, but somewhat dry. If the swelling have existed for a long time, it may give rise to deformity of the teeth, and of the alveolus of the lower jaw, which is pushed forwards. The protruded tongue is liable to attacks of subacute inflammation, which lead to its still further increasing in size. The *Pathology* of this condition was first clearly pointed out by Virchow. There is a great overgrowth of the interstitial connective tissue of the tongue, and in this tissue are found dilated lymphatic vessels of considerable size, and spaces filled with lymphoid cells. It presents, therefore, a close analogy to elephantiasis. The dilated

Fig. 738.—Macro-glossia.

condition of the lymphatics is regarded as the primary change, and thus the disease is often spoken of as "lymphangioma of the tongue." This view of its pathology is supported by the occasional association of macro-glossia with cystic hygroma of the neck. In the *Treatment* of this disease pressure has been attempted by strapping the protruding part, but without benefit. Excision of a portion of the tongue with the knife or scissors is the only efficient remedy. In some cases the removal of a V-shaped piece will give the best result. This operation was successfully performed by C. Heath in the case from which the accompanying drawing was taken (Fig. 738).

**Acute Inflammation of the Tongue or Glossitis** is not a common affection. The most frequent form is that which arises from immoderate and injudicious administration of mercury. In this the tongue becomes greatly swollen; it may hang from the mouth, with profuse salivation and inability to swallow or speak. The sides are marked by deep impressions of the teeth, in which after a time foul ulcers may form. Acute glossitis with great swelling of the organ occasionally occurs after fevers, and more rarely without any apparent exciting cause, when it is thought by some to be catarrhal, and to result from exposure to cold. In this form there is acute pain, with considerable febrile disturbance. The tongue swells rapidly, so that in a few hours it may reach such a size as to threaten suffocation. The dyspnoea may be due to the obstruction caused by the swollen tongue, or to extension of the oedema to the arytæno-epiglottidean folds. The inflammation may end in resolution or lead rapidly to the formation of pus. The *Treatment* of glossitis varies with the cause and the degree of swelling. If of mercurial origin, the removal of the cause, and the administration of saline purgatives and a chlorate of potash gargle, will usually arrest the progress of the inflammation. If the swelling be very great, more especially in the idiopathic form of the disease, the only efficient treatment consists in making a free incision along the dorsum of the tongue on each side of the raphé, which gives free and immediate relief by the escape of blood and infiltrated fluids. I have seen a patient, who was nearly suffocated by the size of his tongue, relieved at once by such incisions, and nearly well in the course of a few hours.

**Chronic Abscess of the Tongue**, though rare, occasionally occurs. I have seen several instances of it. The abscess forms a small deeply seated elastic but firm tumour, which sometimes feels slightly movable. There is no discoloration or other change in the mucous membrane or epithelium of the tongue. The walls of these abscesses are very thick and dense; hence they may easily be mistaken for solid tumours. The abscess is always very chronic, hence the liability to error in diagnosis is increased. It is commonly seated at the edge and towards the anterior part, but it may occupy the middle of the tongue. It is probable that in some cases at least the abscess is tuberculous. A boy was once brought to me with an elastic tumour of slow growth, and of about the size of a small plum, situated deeply in the centre of the tongue: on puncturing it, about half an ounce of healthy pus was let out, after which the cavity speedily closed. The *Treatment* consists in making a longitudinal incision into the abscess. In all cases of doubt in diagnosis, this should be done before any other operation is undertaken.

**Chronic Superficial Glossitis—Psoriasis or Ichthyosis of the Tongue—Leucoplakia.**—Under these names a diseased condition of the tongue has been described which is far from uncommon in this country and in France, but is said to be much less frequent in Germany. The disease consists essentially of a chronic inflammation of the mucous membrane of the tongue. In the earliest stages there is hyperæmia of the papillæ, with some swelling. If seen at this period the mucous membrane presents red patches, usually limited to the dorsum of the tongue, but occasionally appearing simultaneously on the cheeks, and passing through the same stages there as on the tongue. It can be recognized clearly only after the mucous membrane has been thoroughly dried with a towel. This must never be omitted, for unless the surface is well dried it is impossible to observe accurately the condition of the

papillæ and epithelium. As the disease advances, an excessive growth of epithelium takes place over the swollen papillæ. The superficial layers of cells become horny and opaque, the neighbouring spots coalesce, and thus white patches of considerable size form on the mucous membrane, from which appearance the name of *leucoplakia* was suggested by Schwimmer. As the

Fig. 739.—Chronic Superficial Glossitis, showing the alteration in the size and shape of the papillæ, the flattening of the surface with heaped-up epithelium, and the small-cell infiltration of the subepithelial tissue.

disease advances, the papillæ and the superficial parts of the corium present the ordinary signs of chronic inflammation, the vessels are dilated and the surrounding tissues infiltrated with small round cells (Fig. 739). The next stage in the process is characterized by atrophy of the papillæ. The opaque patches then become perfectly smooth. In this stage the surface of the tongue is some-

Fig. 740.—A portion of the same tongue, nearer the tip, showing the development of squamous carcinoma. The epithelium is invading the deeper tissues in processes or columns.

what indurated, having upon its surface smooth patches of a dead-white colour irregular in shape, and varying in size from that of a split pea to an inch in diameter. This condition closely resembles the appearance of psoriasis of the palms of the hands, and from this resemblance has been termed *psoriasis of the tongue*. When the disease has reached this stage, cracks, fissures, or superficial ulcers may form in the opaque patches. The ulceration takes place mostly by

an exaggeration of the process already described. At some point, possibly as the result of injury, the small round cells become increased in number by migration from the vessels, the epithelium becomes loosened and is rubbed off by the movements of the tongue, and a raw surface is thus left, from which ulceration may gradually extend. A more serious result is the supervention of carcinoma, which is a common termination of the disease. Microscopic examination of a tongue in which this is taking place may show all the stages of the disease in one section: at the margin of the patch will be enlarged papillæ covered with a thick layer of epithelium; nearer the centre the papillæ have disappeared, the corium being covered by a thick layer of epithelium, the greater part of which is composed of flattened horny scales; near the centre the cells of the rete mucosum are seen to be growing actively and forming columns which force their way into the spaces of the submucous tissue, and further on, amongst the muscular fibres. These columns are surrounded by the zone of small-cell infiltration always seen at the edge of a growing cancer (Fig. 740).

Various modifications of the process above described may be met with: thus, in some cases the growth of epithelium is less abundant, so that instead of the formation of white patches, the surface of the tongue becomes smooth, red, and shining, giving rise to the condition known as the "*glazed red tongue*." In other cases the growth of epithelium may be very excessive, forming thick scaly masses on the surface, from which this variety has been termed *ichthyosis of the tongue*. These forms, though differing in detail, are essentially the same pathologically.

All forms of the disease are accompanied by some discomfort, though usually no actual pain. The tongue is tender, so that the patient cannot take mustard, or spices, or drink hot fluids. The speech may become slightly lisping or indistinct. The duration is very indefinite. In some cases it progresses slowly for many years, at last becoming stationary and causing the patient but little inconvenience. In others ulceration may take place after a few years. The invasion of epithelioma may occur after ten or even twenty years, and in many cases the patient escapes altogether. The causes of the disease are not always to be clearly ascertained. The earlier writers believed it to be invariably an effect of syphilis, but there seems no doubt that this view cannot be maintained. A. E. Barker has paid great attention to this subject, and to his valuable article on the "Diseases of the Tongue" in Holmes's System of Surgery I would refer the reader for more detailed information than can be given here. He has collected from various sources 110 cases of chronic superficial glossitis. Of these, 101 occurred in males and 9 in females. Of the 101 cases in males, 55 affected the tongue only; 33 the tongue and cheeks; 12 the lips and cheek; 1 the hard palate, and in 4 the seat was not mentioned. Of the 110 patients, 33 had certainly had syphilis, and 19 certainly had not; in the remaining cases it was doubtful. The fact that nearly one-third of the patients had suffered from syphilis would suggest that though not the sole cause, it may form an important element in the production of the disease. The disease was associated with psoriasis or eczema in 6 of Barker's cases, and with squamous syphilides in 2. It has also been seen associated with ichthyosis of the skin. In 75 cases evidence was given as to smoking. Only 4 patients did not smoke, while 46 are said to have indulged in the habit to excess. Smoking may, therefore, be fairly considered

to have some influence on the occurrence of the disease. Chronic dyspepsia and habitual spirit-drinking are also supposed to act as predisposing causes. That dyspepsia should take a part in its causation is not surprising, as it is well known to every smoker that the tongue becomes sore more readily when "the stomach is out of order."

The *Prognosis* is always bad as to cure. Of the 110 cases recorded by Barker the disease ended in epithelioma in 43. The average duration of the disease before this took place was 14 years. Such cases must be carefully watched for the earlier signs of the invasion of epithelioma, as by early removal the disease might possibly be cured.

The *Treatment* is not usually very satisfactory. If there is any evidence of syphilis, the patient must be treated for that disease. Smoking, the use of hot spirits and hot condiments must be prohibited. In some cases, where there is a tendency to scaliness, arsenic is of use. Locally, before ulceration has taken place, Barker recommends frequent washing of the mouth with a solution of bicarbonate of soda (gr. xx. to 3j.). In a more advanced stage Joseph states that he has found daily rubbing of the surface with a concentrated solution of lactic acid of great use. A weak solution of chromic acid is a useful application. Butlin recommends a solution of one or two grains to the ounce for use as a mouthwash, or a stronger solution (5 to 10 grs. to ounce) to be painted on the patches and ulcers. When the surface tends to become warty, Ingals of Chicago recommends the application of the galvanic caustery. Strong chemical caustics usually aggravate the disease. If simple ulceration has taken place, a solution of bichloride of mercury (gr. ij. to 3j.) applied to the dried tongue with a camel's-hair pencil twice a day will often be found extremely useful. Its chief value is as an antiseptic, as the surface of the ulcer is apt to become very foul.

**Other Superficial Affections of the Tongue.**—Various other superficial affections of the tongue are commonly met with. The small tender whitish patches or *aphthæ* and aphthous ulcers, met with so commonly as the result of dyspepsia and thrush, belong rather to medicine than to surgery, and need not be described here. A peculiar wandering rash which has been described under the name of "**lichenoid of the tongue**" by Gübler, has been called attention to by Barker in this country, who suggested for it the name of "**annulus migrans**." It is characterized by the appearance on the tongue of small circlets or crescentic bands of light-coloured rash, which rapidly spread centrifugally over the tongue. It causes some salivation and itching. It is not apparently due to the presence of a parasite. The disease runs a chronic course, and no treatment seems to have any effect upon it.

**Simple Ulceration** is not uncommonly met with as a result of dyspepsia, but the most important form is that which occurs upon the side of the tongue usually opposite the molar teeth, and is dependent on the irritation of sharp projecting stumps. These ulcers cause considerable pain in eating and speaking; they are red on the surface, with slightly raised but not everted edges, and the base may be slightly indurated from inflammatory thickening. As a rule they readily heal if the offending tooth is filed, stopped, or removed. They form the most common starting point of epithelioma, and in any doubtful case in which simple treatment fails to effect a cure it is wiser to excise the ulcer than to wait until certain signs of malignancy have shown themselves.

**Tuberculous Ulcer of the Tongue.**—Tuberculous ulceration of the

tongue was first noticed by Portal, and has since been accurately described by Raynaud and Nedopil and others. It is not common, but occurs with sufficient frequency to justify a description here. It commences as a minute white spot, over which the mucous membrane gives way and a small quantity of puriform matter escapes, leaving an ulcer which gradually extends. Similar spots appear round about, and the sores thus formed may coalesce, forming a larger irregular ulcer, with a yellowish, uneven surface, and slightly indurated base. The ulceration usually commences at the tip of the tongue and thence spreads along the borders and on to the under surface, but to a less extent on to the dorsum. Deep fissures are sometimes present. The ulcers are extremely painful. They may occur in individuals who exhibit no signs of tubercle elsewhere, but far more commonly are associated with advanced pulmonary or laryngeal phthisis. In such cases it is probable that the disease of the tongue results from the direct infection of an abrasion on its surface by the tuberculous sputum. Microscopic examination of the ulcer shows that it has the usual structure of tuberculous ulcers elsewhere (Fig. 741). The presence

Fig. 741.—Tuberculous Ulcer of Tongue. Tubercles among muscle fibres in base of Ulcer. (96 diam.)

of the tubercle bacillus has been demonstrated in several cases by Watson Cheyne, Hale White, Percy Kidd, and others ; but the bacilli are often few in number and difficult to detect. The prognosis of these cases is necessarily grave.

The *Treatment* of tuberculous ulceration of the tongue depends upon the extent of the ulceration and the general condition of the patient. There can be no doubt that if there are no signs of tuberculous disease elsewhere, or even if such disease be present but not advanced, the ulcerated part of the tongue should, as recommended by Butlin, be freely excised. If the ulcer appear to be primary the reason for this treatment is obvious, and even if secondary, much local relief may be afforded. In a case under the care of Barker the anterior half of the tongue was excised successfully for extensive tuberculous disease, there being only evidence of slight consolidation at the apex of the right lung, and similar treatment was adopted in the case from which Fig. 741 was prepared. In cases too extensive for removal or associated with advanced tuberculous disease elsewhere, relief may sometimes be given by scraping the ulcer with a sharp spoon and applying iodoform. Any teeth which irritate the sore should be extracted. If the soreness be so

great that the patient cannot take food, the surface must be painted before each meal with a 20 per cent. solution of cocaine, or the ulcer may be dusted several times a day with the following powder recommended by Butlin: finely powdered iodoform, one grain; morphia, one-sixth to one-half of a grain; borax, three grains.

**SYPHILITIC AFFECTIONS OF THE TONGUE.**—The following are the chief syphilitic affections met with in the tongue: *Primary sores* (Vol. I., p. 1128)—these are very rare and present nothing peculiar; in the early secondary stage *papules* are not uncommon; later on *small superficial ulcers* may occur; and later still *fissures* with thickened epithelium around them may be met with; *mucous tubercles* are more rare. In the tertiary stage the patient may suffer from fissures and superficial ulcers similar to those already mentioned, from *chronic superficial glossitis* with leucoplakia, from *diffuse induration* of the organ, and from *gummata*. These have already been described in the chapter on Syphilis (Vol. I., p. 1152), and the gummata alone need be further referred to here.

**Syphilitic Gummata** are not uncommon in the tongue. A gumma forms an irregular indurated mass imperfectly circumscribed, and of rounded shape situated in the substance of the organ. It may occur at any part of the tongue, but it is perhaps most frequently met with near the dorsum, sometimes in the middle line, a situation in which epithelioma is very rarely found. It commences distinctly beneath the surface, the mucous membrane covering it being at first unaltered. As it approaches the surface the mucous membrane becomes adherent to it, and dusky red in colour. Under proper treatment the growth may disappear, but frequently it softens; the mucous membrane over it then gives way and a ragged cavity is exposed, in which the remains of the gumma are seen as an adherent slough, resembling wet wash-leather in appearance. If the gumma is watched from the beginning, and presents the typical course and appearances above described, there can be little difficulty in its diagnosis. If, however, it be seen for the first time after the characteristic slough has separated, the foul cavity that is left may closely resemble an epithelioma. If there is any doubt a piece of the floor or edge of the ulcer may be removed and examined microscopically, when the true nature of the disease can usually be determined. The *Treatment* consists in the administration of large doses of iodide of potassium, and if that produces no effect mercury may be given. If the gumma softens and ulcerates, the same constitutional treatment must be continued and the sore dressed with iodoform.

**TUMOURS OF THE TONGUE.—Papillomata.**—Small warts are sometimes formed on the tongue and are easily removed with scissors. Warty growths of larger size are occasionally met with, composed of large papillæ covering the end or side of the tongue. These must always be regarded with suspicion, for epithelioma may assume this form, or if the growth is at first simple it tends soon to become malignant.

Such patches should therefore be excised.

**Adenomata or Glandular Tumours** of the tongue are rare, and for our knowledge of their characters we are chiefly indebted to Butlin and Bland Sutton. Of eight recorded cases Butlin finds that, with the exception of one which affected the under surface of the tongue, all were situated immediately in front of the epiglottis, in or near the middle line. All the cases were females, the ages varying from extreme infancy to thirty-two years. The

growth forms a prominent tumour “not ulcerated, covered with natural mucous membrane, permitting very free movement of the tongue, and causing comparatively little inconvenience.” The structure of these tumours is that of a cystic tubular adenoma, and the remarkable resemblance to thyroid gland tissue has suggested to Bernays and Bland Sutton that these growths are in reality accessory thyroids developed around the upper end of the thyreo-glossal duct (p. 610), rather than true adenomata of the glands of the tongue. In a tumour of this kind removed by J. W. Bond the structure was exactly that of the normal thyroid gland. The *Treatment* consists in the removal of the tumour either by excision or with the galvano-cautery. Partial removal has been followed by somewhat rapid increase and subsequent shrinking of the remainder.

**Nævus and Aneurism by Anastomosis** are but rarely seen in the tongue, and when met with would require to be treated on the same principles that guide us in the management of the disease elsewhere. A very remarkable instance of an erectile tumour of nœvoid character affecting the tongue came under my care, in which the whole of the free extremity of the organ was implicated in the morbid growth, presenting a club-shaped end, which protruded between the teeth and lips of the patient, a girl about three years old. In this case, which had previously been treated by the introduction of setons, I removed all the redundant tissues by means of the *écraseur*, and so reduced the tongue to its normal size.

A form of very vascular local hypertrophy may occur in the tongue at a later period of life, which may perhaps be best classed with these growths. The case of which Fig. 742 is a good representation was of this kind. It occurred in a lady about 50 years of age. The disease was confined to the anterior half of the tongue, which I successfully removed with the *écraseur*.

Fig. 742.—Vascular Hypertrophy of Tongue.

**Cystic Tumours of the Tongue.**—Two forms of cyst have been met with in the tongue: *hydatids*, which are extremely rare, and *mucous cysts*.

*Mucous Cysts* seldom reach any large size. They lie immediately beneath the mucous membrane, usually on the dorsum or at one side. They may be so tense as to resemble solid growths. Chronic abscesses which are occasionally found in the tongue cannot with certainty be distinguished from mucous cysts till the fluid has been let out by a puncture. The *treatment* of a mucous cyst consists in dissecting it out if possible. If this cannot be done it will usually suffice to puncture the cyst and apply a strong solution of chloride of zinc to the interior.

**Fibrous and Fatty Tumours** have been met with in the tongue, but are extremely rare. Should such a growth be met with it may readily be removed by drawing the tongue forwards by means of forceps or piece of whipcord passed through its tip, and then dissecting out the tumour. Any bleeding that occurs may be arrested by ligature, or by passing a suture by means of a curved needle across the gap in the course of the divided vessels, and thus closing the aperture at the same time that the vessels are compressed.

**CARCINOMA OF THE TONGUE.**—**Squamous carcinoma** is the form of cancer met with in the tongue. **Scirrhus** was formerly described as being common, and we are not now in a position to deny that it may occur, if the growth commences in the floor of the mouth, and arises possibly from the sublingual gland. It is however so rare that it need not be further considered in describing cancer of the tongue.

Cancer almost always commences on the edge, usually at the middle third, extending back to the anterior pillar of the fauces, but it may occur at the tip of the tongue, in the floor of the mouth, or, in rare cases, on the dorsum. It most usually occurs in persons between the ages of 40 and 60. It is more frequent in men than in women; according to Barker in the proportion of 247 to 46. It may develop without any evident cause in persons who are otherwise perfectly healthy, whose teeth are sound, and in whom there has been no pre-existing disease of the tongue; but it may also occur in consequence of local irritation, as from the abrasion produced by a broken tooth. In other cases, as before pointed out, it is preceded for some years by super-

ficial glossitis or other chronic disease of the mucous membrane (p. 679). It may arise in an old syphilitic crack or unhealed fissure. If it appear in an otherwise healthy tongue, as a tubercle or warty growth, this is usually flat, indurated, and of a purplish-red colour, gradually running into ulceration; if as a fissure, this from the commencement has an indurated base, a foul surface, and a callous edge. As the ulceration extends, a chasm with everted edges and ragged sides, and a sloughy surface that cannot be cleansed, gradually forms over a widely indurated base (Fig. 743); there is great fetor of the breath, with profuse salivation; and, as the disease progresses, implication of the mucous membrane

Fig. 743.—Carcinoma of Tongue.

and of the structures of the floor of the mouth, and of the glands under the jaw and in the neck, takes place. Sometimes the whole organ is infiltrated by the growth, becoming hard, nodulated, ulcerated, and in some parts covered by thin red cicatrices, and in others by foul putty-like accumulations of epithelium. The pain is very severe in most cases; every movement of the organ in articulation, mastication, or deglutition causing great suffering. The friction or compression by the teeth, and the profuse salivation, all aggravate the patient's distress. The pain is not confined to the tongue, but runs through all the branches of the fifth nerve over the side and crown of the head to the face and the ear. The lymphatic glands under the jaw usually become involved at an early period; though the disease may exist for a year or more without their being implicated.

The fatal termination is brought about by four conditions, either singly or in conjunction: 1. The pain not only wears out the patient by depriving him of rest, but being greatly aggravated by mastication and deglutition, causes him to avoid these acts, and hence leads to a process of gradual starvation, either by his abstaining from food altogether, or taking a liquid and innutritious diet, because it is more easily swallowed than solid and more substantial

meat. 2. The profuse salivation still further exhausts the patient. 3. The swallowing and absorption of the foul discharges lead to chronic septic poisoning: and 4. The occurrence of hæmorrhage, when the disease has eroded so deeply as to open up one of the larger branches or trunk of the lingual artery, may, by repeated recurrence or by sudden gush, destroy life.

If cancer of the tongue be allowed to run its natural course uninfluenced by operation, nothing can exceed the misery of the patient's death. When the patient dies by recurrence of the disease after removal, he has probably obtained some months of immunity from suffering. The fatal termination then usually takes place from recurrence in the glands of the neck, secondary growths in the viscera being very rare, as in squamous carcinoma of other parts. The enlarged cervical glands gradually reach the skin, soften, and break down, leaving foul cavities, and the patient gradually dies exhausted by pain, and poisoned by the absorption of the decomposing discharges. Sometimes the enlarged glands push into the pharynx, obstructing both deglutition and respiration. Still, as a rule, if recurrence in the mouth can be avoided, death is far easier than when due to the primary disease.

**Diagnosis.**—The diagnosis of carcinoma of the tongue in its advanced stages is usually easy enough; the deep foul ulcer, the pain, the fixity of the organ and the enlargement of the lymphatic glands make the nature of the disease unmistakable. At this period, however, little can be done to cure the patient or even to relieve him. To be of any service to the patient, the diagnosis must be made early, while the disease is still localized, and an operation can be undertaken with some prospect of giving lasting or permanent relief.

The diagnosis between the *syphilitic gumma* and *cancer* is most important; here the duration of the disease and the co-existence of constitutional syphilis must be taken into account. It is also of much moment to attend to the mode of commencement and situation of the tumour. The syphilitic gumma commences in the muscular substance of the tongue, and implicates the mucous membrane secondarily; epithelioma is superficial, commencing in the mucous membrane, and secondarily implicating the deeper structures. It must, however, be remembered that a tongue which has long been the seat of those morbid changes in the way of thickening of its epithelium and ulceration of its mucous membrane, which are common sequelæ of syphilis, may at length become affected by carcinoma.

The superficial *syphilitic ulcerations* are usually readily distinguished from carcinoma by their tendency to spread superficially in an irregular manner without extending deeply, by the absence of well defined induration in the base, and often by their multiplicity. The resemblance may, however, be close when a single syphilitic ulcer on the border of the tongue becomes somewhat indurated by inflammatory thickening. The ulcer left by the breaking down of a gumma may somewhat closely resemble a carcinoma, if it be seen for the first time after the slough has separated. This is especially true if the ulcer, as sometimes happens, is situated on the border of the tongue. The induration is, however, less defined; the edges are often rather undermined than everted, and there is an absence of fixation of the affected part of the tongue which is so common in carcinoma.

In the case of a doubtful ulcer the Surgeon must not wait till the nature of the sore becomes evident by enlargement of the glands and extensive implica-

tion of surrounding parts, nor must he waste time in trying the effect of treatment by mercury or iodide of potassium. By so doing he may rob his patient of his only chance of cure. A portion of the ulcer should at once be removed by means of a sharp spoon or a pair of scissors, and submitted to microscopic examination. This may be done painlessly by applying a 20 per cent. solution of cocaine for a few minutes. If there should still be any doubt, the ulcer should be cut out, for the removal of a small and superficial portion of the tongue is a most simple operation, and practically free from danger.

**Treatment.**—In the treatment of cancer of the tongue, medicines are utterly useless, except as palliatives of pain. No measures hold out any chance of cure, or even of prolongation of life, except the complete removal of the diseased structures, and this it is not always easy to accomplish, as the cancerous infiltration often extends much farther than at first appears, passing deeply between the muscular fasciculi and planes into the root of the tongue. In these deep cancerous affections there is usually great enlargement of the glands under the jaw, with infiltration of the floor of the mouth and neighbouring soft parts to such an extent as to render it impossible to excise or in any other way remove the whole of the disease.

Two operations are occasionally practised, having for their object to palliate the suffering or to retard the progress of the disease in advanced cases : viz., Division of the Lingual Nerve, and Ligature of the Lingual Artery.

**Division of the Lingual Nerve.**—Section of the gustatory branch of the fifth nerve was first proposed by Hilton, with the view of relieving the pain of the cancer, retarding its progress, lessening the profuse salivation, and enabling the Surgeon to apply ligatures painlessly for the removal of the growth. This operation undoubtedly accomplished the objects for which Hilton originally practised it ; more especially so far as relief of pain and diminution of salivation are concerned ; and it may be considered one of the most efficient modes of relief in cases in which removal of the disease is not practicable.

Division of the gustatory nerve may be done in two ways. In both operations the nerve is divided in that part of its course which extends from its emergence between the internal pterygoid muscle and the jaw to the point where it enters the tongue. Opposite to the second molar tooth, the nerve lies under the mucous membrane of the floor of the mouth. There it can easily be reached by the division of the mucous membrane covering it, when it will be found close behind the sublingual gland. It may be raised by a blunt hook, seen, and divided. The advantage of this method is, that the nerve can be seen and its division rendered certain. The disadvantages are, that the guides to the spot are not quite certain ; that the cut is apt to be obscured by hæmorrhage ; and that, when the disease has extended to the floor of the mouth, the operation is inapplicable. Moore consequently recommended section of the nerve further back. The guide to it in this situation is the last molar tooth ; and a line drawn from the middle of the crown of the tooth to the angle of the jaw will cross the nerve in the exact place where it should be cut. The nerve lies about half an inch from the tooth, between it and the anterior pillar of the fauces, parallel to but behind and below the bulging alveolar ridge, which can be felt in the lower jaw ascending towards the thin

coronoid process. By entering the point of a knife, therefore, into the mucous membrane of the mouth, three-quarters of an inch behind and below the last molar tooth, and cutting down to the bone, the nerve must be divided. Moore used a curved bistoury as the projection of the alveolar ridge would protect the nerve from a straight blade. If the floor of the mouth is too deeply invaded the nerve may be reached from the outside by enlarging the sigmoid notch (see p. 31). The good effect of the operation is instantaneous: pain ceases in the tongue, ear, face, and head, and the flow of saliva is diminished; and the relief is continuous, for it does not appear that the nerve re-unites.

**Ligature of the Lingual Artery** may be required to restrain profuse hæmorrhage from an ulcerated cancer of the tongue. This operation has been practised also with the view of starving the morbid growth and thus retarding its development. That it does so for a short period is undoubtedly the case,

Fig. 744.—Ligature of Lingual Artery.

but that it does so permanently is a fallacy. The operation is also sometimes done as a preliminary step in excision of the tongue.

The artery is reached with most certainty in the digastric triangle of the neck, where it lies beneath the hyo-glossus muscle. A curved incision carried from about one finger's breadth external to the symphysis menti downwards to the great cornu of the hyoid bone and prolonged upwards and backwards to near the angle of the jaw will expose the lower border of the submaxillary gland. In fat subjects, or when the parts are swollen, the incision must be of the full length above mentioned, but under ordinary circumstances it may be curtailed by about half an inch at each end. The first incision divides the skin, superficial fascia, and platysma, exposing the deep fascia covering the submaxillary gland. This fascia must now be opened, and in doing so care must be taken not to carry the incision too far back lest the facial vein be wounded. The lower edge of the submaxillary gland is raised and drawn upwards towards the jaw. The tendon of the digastric then comes into view, and a space is exposed bounded below and externally by the curved tendon of

the digastric, internally by the free edge of the mylo-hyoid, and above by the hypoglossal nerve, with the ranine vein parallel to and below it. The floor of the space is formed by the part of the hyo-glossus arising from the great cornu of the hyoid bone. The tendon of the digastric is drawn downwards with a blunt hook. The fibres of the hyo-glossus must now be picked up carefully in this space, and divided horizontally, when the lingual artery will come at once into view (Fig. 744). Care must be taken while exposing the artery not to cut too deeply, as it is separated from the mucous membrane of the pharynx merely by a few fibres of the middle constrictor. Sometimes the stylo-hyoid ligament comes into view; it may be recognised at once by its passing upwards and backwards, while the artery is directed upwards and forwards. Should it be seen it may be used as a guide to the artery which passes superficial to it. In rare cases the artery lies with the hypoglossal nerve superficial to the hyo-glossus, in which situation it must be sought if not found in its proper place.

**Operations on the Tongue.**—The operations practised for cancer of the tongue consist in removal of a portion of the organ only, or its complete extirpation according to the situation and extent of the disease. Unless the growth can be thoroughly extirpated, it is better not to attempt any operation,

Fig. 745.—Fergusson's Gag, modified by Mason.

for in no organ is there a greater tendency to recurrence of cancer than in the tongue.

When the disease extends to the floor of the mouth, implicates the arches of the palate, or has largely infiltrated the sub-maxillary lymphatic glands, the propriety of operating becomes very doubtful. Even under these circumstances, however, extensive operations have been performed with at least temporary benefit. In determining the question of operating, much will depend upon the condition of the patient.

If he be otherwise in good health,

though suffering greatly from the pain of the cancer, and if the secondary affection be limited to the glands below the jaw, which can be removed without difficulty, an operation may be undertaken. If he be greatly exhausted by pain and want of food, and more especially if the glands under the sterno-mastoid are enlarged, an operation would at the best give very temporary relief, and would be very likely to be directly fatal.

Before the operation the mouth should be cleaned by the removal of tartar from the teeth, and the free use of a tooth-brush and mouth-washes. The tongue must be thoroughly exposed and kept well under control during the performance. The first object is attained by means of an efficient gag. Fergusson's (Fig. 745) or Langenbeck's (Fig. 746) gag will be found very efficient. Fergusson's is very difficult to keep in position when the back teeth are wanting, as it tends to slip forwards. Langenbeck's gag may then be of service, but it also is uncertain if the front teeth are wanting. Efficient gagging is one of the most essential parts of all operations on the tongue, and the gag should always be entrusted to an assistant, whose sole duty shall be to see that it does not slip. The slipping of the gag and the sudden closure of the mouth at a critical point in the operation may

necessitate a sudden performance of laryngotomy, or may even cost the patient his life. If the patient be efficiently gagged the jet of blood from a divided lingual artery will usually be thrown out of the mouth, and cause but little trouble. If a gag be used which acts on one side only, the tongue must be fully exposed by a cheek-retractor applied on the opposite side. During the operation the tongue must be controlled by a strong whipcord ligature passed through it about an inch from its tip. If only a small portion of the anterior part is to be removed, a single thread will suffice. In removing half the tongue two ligatures must be passed, one on each side of the middle line, so as to control not only the part to be removed, but the remaining part also,

Fig. 740.—Langenbeck's Gag.

so that the stump may be drawn forwards at the end of the operation to arrest hæmorrhage. When a portion only of the tongue is to be removed this may be done by the scissors, knife, or *écraseur*.

For the purposes of operation the tongue may be divided into three regions : viz., the anterior third, the central lateral portion, and the posterior part.

**Excision of a small part of the Tongue** may readily and safely be done when the free anterior portion only is diseased, or when it is only superficially affected at its side or back part. The patient having been gagged, the tongue is secured by passing a thread through it. It is then drawn well forward while the lingual artery is compressed in the way recommended by C. Heath. To do this the forefinger is passed over the dorsum of the tongue till it touches the epiglottis ; it is then turned towards the side on which the artery is to be compressed, and hooked forcibly upwards against the jaw. The diseased portion of the tongue is then cut out with scissors. If the artery be well compressed the operation will be practically bloodless. On removing the pressure the larger vessels are seized in forcipressure forceps, and twisted or ligatured, and the oozing will soon cease on the application of sponge-pressure.

Strangulation of the diseased mass by the ligature is a mode of operating which is now completely abandoned.

**Excision of the Whole or of a Large Portion of the Tongue.**—This operation may be performed in four ways : 1. From the inside of the mouth, without any external incisions. 2. By the submental method, through the mylo-hyoid space. 3. By the buccal method, a free incision being made through the cheek ; and 4. By division of the lower lip and jaw.

1. The excision of the whole tongue **from within the mouth** was rarely performed until the fear of hæmorrhage during the operation was practically removed by the introduction of the *écraseur* by Chassaignac. At the present

time the means of gagging the mouth and of arresting the hæmorrhage during the operation being more perfect, the *écraseur* is rarely used, the tongue being much more frequently removed with scissors in the way first recommended by Whitehead.

**Excision by the *Écraseur*** has been carried out in various ways, but the following method, advocated by Marrant Baker, is the only one likely to be employed at the present day. The gag having been introduced, a stout thread is passed through each side of the tongue about one inch behind the tip. The Surgeon holding one thread and an assistant the other, the mucous membrane and part of the muscular substance of the tongue are divided exactly in the middle line with a probe-pointed bistoury. This incision extends well back beyond the level of the growth, and in front it completely divides the tip. If made accurately in the middle line this incision is almost bloodless. The separation of the two halves is completed with the forefingers. Next, drawing forward the diseased half of the tongue with the thread, the operator snips through with scissors its attachments to the lower jaw and also the mucous membrane along the floor of the mouth, keeping close to the jaw. With the finger the tongue can be separated freely from the floor of the mouth to a level at least an inch behind the growth where the tongue is transfixed with two

Fig. 747.—Wire *Écraseur* for Removal of Tongue.

blunt needles. The loop of the *écraseur* is now passed around the separated half of the tongue behind the needles. By gradually tightening the *écraseur* the division is completed, the tendency of the loop to slip forwards being prevented by the needles. The last strand of tissue left in the *écraseur* usually includes the lingual artery, and this, Baker suggests, should be ligatured. If necessary the other half of the tongue may now be removed in the same way.

In removing the tongue with the *écraseur* the wire instrument (Fig. 747) is far preferable to that which divides with a chain. The form of wire best suited to the instrument is strong piano-wire. It will be found better to attach one end only to the movable part of the instrument, the other being twisted round the handle, as in the figure. It then cuts by a slow sawing movement and divides the vessels more surely. Marrant Baker prefers an *écraseur* with a loop of thick whipcord. In any case the instrument should be worked very slowly.

In this as in all other methods of removing the tongue, it must be remembered that if the attachments of the *genio-hyoid* and *genio-hyo-glossus* muscles have been completely divided there is a tendency for the stump of the tongue to fall backwards into the pharynx, and thus, if it be of sufficient size, to cause asphyxia. This must be guarded against by passing a thread through it and drawing it forwards. If necessary the thread must be attached to the teeth or drawn forwards and fixed to the cheek by plaster.

Middeldorpf's galvanic cantery was much used a few years ago in operations

the tongue (Fig. 748). By working this slowly, and not heating the inum wire beyond a red heat, the tongue may be removed without the loss drop of blood. The galvanic cautery cuts more rapidly than the ordinary rument, and it was at first hoped that its use would considerably simplify operation. Experience has, however, shown that the charred surface left he passage of the hot wire, heals more slowly, with more discharge and gling than that left by the *écraseur*. Secondary hæmorrhage has, moreover, urred in a considerable number of cases after its use. It was urged as her advantage attending its employment, that a charred surface offers a tier to the absorption of septic matter, but the fallacy of this idea has been

Fig. 748.—Galvanic Écraseur.

onstrated by experimental investigations on animals. The instrument has ore been abandoned almost universally.

**Excision with Scissors.**—In 1877, W. Whitehead of Manchester success-removed the whole tongue through the mouth with scissors, and since the operation has been repeated in a large number of cases with excellent a. The operation is conducted as follows: The mouth is efficiently ed, and a stout ligature passed through the tip of the tongue. The ant in charge of this is directed to maintain throughout the operation a y traction upwards and forwards. The operator commences by dividing all attachments of the tongue to the jaw and the anterior pillars of the fauces. tongue can now be drawn freely out of the mouth, and the subsequent stages he operation are thus rendered much easier and safer. The base of the e is next cut across with scissors, until the entire tongue is separated in plane of the inferior border of the jaw as far back as the safety of the ettis will permit. Whitehead originally advised that this should be done series of successive short snips, but he now cuts more boldly until the ity of the main vessels is reached, only stopping if it is necessary to twist orting artery. The position of the lingual vessels being very constant, an ienced assistant can often pick them up with forcipressure forceps before are divided. If not, the divided artery will spurt out of the mouth and adily be secured. Before completing the removal of the tongue a single of silk is passed by a long needle through the remains of the glosso- ttidean fold of mucous membrane, as a means of drawing forwards the of the mouth should secondary hæmorrhage take place. This may be awn on the second day. The hæmorrhage in this method of operating h less than would be expected. Whitehead states that in two cases he ed the whole tongue without twisting a single vessel; this, however, is e exceptional. In most cases the linguals and a few smaller vessels require a. In 1891 Whitehead had removed the whole tongue with scissors cases with only 3 deaths, giving a mortality of 4·5 per cent.

If only half the tongue is affected it may be removed with scissors in the same way. The first step in the operation then consists in passing a ligature through each side and splitting it in the middle line.

In excising the tongue with scissors Christopher Heath uses a large pair of angular forcipressure forceps, with which he seizes the lingual arteries and the surrounding tissue before dividing them. A strong ligature is then passed over the forceps and the included tissue tied *en masse*. This modification may be useful, as Heath suggests, when the Surgeon has not the help of an experienced assistant.

Treves especially advocates the ligature of the lingual arteries in the neck as a preliminary step in the operation of excision of the tongue with scissors, and records 34 cases with only 3 deaths, one of which occurred suddenly from heart disease. The very little trouble which is usually occasioned by the hæmorrhage when Whitehead's method is adopted, scarcely seems to necessitate this considerable addition to the magnitude of the operation.

When the floor of the mouth is implicated, no operation through the mouth should be attempted; as it is impossible by this means to extirpate the whole of the disease, and partial removal of it will be followed only by rapid recurrence and increased activity of development. Slight enlargement of the glands under the jaw should not be any bar to the operation, provided the disease be limited, and the constitution good. As a general rule it will be wise to defer the removal of the glands to a subsequent operation. This is especially advisable when the glandular affection is very slight, as the enlargement may possibly be dependent upon simple irritation, and will then subside after the removal of the tongue.

Fig. 749.—Lines of Incision in Regnoli's Operation.

**2. Submental Operations for Excision of Tongue.**—Regnoli of Pisa published, in 1838, a description of the following method by which the whole tongue can be removed. An incision of a semilunar shape is made along the line of the lower jaw, beginning near one angle and terminating close to the other. A perpendicular incision is carried from the centre of this line immediately under the chin to the hyoid bone (Fig. 749). In making this semilunar incision, care must be taken not to wound the facial artery on either side. The trunk

of the vessel should be protected by the finger of an assistant as it curves round the lower jaw, and the incision should be confined within the space between the two facials. The triangular flaps of skin formed in the manner indicated are dissected back, and the muscles and mylo-hyoid space are now exposed. These must be successively divided: the anterior bellies of the digastrics are cut across, the mylo-hyoid muscle divided transversely at its anterior part; and the attachments of the genio-hyoidei and genio-hyo-glossi are then to be detached from the lower jaw by a few touches of the scalpel, and by separating with the fingers the mucous membrane of the floor of the mouth. An aperture is then made into this by pushing the scalpel through it, and its reflexion from the inside of the lower

jaw is divided as far back as the outer angles of the external incision. The submaxillary glands are pushed aside, and the tip of the tongue being seized with a strong hook or vulsellum-forceps, the organ is drawn out to its full extent on to the anterior part of the neck, between the jaw and the hyoid bone, when the whole of it may be removed close to its attachments to the latter bone by means of the scissors or the *écraseur*. If the *écraseur* be used, it will occasionally be found that the anterior pillar of the fauces is somewhat in the way of the application of the instrument. Should this be so, it may be snipped across before the wire is applied. By means of this operation, which I have several times performed, the whole of the tongue may be shaved off clean from the base of the epiglottis and hyoid bone. After the removal of the tongue the hæmorrhage will usually be found to be trifling; but should one or other of the lingual arteries bleed, it may readily be seized and twisted. The incision in the skin must then be stitched up, a drainage-tube being inserted at the lower end of the vertical incision.

Kocher of Berne, believing that the best hope of giving prolonged relief or possibly permanently curing the patient, lies in a complete removal in every case of the lymphatic glands below the jaw simultaneously with the diseased part of the tongue, has introduced a method of operating which in his hands has been attended with a considerable degree of success. He makes a free external incision, commencing a little below the lobule of the ear and running downwards along the anterior border of the sterno-mastoid to the level of the great cornu of the hyoid bone; from this an incision is carried forwards nearly to the body of the hyoid bone, and then upwards along the line of the anterior belly of the digastric to the jaw. The flap thus marked out is turned upwards over the face. The lingual artery is then tied before it passes beneath the *hyo-glossus*. By a process of careful dissection, all the lymphatic glands are removed from the region exposed by the wound. In so doing the carotid sheath will be exposed, as one gland always lies upon it close to the sterno-mastoid. The facial artery and vein will be divided, and must be secured by ligature. It is necessary to remove the submaxillary and sublingual glands, which otherwise are much in the way. Some lymphatic glands, touching the inner surface of the jaw, between it and the sublingual gland, must be sought for and removed. The mylo-hyoid muscle and the mucous membrane of the mouth are now fully exposed, and must be carefully divided when the side of the tongue to its very root comes into view. If only one side is affected, the tongue may now be split down the middle line from the mouth, and the base cut through from the external wound. If the whole tongue requires removal the other lingual must be tied through a separate incision. Kocher recommends a preliminary tracheotomy and plugging the pharynx during the operation. He also advises that the wound in the neck should be left open. In the numerous cases in which the operation has been performed at University College Hospital tracheotomy has not generally been found necessary, and the external wound has been sutured, with or without the introduction of a drainage-tube. In 14 cases operated on by Kocher only one patient died, from secondary hæmorrhage from the tracheotomy wound. In 8 recurrence of the disease took place, 1 died a year after of pneumonia, and 4 remained well at 14 months, 5, 5 and 6½ years after the operation. The operation requires skill and patience in its performance; but the danger does not seem to be great, and the results are such as to encourage its further use in suitable cases.

3. **The Buccal Operation.**—This method is usually attributed to Farneaux Jordan, but according to Butlin it was first performed by Jaeger in 1831. It consists in dividing the cheek backwards on the affected side as far as the anterior border of the masseter, care being taken to go below the parotid duct. In this way free access is gained to the back part of the tongue, and the removal of the latter is effected with scissors in the usual way. After the operation is concluded, the incision in the cheek is closed with sutures.

4. **Excision of Tongue after Division of the Lower Jaw.**—Sédillot of Strassburg described, in 1855, a method of removing the whole of the tongue, which he stated that he had practised for some years with success. The operation consists in making a vertical section through the lower lip, sawing

Fig. 250.—Removal of Tongue by Division of Lower Jaw and Ecraseur.

through the inferior maxilla at its symphysis, separating the bone on each side, drawing the tongue forward and removing it. In performing this operation, its inventor recommends that the section of the lower lip should be made carefully through the median line, and carried across the chin as far down as the hyoid bone. The lower jaw is then sawn through at its symphysis. In order to fix the bone more accurately after the operation, he recommends that, instead of making one vertical incision, two oblique cuts should be practised with the saw in this shape  $>$ , so as to form a triangle the point of which corresponds to the middle of the body of the bone, so that the two opposite sides may be locked together after the removal of the tongue. Before sawing the bone it may be drilled on each side half an inch from the edge of the intended incision through it. After having divided the lower jaw, the muscles connecting it

to the tongue should be cut across and the mucous membrane forming the floor of the mouth detached from the bone, the two sides of which are drawn asunder; and the tongue then removed from the hyoid bone by being gradually snipped through with scissors. The lingual arteries bleed freely, and must at once be secured. The opposite sides of the jaw-bone are then adjusted by a wire passed through the hole previously drilled on each side. If Sédillot's angular cut be adopted, the bone may be kept *in situ* much more easily than if the vertical incision to which he first of all had recourse, and which is commonly adopted in this country, be practised. The incision in the lower lip must be united in the usual way by hare-lip pins or sutures. This operation was first done in this country by Syme and Nunneley, and has since been practised by many other Surgeons. When the disease has commenced in the floor of the mouth and implicated

the bone, the affected portion may be removed with the tongue. This has been successfully done by Heath, Barker, and others.

**Hæmorrhage during Excision of the Tongue** is the only serious danger of the operation, and so long as the mouth is thoroughly gagged even this need cause no anxiety. If only a part of the tongue is being removed, hæmorrhage may be immediately arrested by drawing the tip well out of the mouth by the ligature through it and compressing the lingual artery against the jaw by the method already described. The pharynx must then be thoroughly cleaned with sponges on holders. When this is done the assistant relaxes his finger, and the bleeding point can usually be seized without difficulty with forcipressure forceps. If the whole tongue have been removed, the stump must be hooked forward with the forefinger and seized in a pair of vulsellum forceps while the artery is compressed as before described. Torsion is the most satisfactory mode of arresting the bleeding. The twisted end of the vessel becomes buried in the tissues of the stump of the tongue and secondary hæmorrhage rarely, if ever, occurs. If the attempts at torsion fail, a ligature may be applied and cut short. The most serious accident is when the gag slips while free hæmorrhage is going on. In a case of this kind I had to perform laryngotomy, as a coagulum formed in the pharynx before the vessel could be secured. The patient made a good recovery, dying two years after the operation from recurrence in the lung and in one of the toes. Oozing of blood may usually be arrested by ice, or if it be more than usually free the bleeding point may be touched with Paquelin's cautery or perchloride of iron, but this should be avoided if possible, as it interferes with the healing of the wound. If very free hæmorrhage is expected it may be advisable in some cases to perform a preliminary tracheotomy and to introduce Trendelenburg's obturator or to plug the pharynx with a sponge.

**After-treatment.**—As soon as all bleeding is arrested the stump of the tongue should be freely sponged with a solution of chloride of zinc (gr. 40 to 3j), care being taken that none of the solution runs down the throat. This whitens the surface but in no way interferes with healing. Iodoform in fine crystals should then be gently rubbed into the raw surface with the finger. Whitehead recommends the application of a "varnish" composed of the same constituents as Friar's Balsam, the spirit, however, being replaced by a concentrated solution of iodoform in ether and turpentine. The chief trouble in the subsequent treatment is to keep the mouth free from decomposing discharges. Various means have been tried for this—chlorinated gargles, Sanitas, terebene, Condy's fluid, &c., but nothing approaches iodoform in efficiency. It should be applied daily in the form of crystals (not precipitated), a small quantity being sprinkled over the raw surface by means of a camel's-hair pencil. Whitehead recommends the daily application of the varnish. The mouth may be washed at intervals after the first thirty-six hours with a weak solution of Sanitas. Ice may be sucked at intervals for the first few days, if it be found grateful to the patient. A tendency to dyspnœa is sometimes manifested after the operation, owing to the stump of the tongue falling backwards. This is remedied by opening the mouth and drawing the stump forwards. If it occurs frequently a thread must be passed through the stump and retained for a few days. Even if the whole tongue have been removed the patient will generally be able to swallow fairly well after the first twenty-four hours. A piece of india-rubber tube long enough to reach to the back of the mouth may

be attached to an ordinary "feeder." The use of the œsophageal tube should be avoided if possible. The constant passage of the tube is a great source of annoyance to the patient, and it will, as a rule, be found better to pass the tube half way down the œsophagus at the time of the operation, and to bring it out at the mouth (or through the wound in Kocher's operation), and to fix it there. This is best done by bringing the tube up the side of the face above the ear and applying a bandage to keep it in position. There is often trouble from profuse salivation for two or three weeks, owing to the patient being unable to swallow the viscid saliva excreted from the wounded and irritated glands. This is best controlled by alum gargles. The patient should be well propped up in bed after the operation, and, as a rule, may be allowed to leave it on the fourth or fifth day.

**Accidents after the Operation.**—*Secondary hemorrhage* may occur about the fifth or sixth day, especially after the galvanic cautery. It rarely, if ever, follows excision by the scissors with torsion of the vessels. In the case of simple oozing, this will often stop if the blood-clot be cleared from the mouth and a small sponge held firmly on the raw surface. Ice may also be applied and if a styptic be required turpentine is probably the best. It should be applied to the surface with a small piece of sponge. If the bleeding be arterial it may be at once temporarily arrested by hooking up the stump of the tongue with the finger, as recommended by Heath. The blood-clot is then removed and if the actual bleeding point is seen this should be seized in forceps and an attempt made to apply a ligature. Failing this the forceps may be left *in situ* or the actual cautery applied. Sometimes when other methods fail the hæmorrhage may be stopped by packing a narrow strip of gauze into the floor of the mouth. As a last resource the lingual may be ligatured above the hyoid bone unless that has already been done as a preliminary step to the operation. *Septic poisoning, and septic infection* are prevented by avoiding those methods of operating which leave a sloughing surface, and by the free use of iodoform in the after-treatment. *Septic pneumonia*, due to the inhalation of decomposing matter from the floor of the mouth, is a common cause of death after excision of the tongue, as after cut-throat and similar injuries. It is characterized by scattered patches of broncho-pneumonia, rapidly ending in breaking down of the lung tissue. Sometimes, apparently by extension from these centres, large areas of lung tissue may become gangrenous. This very fatal complication is best avoided by the use of iodoform and by drainage from the floor of the mouth in cases of removal of the entire tongue. Barker suggested and successfully practised in several cases a preliminary tracheotomy. After the operation the patient was made to breathe by the tracheal opening until the mouth had become clean. The introduction of iodoform has, however, so efficiently prevented septic processes in these cases that tracheotomy is now rarely required.

**Comparison of the Methods of Operating.**—In instituting a comparison between the different methods of dealing with cancer of the tongue it should be understood that the same plan or treatment is not equally applicable to all cases, but that one or other should be adopted according to the situation and extent of the disease. If this be small and situated at the tip, this portion of the organ may easily and safely be excised. If situated towards the side so as to require the removal of perhaps the anterior third of one side of the organ, it may best be done by splitting the tongue and excising

the diseased part with the *écraseur* or scissors, and the same method is equally applicable when half the organ has to be removed. If the posterior part be superficially affected the disease may be cut out and the buccal operation will then, in some cases, be found to expose the part most fully. If the organ be so deeply affected that the whole requires extirpation, this can be done from the mouth with the *écraseur* or by Whitehead's method. In some cases it will be found most convenient to split the tongue and remove the halves separately. If the floor of the mouth is implicated, recourse may be had to Sédillot's operation of division of the lower lip and jaw in the middle line. If it is intended to remove the glands below the jaw, Kocher's method will be found the best. Whichever method be adopted, the sublingual gland should always be removed either with the tongue or by scissors after the main part of the disease has been taken away, as there are some small lymphatic glands buried in its substance which are often an early seat of recurrence of the disease.

With regard to the choice between the *écraseur* and the scissors it may be said that increasing experience shows clearly the great superiority of the latter. The *écraseur* tends to slip forward and so to leave some of the disease behind, it by no means certainly prevents hæmorrhage during the operation, and it leaves a crushed surface which heals less rapidly and from which secondary hæmorrhage is not unlikely to occur. By the use of the scissors the Surgeon can accurately cut beyond the limits of the disease. A clean cut surface is left which readily heals, and if the bleeding vessels are twisted, secondary hæmorrhage is very unlikely to follow. It requires, however, a skilled assistant on whom the Surgeon can rely to seize the bleeding vessels in the forcipressure forceps.

**Results.**—The prognosis in cancer of the tongue is always bad. Removal of the diseased organ in part or in whole may relieve for a time, but very rarely does more than this. The more acute the cancer, the more rapid will be its recurrence, either locally or in the glands. A. E. Barker, who has most carefully investigated this point, states that out of 170 cases collected from various sources he could find only 17 in which recurrence did not take place within one year; and in the whole of medical literature he could meet with the record of only 42 cases in which the patient had remained free from recurrence for a sufficient length of time to justify the hope that he was permanently freed from the disease. One of the most successful cases on record was operated on by C. Heath. The cancer was situated near the *frænum*, adhering to the jaw and extending upwards into the substance of the tongue. The whole incisor portion of the lower jaw and the anterior half of the tongue with the corresponding part of the floor of the mouth were removed in one piece. The patient is still alive and in good health nearly twenty years after the operation.

The mortality directly from the operation though considerable, is not very high when the serious nature of the proceeding is considered.

Barker has collected 218 cases from various sources, and finds that the death rate is 16·9 per cent. It is satisfactory, however, to note that of late years it has considerably diminished. Thus, at University College Hospital, 38 cases were operated on between 1871 and 1881, of which 10 died; 20 of these operations were performed before 1877, and of these 8 died, while of the remaining 18 only 2 died. The diminished death-rate seems to be due in part at least to the more successful prevention of decomposition by the use of

iodoform. The records of excision of the tongue were at one time so unsatisfactory, that some Surgeons have doubted the propriety of performing the operation; but when we remember the terrible fate of the patient if the disease be allowed to run its course, and that cases of apparent cure, although exceptional, are not unknown, there is no doubt that the operation is not only justifiable but advisable. The hope of improvement in the results seems to lie first in early recognition of the disease, so that it may be removed before the glands are affected; and secondly, if this period be passed, in free removal of the diseased organ with the whole of the lymphatic glands which receive lymph from it, if this be possible. The fact that epithelioma seldom recurs in the viscera encourages us to attempt the removal of the affected glands whenever their situation is such that the operation can be safely undertaken. If those cases are included in the statistics in which, in addition to the tongue, parts of the lower jaw are removed, the death-rate is necessarily higher: thus of 75 cases operated upon in University College Hospital between 1881 and 1890, 15 died, giving a mortality of 20 per cent.

**Effect of the Removal of the Tongue on Speech.**—Although distinctness of articulation is necessarily affected for a time by these operations on the tongue, yet it is usually completely restored when only the anterior third or half is removed; the tissue of the organ recovering its normal mobility with remarkable facility. Even after removal of the whole of the tongue, the power of deglutition is preserved, and that of articulation, although at first somewhat imperfect, eventually returns, so that the patient is able to speak so distinctly that strangers would not be aware of the loss he had sustained. Amongst the tortures to which Christian martyrs were subjected in the early ages, and the punishments which have been inflicted on heretics, "cutting out the tongue" was one of the most barbarous. Martyrologists in describing this horrible mutilation have remarked with wonder, that, although it was practised with the view of depriving the sufferers of the power of speech, yet it often failed in its effect, and those who had been subjected to it were able to speak afterwards as plainly as before. This they have attributed to direct miraculous intervention. But, as modern Surgery has shown that the power of speech returns equally, whether a cancerous tongue have been extirpated by the knife of the Surgeon, or a heretical tongue by that of the executioner, we must look upon the return of speech rather as a physiological fact, than as a miracle specially wrought for the benefit of those mutilated by way of religious persecution.

**DISEASES OF THE FLOOR OF THE MOUTH.**—**Solid Tumours** are occasionally met with in this region, *Epithelioma* being the most common. *Adenoma* also may occur in connexion with the salivary glands. *Nevi* also have been observed in this situation. These tumours require removal by irregular operations, varying according to the size and situation of the growth. For these proceedings no special directions can be given. In removing such tumours, when situated under or by the side of the tongue, the knife must necessarily be used with much caution. It must, however, be borne in mind that, if these growths cannot be reached from the inside of the mouth, they may be got at by incision through the mylo-hyoid region, where there is but a slight thickness of soft parts between the surface and the floor of the mouth.

**Cystic Tumours in the Floor of the Mouth** may occur under three forms: 1, Ranula; 2, Dermoid Cyst; and 3, Bursal Cyst.

1. **Ranula.**—A globular swelling, semi-transparent, evidently containing fluid, and often attaining the size of a walnut or a pigeon's egg, may be situated under the tongue, pushing this organ upwards and backwards, and consequently interfering with deglutition and speech (Fig. 751). The wall of the cyst is usually thin, with small vessels ramifying on it; its contents consist of a thick mucous fluid.

It was at one time generally supposed that a ranula was due to dilatation of Wharton's duct; but Morratt Baker, who has investigated the subject, finds that the duct, which can generally be seen lying on the surface of the cyst, is quite free, without any alteration in size, and that saliva may be seen issuing from it. A probe passed into the duct is separated from the ranula by a thin membranous wall, showing clearly that the duct and the ranula do not communicate. It seems, indeed, most probable that the cyst owes its origin to a dilatation of one of the mucous glands in the floor of the mouth; a view which is supported by the fact that the contents consist of simple mucus and not salivary secretion, and that in some cases at least the ranula consists of independent cystic formations, such as commonly occur in connexion with other secreting glands. Furthermore, cystic tumours containing glairy fluid may occur in the substance of the tongue, far away from any salivary duct. According to Von Recklinghausen the particular structure affected is the gland of Blandin, a mucus-secreting gland

Fig. 751.—Ranula: Introduction of Seton.

which usually lies beneath the tongue close to the middle line. I have, however, seen a case in which a ranula resulted from a wound of the floor of the mouth, in the situation of the Whartonian duct. The wound was caused by the slipping of a pair of tooth-forceps during extraction of the first molar tooth. As the wound healed a ranula formed, the contents of which were thick and ropy like the natural secretion of the submaxillary gland. It ultimately reached the size of a plover's egg. That this cyst was formed by an accumulation of the secretion of the submaxillary gland, there can be little doubt; but it is quite possible that the collection formed in the submucous tissue, and that it was not enclosed in an actual dilatation of the duct.

The *Treatment* of ranula consists either in passing a horse-hair seton through its walls, so that contraction may take place on this (Fig. 751); or else in the excision of a large portion of the anterior wall of the cyst, the remainder contracting until it at last becomes obliterated.

2. **Dermoid Cyst.**—This form of cyst is in reality rather a tumour of the tongue than of the floor of the mouth, but on account of its position it may

conveniently be considered here. It lies either in the middle line or laterally, and forms a swelling of varying size, which projects into the mouth beneath the tongue, and may also appear in the neck below the jaw. A specimen, remarkable for its size, is preserved in the Museum of University College. It was removed by Gray, of Bombay, from a negro, aged thirty-five; it is as large as a medium-sized cocoa-nut and contained forty ounces of pultaceous material. The cysts which occupy the middle line between the genio-hyo-glossi muscles probably arise by a dilatation of an unobliterated portion of the thyreo-glossal duct (see Vol. I., p. 1014). This explanation will hardly account for those which are not median, and it is possible, as Barker suggests, that these are due to inclusion of epiblast along the lines where the lateral processes, from which the tongue develops, join the middle one. The structure of dermoids has been considered in Vol. I., p. 1013. The treatment consists in removing the cyst from the mouth, or if this be impossible, through an external incision in the middle line between the chin and the hyoid bone. The operation is troublesome, and may be accompanied by free bleeding.

3. **Bursal Cyst.**—This is believed to arise from enlargement of the bursa above the hyoid bone between the genio-hyoidei and the genio-hyo-glossi. It projects usually more distinctly in the neck than into the mouth, and thus forms a large tumour, soft or elastic, and semi-fluctuating, occupying, perhaps, all the space between the symphysis and the hyoid bone. It may attain the size of an orange. The tumour is best treated by making a free incision into it, from the mouth if possible, and wiping out the cavity with chloride of zinc (gr. 40 to 3j. of water), after which a drainage-tube may be inserted. If the tumour is more superficial externally the same treatment may be carried out from the outside. It is not possible in most cases to dissect the cyst out, as its wall is thin and its connexions deep and important.

**Salivary Calculi** are occasionally met with in connexion with the sublingual, submaxillary, and parotid glands. They consist chiefly of phosphate and carbonate of lime mixed with animal matter. They are most common in the submaxillary gland, and will then be found to be situated in the Whartonian duct, or very rarely in the substance of the gland itself. From this situation I have two or three times removed them. Wherever occurring, they obstruct the duct and produce retention of saliva in it. Hence, when the salivary glands become actively secreting, as at meal-times, the calculus, by preventing the escape of the salivary fluid, causes distension of the gland, with pain and tenderness, rendering mastication difficult. Suppuration occasionally takes place round the calculus, and if it be in the submaxillary gland the pus may burrow downwards and point in the neck near the great cornu of the hyoid bone. This, however, is very rare.

The *Treatment* is simple. It consists in dividing the mucous membrane over the calculus and then extracting the latter with forceps. The largest which I have removed was of the size of a small damson-stone; it was loose in Wharton's duct.

#### DISEASES OF THE PALATE, UVULA, AND TONSILS.

**HARD PALATE.**—The hard palate is liable to *necrosis*, usually the result of syphilis, but occasionally arising from a subperiosteal abscess, starting from a

diseased tooth. These conditions have already been described in the chapter on Diseases of the Jaws. *Epithelioma* is far from common. *Enchondroma*, *Fibroma*, and various forms of *Sarcoma*, have also been met with in this region.

**SOFT PALATE.**—The most common disease of the soft palate is *syphilitic ulceration* (Vol. I., p. 1153). *Tuberculous ulceration* is much less common and is generally met with in children. It usually commences at the free edge of the bladder and gradually spreads with the production of an extensive ulcer, having a pale, feebly granulating surface, and a sharply defined margin. Considerable destruction of the soft palate may result. The treatment is unsatisfactory. Lactic acid has in some cases been used with success; it is painted over the ulcerated surface in a solution the strength of which may be gradually increased from 20 to 80 per cent.

Tumours of the soft palate are occasionally met with, and their nature has been specially studied by Stephen Paget, who has collected and analysed the records of a considerable number of such cases. *Dermoid cysts* have been met with in this region. They are always situated in the middle line, and are supposed to be formed by inclusion of the epithelial layer during development. *Simple mucous cysts* are very rare. *Polypoid and warty growths* are not very uncommon. *Adenomata* form the largest class of tumours met with in this situation. They vary somewhat in structure, some closely resembling the adeno-fibroma of the breast, and others being composed of embryonic or myxomatous tissue surrounding groups of epithelial cells, sometimes forming distinct cell-nests. They are, however, always simple, and usually distinctly encapsuled, so that they can readily be shelled out after the mucous membrane covering them has been divided. They are of slow growth, and usually painless; they are round or oval in form, smooth on the surface and firm in consistence. They are most common about middle life. In a case under the care of C. Heath the tumour, which was easily shelled out, measured one inch and a half in diameter. *Sarcomata* are rare, and are usually round or spindle-celled. *Squamous carcinoma* is also rare. It presents nothing peculiar.

**UVULA.**—**Elongation of the Uvula.**—The uvula occasionally becomes elongated and hangs down into the pharynx, so as to touch the epiglottis and sensitive mucous membrane in its neighbourhood, giving rise to great irritation of the fauces, or to a tickling or spasmodic cough, which can be cured only by removing the pendulous body. This little operation may be readily done after the application of cocaine by seizing the end of the uvula with a pair of polypus-forceps, and snipping it across near the root with a long pair of scissors. Swallowing is less painful after the operation if the uvula be cut in a slanting direction, so that the raw surface looks backwards. It is better not to remove the whole of the uvula. If this be done, throat irritation is apt to continue. I have been most satisfied with the result of those cases in which a stump from a quarter to a third of an inch in length has been left. The soreness of the throat after the operation may be relieved by sucking ice, or a marsh-mallow lozenge.

**TONSILS.**—**Tonsillitis** or **Quinsy.**—The tonsils are not unfrequently acutely inflamed. They then become swollen and red, with much pain in the side of the neck and ear, increased by any attempt at swallowing; there is usually a profuse secretion of saliva, and a good deal of swelling under the angles of the jaw; the tongue is coated with thick pasty mucus, and the voice is thick and nasal. The disease comes on suddenly, often accompanied by

high fever, chills, and occasionally even delirium. The thermometer frequently rises to 105°, or even higher. In some cases, a trace of albumen may be found in the urine. Tonsillitis is often caused by exposure to impure air, such as results from the escape of sewer-gas into a house, and it is not uncommon amongst the residents in hospitals. It occasionally precedes an attack of acute rheumatism, but the connexion between the two diseases is not clear. It may be mistaken for diphtheria, scarlet fever, or erysipelas of the fauces. From diphtheria it is distinguished by the absence of exudation. The mucous secretion from the tonsil may somewhat resemble diphtheritic exudation, but it is distinguished by its want of adherence, as it is easily removed with a camel's-hair pencil. From scarlet fever, tonsillitis is distinguished by the absence of the red tongue, and by the redness of the throat being purple in tint, and limited to the tonsils and their immediate neighbourhood, and later on by the absence of rash. From erysipelas of the fauces it is more difficult to distinguish, but it will usually be found that the redness is darker in tint and less diffused than in erysipelas, and there is less oedematous swelling, and no tendency to the supervention of dyspnoea from oedema glottidis. There is also less glandular enlargement at the angle of the jaw.

The *Treatment* should always be commenced by a good purge; a calomel and colocynth pill will be found most efficacious if it can be taken. Guaiacum in lozenges, or otherwise, is said sometimes to cut the disease short if administered at the very beginning. Salicylate of sodium in 15 or 20 grain doses every three or four hours is often most useful. Hot fomentations must be continuously applied, and the inhalation of the steam from a pint of boiling water, to which has been added a teaspoonful of creasote, carbolic acid, or compound tincture of benzoin, will often give much comfort by lessening the force of the breath. The patient must be well supported by good beef tea and other liquid food. The difficulty in swallowing may be overcome by painting or spraying the throat with cocaine. Much relief may often be given by scarifying the tonsils with a probe-pointed bistoury; and, if abscess form, it should be opened early with a sharp-pointed bistoury sheathed to within half an inch of its point by wrapping strapping round it.

**Chronic Enlargement of the Tonsils** occurs in two distinct forms. In one, the enlargement occurs in otherwise healthy children in consequence of *repeated attacks of inflammation*, and more especially of diphtheria, scarlet fever, and measles. In the second form, it is due to a *true hypertrophy* of the normal structures of the tonsil. The lymphatic follicles are enlarged and increased in number, and the connective tissue between them is more abundant and dense than natural. The crypts are deepened and are filled with an abundant mucous secretion, sometimes of cheesy consistence, and standing out from the mouth of the crypt in the form of white spots. In rare cases, calcareous concretions may be found in the dilated crypts. This form of enlargement may be complicated by the effects of repeated attacks of inflammation.

When the tonsils are chronically enlarged, the condition is obvious on opening the mouth and depressing the tongue so as to expose the fauces fairly, and cannot be mistaken for any other morbid state. The condition is frequently associated with the presence of adenoid vegetations in the nasopharynx (see p. 709).

In *chronic inflammatory enlargement* the tonsils are red, congested, and very

liable, under the influence of slight causes, to violent attacks of acute inflammation with ulceration or abscess.

In *chronic hypertrophy* the tonsil presents different characters ; it is large, rather pale, hard, smooth, and semi-elastic. This disease often occurs in children and young persons who have a general tendency to strumous affections of the mucous membranes. Most commonly it develops without any assignable cause, usually commencing at five or six years of age, and gradually increasing up to puberty, a period during which the functional activity of these glands is greatest, and they are most exposed to irritation from zymotic diseases, especially scarlatina and measles. When once the tonsils have enlarged, they become a source of great inconvenience and even of serious derangement of health. The child is liable to attacks of inflammation of the throat, the tonsils then becoming congested, greatly swollen, and readily running into ulceration or suppuration. In consequence of these repeated attacks of inflammation, the enlargement of the tonsils increases, they become indurated, rugged-looking, and nodulated, projecting far forwards into the fauces, and sometimes even touching each other below the uvula. Respiration, articulation, and deglutition are now seriously interfered with. The mucous membranes of the nose and eyes are often chronically congested, and there is an increased secretion, from the back of the throat and nose, of tenacious, unhealthy, or fetid mucus, the swallowing of which is deleterious. The child cannot sleep without snoring, and is apt to start up with a feeling of suffocation ; the voice becomes thick and husky ; the sense of hearing is blunted ; and, partly from the incipient deafness, partly from the difficulty of breathing causing the child to keep its mouth half open, the countenance assumes a peculiar vacant, semi-idiotic expression, which is very characteristic in advanced cases. The most serious effect is the impediment to inspiration, which in the more chronic and severe cases will prevent the full inflation of the lungs, and thus occasion a permanent contraction of the chest, imperfect aëration of the blood, and an interference with general nutrition.

The *Treatment* of chronic enlargement of the tonsils will vary according to the age of the child, and the degree and kind of the hypertrophy. In the earlier and slighter forms of the disease, the enlargement of the tonsils may gradually subside as the child grows older and stronger ; and it is well not to be in too great a hurry to excise the tonsils in young children, but rather to adopt a course of constitutional treatment with the view of improving the general health. The internal use of iron, and the local application of the tincture of iodine, or of burnt alum, are occasionally serviceable. In the majority of instances, however, the enlargement will not be influenced by such means, and it becomes necessary to remove the tonsil. This may be best done by the ordinary tonsil guillotine (Fig. 752). In adults the throat should first be painted with a 20 per cent. solution of cocaine, but in children who are more frightened than hurt, this will rarely be of any service. The tonsil is made prominent by pressing with the finger behind the angle of the jaw, and the ring of the instrument, which should be adapted to the size of the tonsil, being passed over it and pressed strongly towards its base, the cutting blade is pushed forwards, and thus the projecting part of the growth is removed. In some cases difficulty is experienced in bringing the tonsil fairly into the ring of the instrument ; this may be obviated by drawing it through with a

vulsellum, and indeed, in some guillotines a hook is attached, which draws forwards the tonsil before it is sliced off. In operating on a child, the patient should be held on the knees of an assistant, who controls the legs with his own, steadies the head and presses the left tonsil inwards whilst the surgeon is removing it. It is quicker and easier to use a separate guillotine for each tonsil. Should a guillotine not be at hand, the tonsil may be removed by seizing it with a vulsellum, drawing it inwards, and then taking off a slice with a probe-pointed bistoury, the base of the blade of which should be wrapped round with a piece of plaster, to prevent its wounding the tongue. In excising the tonsil in this way, care must be taken to cut from below upwards and inwards towards the mesial line, and on no account to turn the edge of the knife outwards, lest serious bleeding occur. In some cases the tonsil, although considerably enlarged, projects little into the fauces, and is thus difficult to remove with the guillotine or bistoury. Under these circumstances Bilton Pollard has shown that enucleation may be practised; the mucous membrane is torn through with the finger-nail between the tonsil and the posterior pillar of the fauces, and then the tonsil itself is peeled off the

Fig. 732.—Mackenzie's Tonsil Guillotine.

wall of the pharynx. For three days after the operation the food should be soft and not too hot.

The hæmorrhage that follows excision of the tonsil is usually very trifling, but it has been known to prove fatal. In the event of severe bleeding pressure should at once be applied by one finger in the mouth and another externally below the angle of the jaw. This is often the only treatment required, but if on removing the pressure the hæmorrhage continues and is seen by the aid of a good light to proceed from a definite spot, an attempt must be made to seize this in forceps and apply a ligature. If there be only free oozing which pressure fails to arrest, styptics may be tried. A small pledget of lint soaked in the strong solution of perchloride of iron may be firmly pressed on the bleeding surface, or a styptic paste recommended by Mark Howell may be used (gallic acid, one part; tannic acid, three parts; sufficient water to form a stiff paste). In desperate cases in which all other means have failed, ligature of the external carotid artery is a last resource. There is no reason to expose the patient to the additional risks of ligaturing the common trunk, for the hæmorrhage occurs from tonsillar branches and probably never from the internal carotid.

**Malignant Tumours of the Tonsil.**—Squamous carcinoma, lympho-sarcoma, and round-celled sarcoma are the malignant growths most commonly met with in the tonsil and its immediate neighbourhood. **Squamous Car-**

**cinoma** rarely commences in the tonsil itself, but much more commonly extends to it from the root of the tongue or the pillars of the fauces. The tumour ulcerates early and deeply, and presents the hard base, foul surface, and everted edges observed in ulcerating epithelioma elsewhere. It early affects the glands. **Lymphadenoma** may affect the tonsil in common with other parts in which lymphoid tissue is abundant. In cases of general lymphadenoma the enlargement of the tonsils may be associated with hypertrophy of the lymphoid tissue at the back of the tongue, and on the posterior wall of the pharynx.

**Lympho-sarcoma** (Vol. I., p. 1038) and ordinary **small round-celled sarcoma** are the most common forms of malignant disease affecting the tonsil. The lympho-sarcoma forms a soft, sometimes semi-fluctuating tumour, rounded in form, often smoothly covered by tensely stretched mucous membrane, and projecting beyond the middle line of the pharynx, interfering more or less with deglutition and respiration. In most cases the growth speedily implicates the lymphatic glands along the anterior border of the sterno-mastoid. These tumours may be loosely encapsuled, so that they can be shelled out easily with the finger after the mucous membrane covering them has been divided. Round-celled sarcoma infiltrates the neighbouring parts more widely, and shows the same general malignancy. If these growths are left without operation, swallowing becomes more and more difficult, respiration is impeded, ulceration and hæmorrhage may take place, and the patient dies in most cases from the effects of the local disease, but sometimes from secondary visceral growths.

If the disease is far advanced and widely infiltrating surrounding parts, nothing can be done by operative means for the relief of the patient. In one case of a malignant tumour of the tonsil, however, I obtained some temporary advantage by removing portions of the soft projecting very vascular growth by means of the *écraseur*. When the tumour is stretching the mucous membrane over it without apparently implicating it, and when the whole mass seems movable in the side of the pharynx, it is probable that the tumour is a lymphadenoma or lympho-sarcoma, and it may then in many cases easily be removed from the mouth. The patient must be well gagged, the mucous membrane divided with a Paquelin's cautery-knife, and the mass enucleated with the finger. It is surprising with what ease and with how little hæmorrhage tumours of this kind, even when of considerable size, may be removed. Four cases have been treated in this way in University College Hospital. All recovered and were greatly relieved locally, but in all speedy recurrence took place in the glands of the neck. In one of Barker's cases, the glands were removed, and the patient was in good health a year afterwards.

If the tumour is too deeply attached to be shelled out in this way, it may be brought more fully into view by dividing the cheek as in the buccal operation for removal of the tongue, but this rarely gives enough room. It has therefore been attempted in several cases to expose the tonsil by incisions in the side of the neck. Cheever accomplished this by one incision along the anterior edge of the sterno-mastoid, and another joining it and passing along the lower border of the jaw. This method has been adopted by Golding-Bird and Charasse, who made the second incision into the angle of the mouth instead of along the jaw, and by Haslam, Homans of Boston, and Raymond Johnson, who employed a single incision along the anterior border of the

sterno-mastoid from the ear to the hyoid bone. Foulis and Czerny recommended a more extensive incision, commencing at the angle of the mouth and passing downwards to the angle of the jaw and beyond it towards the tip of the great cornu of the hyoid bone. By sawing the jaw in this line and pulling the parts widely asunder the tonsil is brought very clearly into view. Mikulicz went a step further, and took away a portion of the ascending ramus of the jaw without opening the mouth. The details of these operations must necessarily vary with the seat of the tumour and the extent of the implication of the soft parts. In order to avoid hæmorrhage, the cutting in the deeper parts is best done with Paquelin's knife, and with the same object the external carotid has been tied in at least two cases as a preliminary step in the operation. The *results* have not so far been very satisfactory. Butlin, who has collected 23 cases of removal of malignant tumours of the tonsil, states that although only three died directly from the operation, recurrence had speedily taken place in the great majority of the survivors, only three being known to be alive and well at periods of four, twelve, and twenty-four months respectively after the operation. To Butlin's list may be added at least four cases in which no recurrence took place after many months. Local relief has, however, followed many of the operations, and doubtless, also, in most, life was prolonged. The operation is evidently justifiable in well selected cases, and should be done as soon as the nature of the disease is recognised.

#### DISEASES OF THE PHARYNX.

**Catarrhal Pharyngitis.**—The *acute* form, or the ordinary sore throat, is too familiar to every inhabitant of our damp and cold climate to need any description. Avoidance of cold, warm external applications and steaming the throat by means of an inhaler, usually soon effect a cure, which may be hastened at the end by an alum or port-wine gargle. *Chronic catarrhal pharyngitis* or "relaxed throat" is characterised by some redness and swelling of the mucous membrane, often accompanied by elongation of the uvula. The veins of the mucous membrane are often enlarged and visible, and the follicles slightly increased in size. There is an excess of secretion, usually thick and tenacious in character. It may follow repeated attacks of acute catarrh, but is much more commonly associated with dyspepsia caused by the excessive use of alcohol, tea, or tobacco. It is aggravated by cold and damp weather, and greatly relieved by warmth and dryness. The symptoms are usually worse in the morning, and consist in dryness and uneasy sensations as if from the presence of a foreign body, with a constant desire to clear the throat by coughing or to moisten it by drinking. The *treatment* consists first in avoiding the causes above mentioned. If there is any tendency to constipation, saline purgatives may be given. Pepper, mustard, curry, &c., should be forbidden. Locally, astringent gargles, chloride of ammonium lozenges, and sprays of bicarbonate of sodium, chloride of ammonium or alum, or insufflations of pulv. catechu pallid. will be found most useful. Change of air to a warm dry climate will usually succeed when other means have failed.

**Follicular or Granular Pharyngitis** is an exaggeration of the preceding condition characterised by marked enlargement of the mucous follicles of the pharynx. The chronic catarrh usually extends into the post-nasal

region and to the mucous membrane at the opening of the glottis. The causes are various, amongst the most common being abuse of alcohol and tobacco, but chronic dyspepsia from other causes may predispose to it. Excessive use of the voice is also a frequent cause. The condition is common in scrofulous subjects. The symptoms are those of ordinary catarrhal pharyngitis, increased in severity and accompanied by hoarseness or loss of voice, and frequently by some deafness from obstruction of the Eustachian tubes, and occasionally by loss of smell. On examination the enlarged follicles are seen forming rounded or oval eminences dotted over the mucous membrane, sometimes coalescing and forming larger elevations or ridges. Small tortuous dilated veins are very commonly present. Most commonly there is little or no excess of secretion, the throat being more or less dry and glazed, often with crusts of dried mucus upon it, especially visible on turning the velum upward. In another variety of the disease, described as the exudative form, there is a thick, opaque, tenacious secretion which hangs about the orifices of the follicles at the back of the pharynx. The *treatment* is often very unsatisfactory. The avoidance of all sources of irritation, of alcoholic excess, and of over-use of the voice is essential. The digestion must be attended to and the bowels kept regularly open. Locally the throat may be sprayed with astringent lotions, such as alum or tannic acid, or may be painted with glycerine of tannin, care being taken to pass the brush up behind the soft palate. When there is an accumulation of viscid mucus or dry crusts in the pharynx, sprays through the anterior nares, and behind the palate, give great relief. The patient should learn to do this himself. If the throat is dry, chloride of ammonium lozenges give much relief. The application of solid nitrate of silver to the enlarged follicles is sometimes of use, and in extreme cases they have been destroyed by the application of powerful chemical caustics or by the galvanic cautery, not merely rubbed over, but pushed into each separate follicle. Cocaine should be applied first, and a little (gr.  $\frac{1}{4}$  to  $\frac{1}{2}$ ) of morphia in powder with starch blown over the part afterwards. If these severe measures are adopted only a few follicles must be treated at a time, otherwise dangerous inflammatory swelling may result.

**Adenoid Vegetations.**—A condition was first fully described by Meyer of Copenhagen under the name of “follicular hypertrophy,” which is characterised by a general overgrowth of the lymphoid follicles situated about the posterior nares and the upper part of the pharynx. The condition is extremely common in children and young adults, and is especially frequent among the inhabitants of cold damp climates. It is favoured by any conditions which tend to cause a chronically inflamed and relaxed state of the throat, and thus it is common in strumous subjects and often appears to result from measles or scarlet fever. In all cases the lymphoid tissue which is solely or chiefly affected is that which stretches across the posterior wall of the pharynx on a level with the orifices of the Eustachian tubes. This becomes transformed into a soft spongy cushion, or even into a mass of polypoid vegetations which may completely block the posterior nares. The condition can be recognized by posterior rhinoscopy (p. 587), or more readily by passing the index finger above the soft palate. The *symptoms* are for the most part the result of obstruction to nasal respiration, and are thus identical with those produced by chronic enlargement of the tonsils (p. 705). The two conditions are indeed frequently associated, and in any case of enlarged tonsils in which the signs

of nasal obstruction are pronounced, the presence of adenoids should be suspected. Deafness is very commonly the result of chronic catarrh of the Eustachian tubes, the orifices of which are in close relation with the diseased area. Suppuration in the middle ear is by no means an uncommon complication. Lastly, it may be pointed out that a condition of follicular hypertrophy, insufficient to cause nasal obstruction and possibly not associated with deafness, may still be of importance as a source of unhealthy absorption, which is evidenced by obstinate glandular enlargement in the neck.

The *treatment* of the slighter cases should consist in attention to the general health and the use of astringent injections into the nose. Except in the very slightest forms, any local treatment other than removal of the adenoid vegetations by operation is generally useless. For this purpose various kinds of forceps, curettes and ring-knives have been invented. Löwenberg's forceps are largely employed, and Gottstein's curette will be found a most efficient instrument. The operation is performed as follows:—Chloroform is administered in amount sufficient just to produce unconsciousness, but on no account must the anæsthetic be pushed to deep insensibility, or the risk of blood entering the larynx is greatly increased. The child being drawn to the end of the table, so that the head hangs slightly over it, a Mason's gag is inserted on the left side, the Surgeon standing on the right.

If the tonsils are enlarged these are first removed. The curette is then passed up behind the soft palate and is drawn firmly from above downwards over the pharynx several times, so as to scrape the vegetations from its posterior wall. After the bulk of the growths has in this way been removed, the nail of the index finger will be found most useful in detaching the smaller fragments, especially at the sides, which are liable to escape. The bleeding is often very profuse, but in the majority of cases it quickly ceases. The blood is prevented from entering the larynx by repeatedly sponging out the pharynx, but especially by keeping the head slightly dependent and turned well on to the right side so that the blood collects in the cheek. If the bleeding is unusually free the pressure of a sponge will almost certainly arrest it, and it has very rarely been found necessary to plug the posterior nares. After the operation the child should be kept indoors for two or three days, beyond which no after treatment is necessary. The cure is usually permanent if the removal of the adenoid vegetations has been thorough.

**Erysipelatous Pharyngitis** is occasionally met with. It is characterised by an invasion and subsequent constitutional disturbance, like that of erysipelas. (Vol. I., p. 945), with enlargement of the glands under the jaw. The mucous membrane is of a brilliant red colour, and considerably swollen. There is great pain in swallowing, and severe or fatal dyspnoea may follow from œdema of the glottis. The *prognosis* in these cases is always grave. The *treatment* consists in the external application of heat, the local application of a strong solution of perchloride of iron or nitrate of silver, and steaming the throat. The strength must be maintained by liquid food and stimulants. Should dyspnoea occur, the larynx or trachea should be opened at once.

**Diffuse Cellulitis of the Submucous Tissue of the Pharynx or Phlegmonous Pharyngitis** is a very rare affection, arising occasionally from injury, but in other cases without evident cause. It commences with redness, swelling, and pain in swallowing, but the serious nature of the case is

soon shown by the great elevation of temperature and severe constitutional disturbance. Edema of the glottis sets in early. The disease is very fatal. After death the areolar tissue around the pharynx and larynx will be found soaked in pus and sometimes gangrenous. The *treatment* is very unsatisfactory. Scarification of the wall of the pharynx may be of use if there is great œdematous swelling, after which a solution of perchloride of iron (30 per cent.) may be painted on. Heat and moisture must be applied externally. Laryngotomy or tracheotomy may be required at any moment. As long as the patient can swallow, fluid nourishment and stimulants must be freely administered.

**Acute Retropharyngeal Abscess** is occasionally met with in young children, usually under two years of age. The suppuration occurs in the loose areolar tissue between the pharynx and the prevertebral muscles, and is independent of disease of the cervical vertebræ. Bilton Pollard, who has lately called especial attention to this affection in young children, refers to the observation of Edmund Simon, that the plexus of lymphatics in the retropharyngeal tissue terminates in two lymphatic glands which lie one on each side of the middle line. The view that the suppuration commences in these glands secondarily to some unhealthy condition of the neighbouring mucous surfaces is a very probable one; and is supported, as Pollard points out, by the unilateral position of the pus in most cases; whilst the age at which acute retropharyngeal abscess is common harmonises with Simon's statement that the glands disappear after the third year. The *symptoms* are fever with considerable constitutional disturbance, interference with deglutition and respiration, alteration in the voice, and glandular enlargement in the neck. On examination of the back of the pharynx with the index finger an elastic or actually fluctuating swelling will readily be detected.

*Treatment.*—In order that the abscess may be treated aseptically, Pollard recommends that it be opened in the neck at the posterior border of the sternomastoid in the manner adopted in cases of chronic retropharyngeal abscess resulting from caries of the vertebræ (see p. 50), care being taken that a drainage tube is introduced well into the cavity. The incision should be an inch in length, and commence at a point on the posterior border of the sternomastoid an inch below the mastoid process. The objection to opening the abscess into the pharynx is not nearly so great as in cases of chronic retropharyngeal abscess due to spinal disease, and if the symptoms are urgent this should be done, unless the means for carrying out the other operation are at hand. A free vertical opening should be made with a sharp-pointed bistoury properly protected. Urgent dyspnœa is an indication for tracheotomy.

**Syphilitic Affections** of the Pharynx have already been described (Vol. I., p. 1153). The consequences of extensive syphilitic ulceration may, however, be alluded to here, as they occasionally call for surgical interference. As the ulcers heal the pharynx may contract so that deglutition becomes difficult, fluids only being able to pass. In such cases some relief may occasionally be given by careful division of some of the tight cicatricial bands which narrow the fauces, followed by the passage of bougies. Sometimes the soft palate becomes adherent to the posterior wall of the pharynx, completely shutting off the nasal cavity. For this condition nothing can be done, as it is impossible to set the soft palate free, and an opening through it would only add to the patient's discomfort.

**Tumours** are occasionally met with in the retropharyngeal areolar tissue, giving rise to the same swelling, difficulty in respiration and deglutition, and lateral projection, as are caused by abscess of this region. These growths are mostly malignant, and speedily prove fatal. *Polypi* in the pharynx usually come down from the nasal cavities, but sometimes spring from the inside of this canal on one or other of its margins. They are usually malignant, and grow with great rapidity, eventually causing death from obstruction to deglutition and respiration. The so-called *fibrous polypus* projecting from the base of the skull into the pharynx has already been described (p. 596). *Epithelioma* of the pharynx has occasionally been met with (Fig. 753). This form of the disease, which is of rare occurrence, does not differ from similar growths elsewhere.

#### DISEASES OF THE ŒSOPHAGUS.

In discussing the diseases of the Œsophagus it will be most convenient to consider first the diseases that may affect that canal, most of which cause narrowing of its lumen and consequent dysphagia, and subsequently to describe the symptoms and treatment of stricture of the Œsophagus in general.

**Congenital Malformations** are very rare, the most common being a communication between the Œsophagus and the trachea which is incompatible with life. Congenital fistulae and diverticula have also been met with, and cases have been recorded of difficulty in swallowing existing from an early age to adult life, and proved after death to have been due to narrowing of the upper end of the Œsophagus. Complete atresia may also occur, and may be associated with a fistulous communication between the Œsophagus below the occlusion and some part of the air passages, usually the trachea.

**Inflammatory Affections of the Œsophagus** are not common, except as the result of injury or the swallowing of corrosive fluids. Chronic catarrh, with enlargement of the mucous glands, is said to occur in spirit-drinkers. Superficial ulceration may then take place, and has been known to give rise to somewhat profuse hæmorrhage. Chronic catarrh is usually accompanied by some muscular hypertrophy. The symptoms of this condition are too indefinite to allow of accurate diagnosis, and the pathological appearances have been observed in patients who died from other causes. It is possible, however, that long-continued catarrh may be a cause of simple stricture.

**Varices** of the Œsophageal veins in cases of chronic alcoholism, usually with well-marked cirrhosis of the liver, have occasionally been described. The veins of the lower end of the Œsophagus have been chiefly affected. The symptom produced by such a condition is hæmatemesis, which has been known to prove fatal.

**Ulceration of the Œsophagus** may be simple, syphilitic, tuberculous, or malignant, all of which are rare except the last. Simple ulceration is most commonly traumatic, arising from the impaction of a foreign body or from swallowing a corrosive fluid. It may in rare cases arise as a consequence of chronic catarrh. Chronic ulceration of the same nature as that occurring in the stomach is said to occur in the Œsophagus at the cardiac end, but this is somewhat doubtful. The Œsophagus may, however, be implicated in a gastric ulcer, and the cardiac orifice thus narrowed. Syphilitic and tuberculous ulceration are both decidedly uncommon, though several such cases have been

recorded. Perforation of the œsophagus, as the result of ulceration, very seldom occurs except in malignant disease. All forms of ulceration tend to cause narrowing of the canal. In the malignant form this is the result of the cancerous growth surrounding the tube; in the other varieties it is due to cicatricial contraction as healing takes place. The symptoms of ulceration of the œsophagus are pain and difficulty in swallowing, usually referred to some definite spot. The patient may occasionally bring up blood. The diagnosis of one form of ulceration from another must always be uncertain. Little can be done in the way of treatment beyond supporting the patient's strength by the administration of fluid nourishment. If there is any reason to suspect ulceration great caution should be exercised in passing a bougie, lest the diseased coats be perforated. If the ulceration be not malignant the signs of stricture of the œsophagus manifest themselves as the sore heals.

**Diverticula from the Œsophagus** are occasionally met with. According to Zenker and Von Ziemssen they are of two kinds, one being due to pressure from within, and the other to traction from without. The former are not common: they are formed by a protrusion of the mucous membrane through the muscular coat, usually rather in the lower end of the pharynx than in the œsophagus. The pouch thus formed has varied in the recorded cases from the size of a hazel-nut to that of a child's head. It is always situated behind, lying between the vertebræ and the œsophagus, and extending downwards along the spine, in some cases reaching even to the bifurcation of the trachea. The development of the sac is very slow, some of the recorded cases having lasted for ten or even twenty years before giving rise to serious symptoms. The symptoms produced by these diverticula are due to the distension of the sac with food, by which the œsophagus is pressed upon and deglutition interfered with to such an extent as even to cause death. When the sac is distended with food it forms a swelling on each side of the neck, in which a gurgling may be felt on manipulation. By firm pressure the food, sometimes in a more or less advanced stage of putrefaction, may be forced back into the pharynx. In some cases the patients have learned to do this for themselves, and by repeatedly emptying the sac and attempting to swallow again, have managed to get down sufficient food to maintain life. A bougie passed down the throat commonly enters the pouch, and can be moved about in it; great care must, however, be used if a diverticulum is suspected, lest the instrument be forced through its wall. The *causes* of these diverticula are very uncertain. They have been met with most commonly after the age of 30. They are not connected with narrowing of the gullet below. It is probable that they are due to some congenital weakness or malformation of the part. Until recently the *treatment* of this rare condition was most unsatisfactory. Owing to the difficulty of avoiding the entrance to the pouch, it is almost impossible to feed the patient by means of a tube, and therefore gastrostomy has been performed in cases in which starvation was imminent. During the last few years, however, the suggestion of König—to remove the pouch and close the opening—has been successfully put into practice by Von Bergmann, Kocher and Butlin. Butlin's patient was a man, forty-seven years of age, who presented the characteristic symptoms of an œsophageal pouch. The operation was carried out on the lines adopted by Von Bergmann. An incision was made along the anterior border of the left sterno-mastoid from the hyoid bone nearly to the sternum. The omo-hyoid and superior thyroid artery were then divided

and the carotid sheath drawn outwards. "The larynx was rotated on its long axis by drawing forward the left ala of the thyroid cartilage with blunt hooks, so that the pharynx was separated from its bed and its posterior surface presented towards the left side." The pouch was next freed from its surroundings and a probe passed into it from the mouth. The slightly constricted neck was then cut through and the opening closed with eight fine silk sutures. An œsophageal tube was passed into the stomach, and the wound filled with iodoform gauze, the extremities only being sutured. The tube was removed on the same evening on account of the distress which it occasioned, and the patient fed by the mouth. From the 3rd to the 13th day a little liquid food escaped from the wound. The patient was perfectly well a year after the operation, and "could swallow all kinds of food without discomfort."

The funnel-shaped diverticula due to traction from without are smaller. They are commonly seated near the bifurcation of the trachea, in the anterior wall. They are caused by the contraction following inflammatory processes outside the œsophagus, such as the inflammation of a bronchial gland. They are of little consequence, and give rise to no serious symptoms, unless a foreign body should happen to lodge in the pouch, and there set up inflammation and ulceration. Their presence has only been recognized after death.

**Simple Tumours of the Œsophagus** are rare and usually assume a polypoid form. Fibromata or myofibromata have most frequently been met with, but Klebs states that lipoma and myxoma have also been observed.

Fig. 753.—Carcinoma of Œsophagus.

**Sarcoma of the Œsophagus** is extremely rare. No example of the disease had been brought before the Pathological Society of London until 1889, since which time three specimens have been exhibited, by Targett, L. Shaw and Rolleston.

**Carcinoma of the Œsophagus** is by no means uncommon. It occurs chiefly in three situations—at the upper end of the gullet, implicating also the lower part of the pharynx behind the larynx, about the middle opposite the bifurcation of the trachea, and at the cardiac end; but it has been met with in all parts of the canal. In at least 70 per cent. of the cases the disease assumes the form of squamous carcinoma, and this is almost invariably the case when it is seated at the upper part. At the lower end glandular carcinoma is more common. A few rare cases of glandular carcinoma (scirrhus or more rarely encephaloid), apparently originating from the mucous glands, have been met with in other parts of the canal. All forms of carcinoma tend to spread round the tube, and thus diminish and finally occlude its lumen, giving rise to the symptoms of stricture of the œsophagus. Ulceration occurs sooner or later, and may lead to perforation into the pleural cavity or the trachea according to the situation of the growth, or a large vessel may be opened, causing hæmorrhage. In the great majority of cases, however, death

occurs from starvation before the local disease is sufficiently advanced to cause these complications. Secondary growths are rare except in the lymphatic glands. In a case in University College Hospital, however, secondary growths occurred in several bones as well as in the lymphatic glands and lung. Spontaneous fracture occurred in the humerus on each side, and in one clavicle. Microscopic examination showed the primary tumour, which was seated a little below the larynx, to be a glandular carcinoma. The further symptoms and treatment will be discussed with stricture of the œsophagus.

**Stricture of the Œsophagus and Dysphagia.**—The characteristic feature of all forms of œsophageal obstruction is that the patient is conscious of the fact that the bolus of food after leaving the pharynx is arrested at some point on its way to the stomach. He will usually indicate the point with his finger externally, and often with great accuracy. Dysphagia may be due to three classes of causes: first, to conditions unconnected with any actual narrowing of the œsophagus; secondly, to nervous or spasmodic stricture; and thirdly, to organic stricture.

**Conditions producing Dysphagia independently of Stricture.**—These are numerous, and may be divided as follows:—

1. **Tumours connected with the Pharynx.**—Putting out of consideration tumours of the tonsils, which would always be readily discovered, *polypus* of the pharynx may hang down and offer obstruction to the passage of food. In all polypoid growths connected with the pharynx (which are exceedingly rare) the nature, connexions, &c., of the growth may be made out by drawing the tongue well forward, keeping it fixed with a spatula, and passing the finger well down behind the root of the organ; the pharynx can thus be explored, even below the root of the epiglottis, without much difficulty. *Abscess* may exist between the posterior wall of the pharynx and the spine, or a *retropharyngeal tumour*, as, for instance, a sarcomatous growth, may be developed from the bodies of the vertebrae, and push the pharynx forwards. The eye is often deceived in these cases, failing to detect the existence of an enlargement at the back of the pharynx; but the finger readily recognizes it. In the case of abscess there is fluctuation, and the dysphagia will be removed by opening the abscess and letting out the contents; and the solid, or semi-solid and soft, or other feel of a tumour in this situation will suggest its probable nature. Diverticula from the upper end of the œsophagus or lower end of the pharynx (p. 713), are also a rare cause of dysphagia. Angular curvature forwards of the cervical spine projecting into the pharynx has been recorded as causing dysphagia.

2. **Morbid Conditions of the Larynx.**—Œdema about the back of the epiglottis, or ulceration, and thickening of the mucous membrane, dependent upon syphilis or tubercle, or œdema about the rima glottidis, may give rise to a tendency for liquids to pass into the air-passages, and thus occasion a serious impediment in swallowing, the difficulty being attended with a feeling of spasm and suffocation. By passing the finger down behind the root of the tongue, the state of the parts can sometimes be felt, and the actual condition can readily be ascertained by the use of the laryngoscope; but the combination of dysphagia with a suffocative fit, and these probably associated with laryngeal cough, are the chief points in the diagnosis.

3. **Tumours in the Neck outside the Œsophagus.**—Enlarged glands or a carotid aneurism, developing posteriorly, as has been known to occur

with the internal carotid artery; or a tumour connected with the thyroid body, tightly bound down by the sterno-mastoid muscles and cervical fascia, may, by pressing on the Œsophagus, give rise to dysphagia. In all cases where that symptom is complained of, the neck should be examined carefully for tumours, which will generally be very readily detected, especially when the difficulty has existed for some time, and there is much emaciation.

4. **Aneurism of the Innominate Artery.**—When this disease has risen into the root of the neck it is easily recognizable; but in certain cases it develops first in a direction backwards, and then one of the earlier symptoms is dysphagia. Indeed, the patient may suffer but little from any other symptom, and may apply to the Surgeon for relief from it alone, quite unconscious of the existence of any serious disease. The diagnosis will be effected by careful attention to the symptoms described at p. 161 *et seq.* In such a case, much danger might be incurred by passing a bougie into the Œsophagus, under the impression that stricture existed; for the point of the instrument might perforate the sac of the aneurism, and so give rise to instant death.

5. **Aneurism of the Aorta**, whether of the fusiform or the sacculated variety, may give rise to difficulty of deglutition by pressure on the gullet. In this case, also, there is great danger of the aneurismal sac being pierced by an instrument passed down for the purpose of ascertaining the existence of stricture. The presence of the symptoms of intrathoracic aneurism, described at p. 153 *et seq.*, will determine the diagnosis.

6. **Intrathoracic Tumours**, such as enlarged bronchial glands, or sarcomatous and other growths, projecting from the thoracic spine into the posterior mediastinum, may compress the Œsophagus. In such cases the diagnosis is very difficult. It is difficult enough to determine the existence of a tumour, but still more so to distinguish it from a consolidated aneurism; but dulness on percussion, and dyspnoea with dysphagia, together with fixed pain in or to one side of the spine, with neuralgia down the arms or up the side of the head, and a dilated condition of the superficial veins of the chest, are the signs on which we chiefly rely in diagnosing the existence of a tumour.

7. **Dislocation of the Sternal End of the Clavicle Backwards**, whether traumatic, or produced in consequence of excessive lateral curvature of the spine, may give rise to difficulty of deglutition. Of the latter kind there is one case recorded by Astley Cooper, in which the sternal end of the clavicle so obstructed the passage of food, that the patient was brought into a condition of extreme danger. Davie, of Bungay, under whose care the woman was, sawed off the sternal end of the clavicle, and thus completely relieved her.

8. **Impaction of a Foreign Body in the Gullet.**—Although a foreign body, such as a piece of bone, or the setting of artificial teeth, generally lies across the gullet in such a manner as to be easily felt with a probang, there are cases in which it becomes so lodged in the canal as to escape detection. I once saw a man who was said to have swallowed a piece of gutta-percha, with which he had endeavoured to construct an artificial masticatory apparatus for himself. A Surgeon who examined him a few days afterwards failed to detect any foreign body. Inability to swallow solids came on, and when I saw him six months afterwards, the question was, whether the foreign body was still impacted in the Œsophagus, or whether the symptoms arose

from damage inflicted on that tube. I examined the œsophagus carefully, but failed to discover the existence of any foreign body. I thought that the œsophagus had been injured in some way, and that probably epithelioma was developing. One day, while at dinner, the patient suddenly vomited a large quantity of blood, and fell down dead. On examination, we found that the piece of gutta-percha was imbedded in the wall of the œsophagus, and that the ulceration of the mucous membrane caused by its presence had opened some vessel—which, we could not ascertain (it was not, however, either the carotid artery or the jugular vein)—thus giving rise to the sudden hæmorrhage which had caused the patient's death. The surface of the gutta-percha which looked into the œsophagus, being constantly covered over by mucus, and being protected, as it were, by a rim of swollen mucous membrane, had allowed the bougie to pass easily without its presence being detected.

9. **Paralysis of the Muscles of Deglutition** occurs occasionally as a sequel of diphtheria, and in the rare affection of the medulla known as labio-glosso-pharyngeal paralysis, but this is hardly to be confounded with obstruction of the œsophagus.

In the **Diagnosis** of stricture of the œsophagus it is necessary to bear these conditions in mind, and if possible to exclude them before proceeding to examination of the gullet by means of a bougie.

**Hysterical or Spasmodic Stricture** is met with chiefly in females under twenty-five, though it may occur in older persons of the hysterical temperament. It is possible for it to occur without any evident organic disease, but I believe that simple uncomplicated hysterical stricture is very rare. In the majority of instances it will be found to be dependent upon some simple condition, such as chronic inflammation of the pharyngeal mucous membrane, or follicular inflammation about the epiglottis and posterior part of the larynx. The disease in many cases is supposed to have been occasioned by the swallowing of a foreign body, which after many months is still thought to be impacted. This is almost always erroneous. The foreign body may have been swallowed, and may have been the starting-point of the slight inflammation or ulceration that occasions the dysphagia, but it has long since disappeared, leaving merely a series of troublesome consequences in its train. The obstruction is generally high up in the pharynx, rather than in the œsophagus; being produced by the contraction of the constrictor muscles. The dysphagia is intermittent; when the patient's mind is allowed to dwell long on the affection, and she becomes anxious about it, then the difficulty is greatly increased; whilst at other times, when her thoughts are diverted from it, food passes easily. It will be found also, in these cases, that on attempting to pass a large bougie, its progress will at first be resisted, but, by gently pressing upon the stricture, the instrument will soon pass easily.

**Organic Stricture**, as before stated, may be fibrous or cancerous. *Fibrous Stricture* is in the great majority of cases due to the contraction of a scar resulting from injury or from the swallowing of corrosive fluids. It is said in very rare cases to be a consequence of chronic catarrh, or of syphilitic or tuberculous ulceration. At the cardiac orifice it may be due to the contraction caused by the healing of a chronic ulcer of the stomach. *Cancerous Stricture* is more common than fibrous. The nature of the growth has already been described (p. 714).

Organic stricture, whether fibrous or cancerous, is characterised by a

progressively increasing difficulty in swallowing, often unaccompanied by pain. At first the difficulty occurs only with somewhat large solid masses; then the patient can only swallow soft or finely divided substances; then fluids pass with difficulty, and finally complete obstruction sets in, and unless relieved the patient dies of starvation. If the obstruction is some way down, the œsophagus commonly becomes dilated above it, and a pouch is thus formed, which may contain some ounces of fluid. Small quantities are thus apparently swallowed, but after a short time are returned. Sometimes the regurgitated fluid is brought up suddenly with some force, as if squirted up rather than vomited. It may thus come out partly through the nose. The matter brought up shows evidence of not coming from the stomach, being still alkaline, if so when swallowed. By auscultation along the back while the patient swallows a mouthful of water, it is sometimes possible to ascertain the point at which the downward passage of the fluid is arrested. A harsh cough, with hoarseness or aphonia, is sometimes met with, probably from irritation of the recurrent laryngeal nerve. The patient may suffer much from accumulation about the glottis of mucus, which he can neither bring up nor swallow. Occasionally much discomfort may be caused by flatus rising from the stomach into the œsophagus below the stricture.

In the **Diagnosis of Organic Stricture** it is necessary to determine first the presence of the stricture, and secondly, if possible, whether it be fibrous or cancerous. The other causes of dysphagia having been excluded if possible, the presence of the organic stricture may be determined by examining the canal with a bougie.

To pass an œsophagus-bougie the Surgeon should stand before the patient, who should be seated. The bougie should be softened in warm water and greased with glycerine. The head must be inclined slightly forwards; if it is thrown back the larynx is pressed against the spine, and the bougie will not pass readily. The obstruction thus caused is easily mistaken for a stricture. The instrument before being passed may be slightly curved, and it must be guided down the pharynx by the forefinger passed into the mouth. It commonly causes retching and some dyspnoea as it passes the glottis. There is no fear of passing the bougie even when small into the larynx by mistake, as the point of the instrument is directed towards the posterior wall of the pharynx. After the point of the instrument has passed the glottis, the patient will breathe more easily, and it may then be steadily passed onwards. If an obstruction is met with the bougie may be gently and steadily pressed against it, but if it does not readily yield a smaller instrument must be tried, and so on until one passes if that be possible.

The facts ascertained by the use of the bougie are the seat and degree of the stricture. It may also furnish some evidence as to the nature of the disease. If it gives the sensation of passing over a rough irregular surface, and if when no force has been used blood is found on the bougie or is brought up afterwards, this would suggest the existence of a malignant growth, but the absence of these signs by no means proves that the stricture is fibrous.

The diagnosis may, however, be made by attention to the following points. In *simple stricture* there is probably a history of the cause, such as injury, swallowing caustic fluids, or possibly of syphilitic ulceration in the pharynx. A stricture in a patient below 30 is probably not cancerous. Slow development of the obstruction is in favour of a fibrous stricture. In *cancerous*

*stricture* the disease occurs after 30, and in men more often than in women. It develops rapidly, the history seldom extending beyond six months when the case is first seen. Blood and pus may be brought up with the regurgitated matter. The mass formed by the tumour may sometimes be felt in the neck, and enlargement of the lymphatic glands is commonly present. The diagnosis will, however, often be uncertain, especially when it is remembered that epithelioma may commence in a scar in the œsophagus as in other parts of the body. The electric *œsophagoscope* does not appear to be of much practical utility.

The **Treatment** of a stricture of the œsophagus will depend upon its nature. In the *hysterical variety*, the occasional introduction of a full-sized bougie, the application of belladonna to the neck, and anti-hysterical treatment generally, iron, aloëtics, assafoetida in large doses, douches, and diverting the patient's mind, are the means to be employed.

In the treatment of *organic stricture* care must be taken to maintain the patient's strength by proper feeding. Finely minced meat, strong soups, raw eggs, and soft puddings should be given so long as the patient can swallow them. As the difficulty becomes greater, so that even liquids can be taken only slowly and in small quantities, it becomes necessary to feed the patient through a gum elastic tube passed beyond the stricture.

When feeding by a tube becomes necessary, it has been recommended to tie it permanently in position. This, however, prevents the swallowing of the saliva and causes considerable irritation where it lies against the larynx. To obviate this, Charters Symonds has successfully used a gum elastic tube, about six inches in length and the size of a No. 10 or 12 catheter, the upper end of which is funnel-shaped, so as to rest upon the stricture. To the edges of the funnel two silk threads are attached and brought out at the mouth by which the tube can easily be removed when necessary. It is passed by means of a common bougie inserted into the funnel. In one of Symonds's cases the man wore the tube for eight months after natural deglutition had become impossible, swallowing easily through it. It was changed about once in two weeks unless it became choked. Although the stricture was malignant the presence of the tube did not seem to aggravate the disease.

When feeding by a tube is impossible, the patient may still be kept alive for some weeks by nutritive enemata, but unless relieved by operation inevitably dies before long of starvation.

In the treatment of the stricture much will depend upon its degree and nature. In *simple cicatricial strictures*, if not very extensive or very narrow,

Fig. 754. — Epithelioma of Pharynx and Œsophagus causing Stricture.

much may be done by the repeated passage of conical bougies, which the patient may be taught to use for himself. In this way he may succeed in keeping the canal patent; but should he neglect the treatment a relapse speedily follows. In introducing bougies into the stricture there is often a good deal of difficulty, more particularly when the constriction commences suddenly and the œsophagus is dilated above it. This may, however, be overcome in most cases by patience and care. Besides the simple dilatation by bougies, various other modes of treatment analogous to those adopted in stricture of the urethra have been tried with more or less success. I have in some cases seen temporary benefit result from the use of a catheter, surrounded by a tube of vulcanized india-rubber, which admitted of dilatation by the injection of water or air when introduced through the stricture; or from the employment of a tubular instrument, by passing a long small-sized bougie through the constriction, and then slipping over it a gum elastic catheter with a rounded terminal aperture. It is needless to observe that, in the treatment of stricture of the œsophagus with bougies, no force should be used, lest the walls of the canal be perforated.

Various instruments have also been invented for mechanical dilatation by separation of metal blades by a screw action, but the results obtained by their use have not as a rule been satisfactory. Internal division of the stricture by a concealed knife passed through it has also been attempted. Gross collected 18 cases in which this operation was performed. Of these 2 died of peritonitis, 2 from the effects of complete division of the œsophagus, 1 from hæmorrhage, and 1 from pleurisy; and of the survivors only 3 seemed to be really benefited. In three cases of simple stricture at the cardiac orifice Loreta dilated the lower end from an opening made in the stomach, which was closed at once; all recovered. Kendal Franks has collected 18 other cases, including one of his own, in which this so-called "retrograde dilatation" has been practised with very satisfactory results. If other means fail, as they most commonly do, the operation of gastrostomy must be performed as in malignant stricture; there is a fair hope of thus restoring the patient to tolerable health, especially in cases of cicatricial strictures after swallowing caustics in children. In two such cases Clutton and Morgan were able subsequently to dilate the stricture and allow the gastric fistula to close.

In a case in which Eve performed œsophagotomy for the removal of a Symonds's tube which had become impacted in a fibrous stricture, the latter was freely divided with a most satisfactory result.

In *malignant stricture* a Symonds's tube has in some instances been used with success (p. 719), but in most cases the passage of a long œsophageal tube is required, and should be continued as long as plenty of nourishing food can be administered through it. Sooner or later this treatment generally becomes impossible on account of the contraction of the stricture, or the pain or hæmorrhage caused by the passage of the instrument. Under these circumstances the choice lies between the use of nutritive enemata and the performance of gastrostomy as proposed by Sédillot. By *Gastrostomy* is meant making a fistulous opening into the stomach by which food can be directly introduced. If this operation is to take its place as a useful means of treatment, it should be performed as soon as any real difficulty occurs in feeding the patient with a tube, and before he is reduced to a hopeless condition by prolonged starvation. By the use of enemata I have known

life prolonged, by a frail tenure it is true, for many weeks. In such cases it is an interesting physiological fact that, although the patients may continue to be moderately well nourished, and do not feel the pangs of hunger, they suffer excessively from thirst.

**Operation of Gastrostomy.**—The object of the operation is to expose the stomach, and to make a fistulous opening in that part of it which is naturally in contact with the abdominal wall, and uncovered by the ribs. The operation consists of three stages:—1. The exposure of the stomach; 2. Its adhesion to the lips of the incision in the abdominal wall; 3. The making of an opening into it. The area to be exposed is not large, and corresponds externally to the cartilages of the eighth, ninth, and tenth ribs; above and internally it is bounded by the lower edge of the liver. In the contracted state of the stomach the pylorus lies immediately to the right of the middle line; it is advisable, therefore, to make the incision as far to the left as can conveniently be done. Labbé recommends an incision about an inch and a quarter to an inch and a half in length, parallel to the left costal cartilages, and one inch from their borders, terminating below at an imaginary line drawn between the most prominent points of the convexities of the two ninth cartilages. This incision will be found to divide a few fibres of the external oblique and notch the edge of the rectus; beneath this is the expansion from the internal oblique and the upper fibres of the transversalis, under which lie the transversalis fascia and the peritoneum. Howse, who has had great experience in this operation, recommends a somewhat longer incision in the same direction, commencing about one inch and a half from the middle line. When the sheath of the rectus is exposed he holds the wound widely open, and makes a vertical incision in it a little way from its outer margin. The fibres of the muscle are then separated with the handle of the scalpel, and the posterior layer of the sheath and peritoneum is also divided vertically. The fibres of the rectus thus exert a sphincter-like action on the opening when the wound is healed. In whichever way the abdominal wall is divided, all bleeding must be carefully arrested before the peritoneal cavity is opened. On dividing the peritoneum the stomach may present at the wound, and may be grasped with the fingers and drawn out. If it is not at once seen the finger must be introduced and the lower border of the liver felt for, immediately below which will be the stomach. When the stomach is felt, it may be drawn up into the wound by the fingers, if possible, if not, by a pair of ring-forceps; vulsellum-forceps must on no account be used. If the omentum presents in the wound, it should be drawn gently downwards until the stomach comes into view. The only viscus which can be mistaken for the stomach is the transverse colon, the left end of which may present in the wound. The stomach can be recognized by the thickness of its walls and the extent and smoothness of its surface. The next step is to secure it to the opening. This is best done by carbolized silk sutures passed through the serous and muscular coats only. This is easily accomplished by gently pinching the coats of the stomach between the finger and thumb, when the mucous coat will be felt to slip away, leaving the other two in the grasp of the fingers. A series of six or eight sutures is passed in such a way as to include a circular area of the stomach about an inch and a half in diameter. Each end of each suture is then separately threaded on a needle, brought out through the whole thickness of the abdominal wall at a short distance from the edges of the incision, and the ends knotted together

over small pieces of gauze. The ends of the opening in the abdominal wall are closed by one or two sutures previously inserted, and finally, a fine continuous stitch is inserted in such a way as to approximate the serous coat of the stomach to the skin, leaving exposed an area of the former equal in size to a shilling. In the centre of this two silk sutures about a third of an inch apart are inserted; the ends of these, which are left long and not knotted, serve as guides to the stomach when it is subsequently opened. This method of suturing, which differs only slightly from that recommended by Howse, has been variously modified. Thus Greig Smith passes a continuous circular suture, which is left projecting in loops at short intervals. Each loop is threaded on a needle, brought out through the abdominal wall, and drawn tight over a piece of indiarubber tube slipped through it. Some operators have dispensed with the use of sutures by passing two hare-lip pins through the wall of the stomach, transversely to the direction of the wound.

After the operation a small quantity of beef-tea may be introduced into the stomach with the finest aspirator-needle if the patient is very exhausted, and this may be repeated daily, but if the strength is fairly good he should be nourished for the next four or, if possible, five days by nutritive enemata. By that time the stomach will have formed firm adhesions, and may safely be opened. This is done by gently drawing forward the two silk sutures already in position and puncturing the stomach between them with a sharp tenotome. The opening should be large enough to admit a No. 10 india-rubber catheter, which may be secured by twisting the silk stitches round it. At first only milk or pancreatized food should be introduced, but, as the stomach becomes stronger, minced meat, bread, and other food may be used.

The risk of peritonitis has been very greatly diminished, first by the adoption of the method of operating in two stages, and secondly by the use of antiseptics. The advantage of delaying the opening till firm adhesions have formed is clearly shown by the statistics published by C. L. Vitringa, who has collected altogether the records of 155 cases of gastrostomy. From these he shows that before the introduction of antiseptic treatment 55 per cent. of the patients died directly from the operation, but since that period the death-rate has been reduced to 27 per cent. If the antiseptic cases are divided into those in which the opening was made into the stomach at the time of the operation and those in which it was delayed till adhesions had formed, we find the death-rate was 53 per cent. in the former and only 17.5 per cent. in the latter. In many cases, although the patient does not die directly from the operation, life is but little prolonged by it, as the stomach seems unable to resume its functions. This most commonly has happened in cases of malignant stricture, in which the operation has been deferred till the patient was in the last stage of exhaustion. This is clearly shown by the statistics collected by Gross of 167 cases in which the operation was performed for malignant stricture. Of these 117 died within the first month, 49 directly from the operation, 28 more died under ten months, and only 1 survived a year. In such cases the advantages and the dangers of the operation must be laid fairly before the patient, but it is not the duty of the Surgeon to urge him to submit to it.

In cicatricial strictures, on the other hand, when death from starvation is otherwise inevitable, the Surgeon is justified in advising the operation. Gross has collected 37 cases of this kind. Of these 20 died within a month, 11 directly from the operation. Of the remaining 17, 9 survived to the fourth

year, in 1 the record was incomplete, and 7 were living at the time of the report. In a case of this kind operated on by Trendelenburg, the patient was alive and well many years after the operation. He took food by masticating it thoroughly and then blowing it from his mouth into the stomach through a tube fitted to the cannula.

In many cases a good deal of trouble has been occasioned after the operation by the escape of gastric juice from the fistula. This causes great irritation of the surrounding skin, apparently by a process of digestion. It is best avoided by not making a larger opening than is absolutely necessary. In the vertical incision adopted by Howse the sphincter-like action of the fibres of the rectus tends in great measure to prevent this complication. Should the skin become sore it may be relieved by being washed with an alkaline solution and protected by vaseline.

In a few cases **oesophagostomy**, or making a fistulous opening in the gullet below the obstruction, has been practised instead of gastrostomy. The operation is performed in the same way as for removal of a foreign body (Vol. I., p. 845), a tube being inserted through which food can be administered. Gross has collected 21 cases of malignant stricture treated in this way. Only four recovered from the operation, and all these died within six months. Of five cases of simple stricture treated by this method none recovered. It is evident, therefore, that this operation is not preferable to gastrostomy.

**Cesophagotomy**, or excision of the cancerous portion of the œsophagus, can be practised only in the early stages of the growth, before it has formed any adhesions to important parts, and only when the disease is seated at the upper extremity of the œsophagus. It was suggested by Billroth, and first successfully performed by Czerny in 1877. Since then the operation has been performed in five other cases. Of the six, three died directly from the operation, and of the survivors all died within a year, of recurrence.

In the later stages of malignant stricture of the upper part of the œsophagus, *tracheotomy* occasionally becomes necessary, from implication of the glottis or larynx.

#### DISEASES OF THE LARYNX.

The larynx may be the seat of a great variety of morbid conditions. Acute inflammation, œdema, and follicular inflammation; ulcerations and chronic thickenings of the mucous membrane; inflammation and necrosis of its cartilages; and the formation of tumours or polypoid growths in its interior, may all occur.

**LARYNGOSCOPE.**—It is of the utmost importance in the diagnosis, and for the proper treatment of these affections, that a view should be obtained of the parts that are the seat of disease. This can be done only by means of the **Laryngoscope**. The introduction of this instrument into practice and its perfection have been a work of time. It appears to have been invented and first used in 1829, by Babington, who, under the term "Glottiscope," described an instrument consisting of a small mirror fixed to a wire shank, which, being placed against the palate whilst the tongue was held down, enabled him to view the glottis and upper part of the larynx; more especially when he illuminated these parts by throwing reflected light upon them from a mirror held in his left hand. Liston, Trousseau, and Avery all made attempts in the

same direction. It was, however, the celebrated singer Garcia, who, in 1854, by throwing the sun's rays into the back of his mouth from a mirror held in his left hand, and then introducing a dentist's reflector into his mouth, saw the image of his own larynx and studied its movements in the reflection of the looking-glass. But it is undoubtedly to Czermak that the merit is due of having been the first, in 1857, to apply laryngoscopy to the study and diagnosis of diseases of the larynx.

The *laryngoscope* essentially consists of two instruments, a reflector, which may be attached by a spectacle-frame or an elastic band to the Surgeon's forehead, and a mirror (Fig. 755), which is held in his right or left hand, according to circumstances. The patient sits with his back to a good light; that of the sun does very well if it can be obtained, but usually artificial light has to be employed. This may be obtained from a lamp, the flame of which should be a little above the level of the patient's ear. The Surgeon, facing the light, arranges the reflector in such a way that, whilst both he and the patient are

Fig. 755.—Throat Mirror.

in easy positions, a well defined circle of light covers the patient's mouth. If, as in many arrangements, the reflector be over one eye of the Surgeon, he must so place it that he sees clearly through the hole in the centre, and can consequently employ both eyes in examining the throat. The patient now having the head very slightly inclined backward, opens his mouth and puts out his tongue. The Surgeon grasps the tip of the tongue gently between the forefinger and thumb of his left hand, covered by a cloth or pocket-handkerchief. He must be careful not to drag on the tongue, but merely to hold it steady, supporting it underneath and keeping it from being hurt by the lower teeth, by the forefinger passed across its under surface. He now takes the small mirror and warms it over the lamp, so that the patient's breath may not condense on it and obscure the image of the larynx. Having warmed it till he sees the cloud of condensed moisture from the lamp disappear, he tests it against his own cheek to feel that it is not too hot, and then introduces it in the following way: The handle being held like a pen, and rather to the left side of the patient's mouth, the mirror is passed in carefully, having its surface parallel to the dorsum of the tongue, until the tip of the uvula rests on its back, and is pushed slightly backwards and upwards by it. Care must be taken in doing this that the reflecting surface does not touch the tongue, and that the mirror is not passed so far as to touch the back of the pharynx, which in most patients would cause an effort at swallowing. The mirror being in the position above described, the Surgeon will, if he see anything, view the back of the pharynx reflected on its surface; but, by gently and steadily raising his hand, so as to render the angle formed by the surface of the mirror with the patient's body about half a right angle, he will bring the opening of the glottis into view. By raising the hand still a little further, he can examine the epiglottis and the root of the tongue. It

must be remembered that the image thus produced is reversed in the antero-posterior direction, the parts that appear anterior on the mirror being really posterior ; while in the transverse direction there is no reversal.

When the Surgeon requires both hands, as in the application of caustics or in the removal of growths or foreign bodies, the patient must be made to hold his own tongue, or it must be held by an assistant. The Surgeon then holds the small mirror in his left hand, and the instrument he is using in the throat in his right. Sometimes all view of the larynx is obscured by the patient obstinately arching the tongue in the mouth. It must then be held down by a spatula. In some patients, the fauces are so irritable that the slightest touch causes violent retching. This may be completely overcome by painting the fauces with a 20 per cent. solution of cocaine about five minutes before the examination is made, or by using a spray of a 4 per cent. solution. If cocaine be not at hand, the irritability may be allayed by sucking ice for a short time.

**Laryngitis.**—Inflammation of the larynx occurs both in adults and in children, though more commonly in the former, from exposure to cold, and various other causes. Laryngitis may not only be of an acute or a chronic kind, but the acute form likewise presents two distinct varieties, according to the parts affected, the cause from which it arises, and the condition of constitution in which it occurs : in one, the true **Acute Catarrhal Laryngitis**, the inflammation is seated chiefly in the mucous membrane ; in the other, the **Œdematous Laryngitis**, the affection extends to the submucous areolar tissue, within and around the larynx.

In all inflammatory affections of the larynx, whether acute or chronic, there is danger to life ; the narrow chink of the glottis rapidly becomes occluded, and asphyxia consequently results. This may happen either by the swelling of loose folds of mucous membrane about the upper opening of the glottis ; from membranous exudation upon the vocal cords ; or by the occurrence of spasm in the larynx. Indeed, there is usually more or less spasm conjoined with all the acute inflammatory affections of this part ; and the spasm, superadded to already existing mechanical occlusion, is a common cause of death. The spasms do not at first recur oftener than at intervals of half an hour or an hour ; but as the disease advances they become more frequent, and in any one of them the patient may be carried off. This freedom from permanent occlusion commonly occurs in cases of laryngitis ; and the immediate cause of death in the majority of instances appears to be spasm, conjoined with defective arterialization of the blood, which causes congestion of the lungs and convulsions.

**Acute Catarrhal Laryngitis** may arise from exposure to cold, from violent strains of the vocal apparatus, or from extension of catarrh from the nose or pharynx. It is most common in adult males, but may occur in children. One attack predisposes to another. The mucous membrane only being affected, the *symptoms* are not indicative of such marked interference with respiration as is met with in the Œdematous form of the disease. There are dryness of the throat and hoarseness, with pain varying from mere tickling to a severe sense of constriction. Occasionally there are pain and tenderness on pressing upon the larynx, more especially about the pomum Adami. The voice is at first harsh and rough, then stridulous, and finally may be completely lost ; there may be some pain and difficulty in deglutition.

In simple catarrhal laryngitis there is rarely any serious dyspnoea or spasm, but in children there may be considerable difficulty in respiration, especially if the glottis becomes covered with dried mucus during sleep. There is expectoration of frothy mucus, sometimes tinged with blood, and the act of coughing is accompanied by considerable pain. With the laryngoscope the intensely injected state of the mucous membrane of the larynx can be seen ; but this is not accomplished without difficulty, partly from the irritability of the fauces, and partly from the large amount of tenacious mucus which usually surrounds the glottis. In very severe cases the inflammation may extend to the submucous tissue, and be accompanied by exudation into the loose areolar tissue, and the symptoms then gradually merge into those of the oedematous form of laryngitis presently to be described.

*Treatment.*—The patient should be placed in a warm atmosphere, which should be kept moist by steam carried into the room from the spout of a kettle. This is especially important in children, to prevent the drying of the mucus during sleep. Hot fomentations may be applied to the throat, and the patient should be made to inhale the steam from a pint of hot water, to which a teaspoonful of compound tincture of benzoin has been added. A free purge will generally be found useful at the onset of the attack, and should there be much pain and cough small doses of opium should be administered. Should symptoms of dyspnoea appear, indicating a tendency for the inflammation to assume the oedematous form, more active measures must be adopted, which will be described with that affection.

**Acute Oedematous Laryngitis** may arise as an intensification of simple catarrhal inflammation, as an independent affection by extension from neighbouring parts, or as a complication of various chronic affections of the larynx. In many cases it seems to be erysipelatous in character, occurring as the result of exposure to the impure air of crowded hospitals, to sewer gas, or to the specific infection of erysipelas. In fact, it appears to be at times epidemic, and in its pathological conditions to resemble closely phlegmonous erysipelas of the part, the mucous membrane becoming red, pulpy, and swollen, and the submucous tissue infiltrated with sero-purulent fluid. Oedematous laryngitis is occasionally met with in fevers, especially in scarlet fever, and it is predisposed to in some cases by Bright's disease. It is most commonly met with in adults, being very rare before the age of eighteen. The *symptoms* are usually well marked. The fauces are reddened, dusky, and swollen ; difficulty in swallowing is often an early and prominent symptom, and continues throughout ; dyspnoea, often of a spasmodic character, then appears, the lips becoming livid, the nostrils dilated, the features pale and bedewed with perspiration, the eyes watery and bloodshot, and the respiratory muscles are called into violent action ; gasping efforts at breathing and sudden fits of increased difficulty in inspiration come on ; at the same time the pulse is feeble, though it continues rapid ; and, unless efficiently relieved, the patient will speedily sink. The voice is at first hoarse, but is speedily lost, and there may be some tenderness about the larynx. The dyspnoea is usually peculiar in character in the intervals between the spasms. Inspiration is always more or less difficult, as the swollen parts fall together in a valve-like manner over the opening of the glottis. Expiration, on the other hand, may be comparatively easy. The fatal result is frequently due directly to spasm. The spasms come on early, and are very apt to be brought on by speaking or swallowing ;

but as the disease advances the dyspnoea becomes more continuous, until stupor at length supervenes, and speedily terminates in death. There is usually well-marked febrile disturbance. If the finger be passed over the back of the tongue the rigid swollen epiglottis may be distinctly felt. Laryngoscopic examination shows the epiglottis forming a red semi-transparent roll, usually bent upon itself transversely. It may completely conceal the parts beneath, but in many cases the œdematous aryteno-epiglottidean folds may be seen on each side. It is rarely possible to obtain a view of the cords.

The œdematous infiltration in this form of laryngitis is confined principally to the submucous areolar tissue around the epiglottis, in the aryteno-epiglottidean folds, and over the arytenoid cartilages. In these situations the tissue is distended with an abundant inflammatory exudation, of an opalescent appearance, so that the swollen membrane may almost completely occlude the rima glottidis (Fig. 756). It is a pathological fact of much importance that the effusion never extends below the true vocal cords, being limited at this point by the direct adhesion of the mucous membrane to the subjacent fibrous tissue, without the intervention of any loose areolar tissue.

Fig. 756.—Acute  
Œdema of the Glottis.

*Diagnosis.*—It is of great importance to recognize œdematous laryngitis early, and not to confound it with simple catarrhal inflammation. The laryngoscope is of the greatest use in arriving at a correct diagnosis. It is somewhat difficult to use in these cases, especially if there be much dyspnoea, but supposing even a momentary glance be obtained of the opening of the glottis, the condition depicted in Fig. 757 may readily be recognized. In addition to this, the occasional epidemic character of the affection, the early dyspnoea, and the dusky swollen fauces will point to the œdematous variety.

The *Treatment* should be antiphlogistic, though in many cases the constitution will not bear very active measures. In some cases aconite, antimony, or salines might be of use, but very often the invasion of the inflammation is so rapid that local means must be relied upon rather than constitutional. In cases where there is much œdema scarification with a sharp-pointed bistoury, sheathed with plaster to within a quarter of an inch of its point, will be found the most ready means of unloading the infiltrated mucous membrane. The operation of scarification may be more accurately performed by using the laryngeal lancet, whilst the glottis is brought into view by the use of the laryngoscope. After this, inhalations of the steam from a pint of hot water to which twenty drops of carbolic acid or a drachm of compound tincture of benzoin has been added, will be found to give most relief. Hot fomentations must be applied externally and frequently changed. In the early stages ice may be sucked and applied externally, but after the swelling has commenced steaming the throat usually gives more relief. A 10 per cent. solution of cocaine applied directly to the larynx with a brush or used in the form of a spray will sometimes prove beneficial. If, notwithstanding these remedies, the difficulty in respiration continues to increase relief must be afforded by intubation or by opening the wind-pipe before the lungs and brain have become

hopelessly engorged. The choice between these methods of treatment will be considered in the following chapter. Under no circumstances should the Surgeon delay interference until extreme and continuous dyspnoea has set in; this may never occur, the difficulty in breathing being rather spasmodic than continuous, and in one of the spasms death may suddenly occur. When once dyspnoea with laryngeal spasm has fairly set in, every moment is precious, as the patient may at any time be carried off by the recurrence of the spasmodic seizures. The lungs also may become fatally congested if the difficulty in breathing be allowed to continue too long.

In some cases sloughing and putrid suppuration of the submucous tissue may occur, as in phlegmonous erysipelas of other parts of the body, and the patient may die partly from asphyxia and partly from blood-poisoning. In these cases the administration of stimulants and tonics, more particularly port-wine and bark, with free use of antiseptic inhalations, will be urgently required.

**Traumatic Laryngitis** from scalds, corrosive fluids, &c., has already been alluded to in Vol. I, p. 837. It usually assumes the oedematous form, and requires the same treatment.

**Chronic Laryngitis.**—The larynx is liable to various chronic diseases of a serious character, some of which are incurable, leaving a permanent impairment of the vocal and other functions of the larynx. Chronic laryngitis is usually divided into three varieties, Simple or Catarrhal, Syphilitic, and Tuberculous. All forms give rise to interference with the voice, and some to Aphonia, or complete loss of voice.

**Simple Chronic Laryngitis.**—This affection is common amongst those who habitually exert the voice, and from its frequency amongst clergymen is familiarly known as the *Clergyman's Throat*; it is also of frequent occurrence amongst singers, but may be met with in all classes of the community. In some cases it is the result of a previous attack of acute laryngitis, and it is predisposed to by gout and alcoholic excesses. The voice at first becomes hoarse, and may at last be reduced to a whisper. There is a slightly increased secretion of mucus, but it is never abundant. The patient is constantly troubled by a tickling or spasmodic cough, and at the same time there is usually a feeling as if there were some constant cause of irritation in the throat, attended by a desire to cough up and expectorate. Laryngoscopic examination shows diffused redness, with here and there ramiform injection of the vessels. The true vocal cords have lost their sharp edges, and are somewhat rounded, and at the same time, instead of the pure white colour natural to them, they are usually of a pink tint. Occasionally small wart-like growths or minute superficial erosions may appear on the vocal cords or on other parts of the glottis, as the result of simple chronic laryngitis. In many cases the appearances may be more or less obscured by adherent pellets of tough mucus.

**Treatment.**—The treatment of simple chronic laryngitis requires to be conducted by careful regulation of the general health and selection of climate, avoidance of exposure to cold, attention to digestion and diet, and rest of the parts. All loud or prolonged speaking should be strictly forbidden. In addition to this the local applications of various astringent vegetable and metallic solutions is of the greatest service.

In the milder forms of the disease, glycerine of tannin, applied by means of a

camel's-hair brush, will be found useful. In many cases the best results follow the inhalation of solutions of tannin or sulphate of zinc in a pulverized form, applied by means of the ordinary spray-producer. Mackenzie recommended insufflations of pale powdered catechu with bismuth and a little morphia, and when this does not make much impression, insufflation of eucalyptus (red gum) powder. Stimulating inhalations are also very largely employed; of these the most useful are the officinal vapor olei pini sylvestris and creasote in the strength of 80 drops to half a pint of boiling water.

In the more obstinate cases, especially where there is much thickening of the mucous membrane, astringent solutions should be directly applied to the larynx by means of a laryngeal brush (Fig. 757). The solutions most extensively employed are nitrate of silver (10 to 40 grains to the ounce), and chloride of zinc (20 to 30 grains to the ounce). In using the laryngeal brush the surgeon should be guided by the laryngoscope so that he may see clearly the parts to which he applies it. As the brush is applied the patient should be made to say "ah," so as to raise the epiglottis, and the Surgeon should actually see the brush go behind it. Guided by the laryngoscope, the brush may be momentarily passed between the vocal cords, but the spasm so caused renders it impossible to do more.

Fig. 757.—Laryngeal brush.

The application should at first be repeated about every second or third day, in order to ensure its full effects, but afterwards it may be made at longer intervals.

**Syphilitic Laryngitis.**—According to Morell Mackenzie, syphilitic disease forms about 3 per cent. of all affections of the larynx. In the early stage of syphilis, slight hyperemia, with a little hoarseness, is not uncommon, but it is usually so slight as to pass unnoticed. In the later secondary stages, condylomata or mucous tubercles may be met with. They can be recognized only by the laryngoscope, by means of which they can be seen forming smooth greyish elevations, usually on the epiglottis or the inter-arytenoid fold of mucous membrane. These may be followed by superficial ulceration. The most common and characteristic of the syphilitic affections of the larynx are those met with in the tertiary stages of the disease. The pathological changes observed are the same as in other parts—diffuse overgrowth of the connective tissue or gummatous infiltration, and the formation of isolated gummata. The subsequent softening of the gummata gives rise to wide-spreading, destructive ulceration, and should the patient recover and the ulcers heal, cicatricial contraction follows, sometimes to such an extent as almost to close the opening of the larynx. The parts first affected are usually the epiglottis and the aryteno-epiglottidean folds, and from these points the ulceration extends inwards towards the glottis. Sometimes the gummata may be seen as pale yellowish elevations in the mucous membrane, and should softening and ulceration follow, the yellowish adherent slough may possibly be recognized. Syphilitic ulceration not uncommonly leads to complete destruction of the epiglottis, and in the later stages necrosis of the cartilages frequently occurs. The disease is usually associated with similar ulceration in the pharynx. The symptoms are those of chronic

laryngitis, with muco-purulent expectoration and gradual loss of voice. Gradually increasing dyspnoea is not uncommon from contraction of the opening of the glottis.

*Diagnosis.*—Syphilitic ulceration of the larynx is recognized by the history of syphilis and the presence of other manifestations of the disease, by the rigidity of the affected tissues, by the early affection of the epiglottis, the foul grey surface of the ulcers, or the presence of adherent yellow sloughs, and by the fact that the ulceration commences in the peripheral parts, and spreads towards the central. The rapidity with which the destruction of tissue may take place serves to distinguish it from carcinoma.

*Treatment.*—The usual constitutional treatment of syphilis must be actively adopted. Locally a solution of perchloride of mercury (gr. ij. to ʒj.), may be applied with a sponge or brush, or a preparation of half that strength used as a spray. Iodoform mixed with twice its bulk of starch may be blown into the larynx by means of an ordinary laryngeal insufflator. When healing is taking place nitrate of silver may be of use, but it is not so efficacious as in simple chronic laryngitis. Should the dyspnoea become a marked symptom, tracheotomy must be performed, unless intubation be tried and found successful.

**Taberculous Laryngitis** is usually met with only in advanced disease of the lungs, but occasionally it is the earliest sign of phthisis, and the disease may run its course and terminate fatally without the lungs being extensively affected. This variety is sometimes spoken of as *Laryngeal Phthisis*. The earliest symptoms are merely those of chronic laryngitis. As it advances the voice is lost, there is constant cough, with frothy muco-purulent expectoration and great pain. Deglutition becomes more and more painful, till at last the patient can scarcely be induced to swallow, and death takes place gradually from exhaustion. Laryngoscopic examination may at first show nothing more than marked anæmia of the whole of the larynx without any definite lesion. This should always be looked upon as a suspicious sign, and proper precautionary measures should be taken without delay. Before long, however, a peculiar swelling is observed in the mucous membrane covering the arytenoid cartilages and the neighbouring parts of the aryteno-epiglottidean folds. This gives rise to two pyriform swellings of sufficient size to meet in the middle line posteriorly. It is this swollen mass projecting backwards that causes the pain and difficulty in swallowing. Numerous small ulcers then appear, first in the central parts, and subsequently extending to the peripheral. The under surface of the epiglottis may be early affected. These ulcers gradually coalesce and extend, forming crenulated sores, destroying the vocal cords and neighbouring parts. At any stage of the disease dyspnoea may supervene as the result of œdematous swelling. In the later stages, if the patient survive sufficiently long, necrosis of the cartilages may take place.

The *Diagnosis* is made by the presence of disease of the lungs, the peculiar swelling over the arytenoid cartilages, by the multiplicity of the ulcers and their comparatively superficial character, and by the fact that they appear first in the central parts of the larynx and spread towards the peripheral. One very characteristic mark in pronounced cases is that the whole of the inside of the larynx seems bathed in an abundant creamy secretion. In a doubtful case, the presence of tubercle bacilli in the sputum will confirm the diagnosis.

The *Treatment* of this affection belongs rather to the Physician than the

Surgeon. Local treatment can at most give some slight relief. Mackenzie recommended soothing inhalations, such as the compound tincture of benzoin, or the insufflation of from one-eighth to one-fourth of a grain of morphia diluted with starch and oxychlorate of bismuth, twice a day. From half a grain to a grain of iodoform may advantageously be added. Good results have been obtained by Heryng of Warsaw, Krause of Berlin, and others, by the use of lactic acid. This may be painted on the ulcers as a solution, gradually increased from 20 to 80 per cent., the application being made every day or less often. A more thorough method consists in anesthetizing the larynx with a 10 per cent. cocaine spray, and then scraping the ulcers with a laryngeal curette, and thoroughly applying pure lactic acid by means of a small plug of cotton wool held in laryngeal forceps. The dyspnoea is rarely such as to necessitate tracheotomy. The difficulty in swallowing when due merely to pain may be relieved by the application of a 20 per cent. solution of cocaine to the larynx by means of a brush, or a 4 per cent. solution in spray with an ordinary spray-producer, before a meal. If it arises from the food finding its way into the larynx, the patient must be fed by means of a tube, the passage of which may be facilitated by the application of cocaine.

**Complications of Chronic Laryngitis.**—In all cases of chronic laryngitis there is a tendency to *acute inflammation* supervening on the chronic disease. The affection may then prove fatal by the induction of œdema glottidis, often coming on with great rapidity. *Necrosis of the Cartilages of the Larynx* is most commonly a complication of the more advanced stages of syphilitic laryngitis, and less frequently of tuberculous disease. It has been known in rare cases to follow typhoid fever, and still more rarely to occur without any evident cause. It gives rise to copious expectoration of large quantities of fetid puriform sputa, often streaked with blood, and occasionally containing masses of necrosed and usually calcified cartilage. In many cases abscesses form outside the tube, and after much irritation and distress open externally; and not unfrequently they are so extensive as to undermine and disorganize the greater portion of the tissues of the anterior part of the neck. Where they correspond to the necrosed patches of cartilage, they give rise to aërial fistulae, through which bubbles of air escape during respiration. Tracheotomy is often required in these cases.

In cases of long-standing laryngeal disease, either syphilitic or tuberculous, it has been proposed by Bryant to perform tracheotomy with the view of giving the diseased organ rest, the operation being undertaken, not for the relief of laryngeal obstruction, but with the object of aiding other curative means in an otherwise intractable disease. This suggestion appears to be founded on sound principles, and is of peculiar importance when we consider that patients suffering from chronic laryngeal disease are never safe from the sudden super-vention of œdema glottidis. Whenever acute inflammation supervenes, with a tendency to œdema about the glottis, the patient should be narrowly watched, as he may be carried off by the sudden swelling of the lips of the rima, or by the occurrence of spasm. In such cases tracheotomy may have to be performed; and this must not be delayed until the patient falls into an asphyxial condition.

**Nervous Affections of the Larynx** occur both in children and in adults. In *children* the affection, commonly called **Laryngismus Stridulus**, is frequently associated with rickets. The child is seized, often without previous

warning, with difficulty in breathing, makes violent efforts to inspire, becomes black in the face and convulsed, and has in rare cases been known to die before anything can be done for his relief; but ordinarily he gapes and gasps a few times, and eventually recovers himself with a long deep-drawn whooping inspiration. The attacks vary in severity and may occur several times daily or only very occasionally. In cases of this kind, the *Treatment* at the time of the fit consists in dashing cold water in the face, in exposing the body to a current of cold air, and in using friction to the extremities. If asphyxia occur, intubation or tracheotomy may be required; but this is very rare. The general treatment of the rickety condition with which the affection is so often associated is most important.

In the *adult*, these spasmodic affections of the larynx may be hysterical, or may result from irritation of the laryngeal nerves by the pressure of tumours or aneurisms. In other instances they arise from the presence of some local inflammatory mischief about the glottis. In the hysterical form of the affection the ordinary remedies for hysteria, together with cold douches, will be of essential service. When the disease arises from irritation to the trunks of the nerves tracheotomy may give relief, but the cause of the pressure on the nerves is usually in itself of a fatal character.

Fig. 758.—Endo-laryngeal Forceps.

**Paralysis of the Larynx**, either unilateral or bilateral, is occasionally met with. When unilateral, it arises usually from pressure on the recurrent laryngeal nerve by an aneurism or other tumour. The varieties of laryngeal paralysis due to the pressure of an aneurism on the recurrent laryngeal nerve have already been considered at p. 155. Bilateral abductor paralysis, which is usually associated with disease of the central nervous system, especially locomotor ataxy, may cause serious dyspnoea necessitating tracheotomy for its relief.

**Tumours of the Larynx.—Simple Tumours.**—*Papillomata* form the most common simple tumours of the larynx. They appear as cauliflower-like growths of all sizes up to that of a walnut. They may be single and pedunculated, or multiple and sessile, spreading widely over the upper opening of the glottis. Their most common seat of origin is the vocal cords. They are met with at any age, but are more common after thirty than before. In structure they resemble similar growths elsewhere, being composed of processes of vascular connective tissue covered with a layer of epithelium. The epithelium is that normal to the part, being, as a rule, squamous, though columnar epithelium is said to have been occasionally observed. *Fibromata* are much less common. They form rounded or smoothly lobulated pedunculated growths, springing usually from the neighbourhood of the vocal cords. They are almost invariably single. They are composed of ordinary fibrous

tissue, covered with a squamous epithelium. *Myxoma*, *Lipoma* and *Nævus* have been met with; *Myxo-chondroma* is of extreme rarity. A case has been recorded by J. W. Bond, in which partial excision of the larynx was performed for a large myxo-chondroma springing from the anterior surface of the posterior part of the cricoid cartilage. *Cysts* arising from retention of the secretion of the mucous glands occasionally develop in the neighbourhood of the epiglottis or false vocal cords. They form smooth, shining, rounded projections. *Polypus of the Larynx* is a term applied to any pedunculated growth, and has no pathological significance.

The simple tumours of the larynx cause alteration in the voice, slight cough, discomfort, and dyspnoea, varying in degree with the size of the growth.

Fig. 759.—Endo-laryngeal Forceps.

Fig. 760.—Endo-laryngeal Forceps.

Their true nature can be recognized only by careful examination with the laryngoscope.

*Treatment.*—These growths may be removed by one of two methods—the endo- or the ecto-laryngeal. There appears to be a general consensus of opinion amongst laryngologists that the endo-laryngeal method should always be attempted in the first instance. Should it fail, then the larynx may be opened and the growth removed from without. The endo-laryngeal method consists in removing the growth by means of instruments specially designed for the purpose, guided by the laryngoscope. The instruments most commonly used are forceps, by which the growth can be seized and torn from its attachments; but in some cases, especially when the growth is of some size and distinctly pedunculated, wire snares or small écraseurs may be of use. In some cases the destruction of the growth may be brought about by simply crushing it with a strong pair of forceps. These operations have been greatly facilitated by the use of cocaine, but still require practice on the part both of the patient and the Surgeon. The patient must be taught to keep steady, to

hold his own tongue, and to tolerate the presence of the instrument. For this purpose it is often necessary to train him for a week or two before any real attempt is made to remove the growth. The smaller papillary growths will sometimes disappear under the application of nitrate of silver: in such cases therefore the Surgeon should not be in a hurry to attempt operative interference. The accompanying drawings (Figs. 758, 759, 760) show various forms of forceps which may be used in these operations.

Should the endo-laryngeal operation fail or be impossible, the growth must be removed by an ecto-laryngeal operation. Mackenzie laid it down as a cardinal rule that no operation of this kind should be undertaken unless there is danger to life from dyspnoea or dysphagia.

The operation most commonly performed is that known as **Thyrotomy**. It is advisable in most cases to perform a preliminary tracheotomy about a fortnight before undertaking the removal of the tumour. When the patient has quite recovered from this and feels no further discomfort from the tube, thyrotomy may be undertaken. The operation is thus performed: An incision is made accurately in the middle line from the thyroid notch to the cricoid cartilage. The thyroid cartilage is then carefully divided with a knife, or, if it be ossified, with a fine saw. The *alæ* are then held apart with blunt hooks and the interior of the larynx is fully exposed. A small piece of sponge may then be passed into the trachea so as to plug the opening above the tube, lest blood should pass into the lungs. The growth may then be removed with scissors, and the surface from which it grew touched with nitrate of silver. After all bleeding has ceased the sponge is removed, and the parts accurately brought together, and the trachea-tube is retained until the patient can breathe through the glottis with ease.

Tumours affecting the upper opening of the glottis or the epiglottis have also been removed by a transverse incision in the thyro-hyoid space—subhyoid pharyngotomy. Malignant recommended that the incision should be made along the lower border of the hyoid bone, partially dividing the sterno-hyoid and sterno-thyroid muscles and the thyro-hyoid membrane. The head being thrown well back, sufficient space may thus be obtained to allow of removal of the epiglottis or a tumour situated in its immediate neighbourhood. This operation can seldom be required, as simple growths in this region can usually be removed from the mouth.

**Malignant Tumours of the Larynx.**—Both carcinoma and sarcoma are met with in the larynx, but the former is far more common, and is met with almost invariably as the squamous-celled variety. Columnar carcinoma has, however, been observed, and hard glandular cancer is said to have been seen. When sarcoma occurs in the larynx it is most commonly spindle-celled, less frequently round-celled or mixed. Butlin, who has collected the records of 23 cases of sarcoma, states that half the cases were spindle-celled. Malignant growths in the larynx may be intrinsic or extrinsic, that is to say, they may commence in its interior, or spring from surrounding parts and secondarily invade it. According to Krishaber the *intrinsic* variety of carcinoma may affect the ventricular band, the ventricle, the true vocal cord or the parts below it; whilst the *extrinsic* variety begins in the epiglottis, the aryteno-epiglottidean fold, the inter-arytenoid fold or the posterior surface of the cricoid. The division is a most important one, for whilst the intrinsic form grows slowly and does not tend to infect the glands, the extrinsic variety is

much more malignant, growing rapidly and often causing early glandular enlargement. All malignant growths in this region tend to assume a papillary form (Fig. 761), though they are rarely polypoid. They are most commonly single. The symptoms they give rise to are those of interference with speech and respiration, with some cough and expectoration, often mixed with blood. The situation of the tumour and its size are usually determined without difficulty by the laryngoscope, but it is not easy in many cases to determine the nature of the growth. For this purpose a piece of the growth can sometimes be removed with the laryngeal forceps, and submitted to microscopic examination. If the fragment so removed presents undoubted evidence of cancer, the diagnosis is made, but if not, great doubt will still exist as to the nature of the disease, for it not uncommonly happens that a malignant growth in this region is surrounded by a warty fringe presenting the structure of a simple papilloma. Death, in cancer of the larynx, is inevitable, either by asphyxia or by constitutional infection, if the disease be left to run its course.

Fig. 761.—Epithelioma in Larynx.

**Treatment.**—Until a comparatively recent period the Surgeon had no other means of prolonging life in cases of malignant disease of the larynx than by performing tracheotomy. During recent years, however, operation has been undertaken in a large number of cases, with the object of removing the diseased tissues from the larynx or of excising, partially or completely, the larynx itself.

Removal of the growth can be of advantage to the patient only in well selected cases in which the diagnosis has been made early. When the disease is extrinsic and is invading the epiglottis and possibly the root of the tongue, or when, having originally been intrinsic, it has spread beyond the limits of the larynx, no good can be expected from the operation. Even if the patient survive, recurrence will certainly take place, and it is probable that life would be equally prolonged and greater comfort secured by the simple operation of tracheotomy.

Butlin urges "that the smallest operation consistent with the widest excision of the disease, and the removal of a wide area of the surrounding tissues, should be adopted." The intralaryngeal method of removal has been performed in certain cases of malignant disease; but this can very seldom be practicable.

**Operation.**—As a general rule it may be stated that the first steps in any operation undertaken for malignant disease of the larynx should consist in the performance of a preliminary tracheotomy and an exploratory thyrotomy. Hahn and many other Surgeons prefer to perform the tracheotomy some days before the operation for removal of the growth is undertaken, especially if the patient is exhausted by previous dyspnoea or from imperfect nutrition. At the time of the operation the trachea may be plugged with Trendelenburg's tube (Fig. 695) or with Hahn's cannula, the outer tube of which is surrounded by compressed sponge, which rapidly swells and completely plugs the air tube. The tracheotomy wound is then prolonged upwards to the body of the hyoid bone, and, all bleeding having been arrested, the thyroid cartilage

is divided vertically in the middle line, and in order to facilitate separation of its two halves it may be advisable to divide the cricoid also. The extent of the disease can now be accurately determined, and the Surgeon must decide whether it is possible to remove the disease from the interior of the thyroid cartilage or whether total or partial excision of the larynx is necessary. In the former case, following Butlin's advice, the Surgeon may proceed to cut away freely the diseased tissues with scissors, either removing no cartilage at all or only such parts as appear to be diseased. Semon especially insists upon the necessity of good illumination; he also recommends that the interior of the larynx should be twice mopped out with a 5 per cent. solution of cocaine, which diminishes the amount of hemorrhage during the removal of the disease. After the removal of all the diseased tissues the bleeding must be thoroughly arrested, and the interior of the larynx dusted with equal parts of iodoform and boric acid. The Hahn's cannula is at once removed and the wound covered with cyanide gauze. The after-treatment consists in keeping the patient in a nearly horizontal position, so that the discharges may have less tendency to enter the air-tubes; dusting the wound twice daily with iodoform and boric acid; changing the gauze dressing as often as it is soiled; and feeding the patient by enemata for the first few days, unless he can swallow fluids in the position proposed by Wolfenden and recommended by Semon, viz., leaning with the upper part of the body well over the end of the bed.

If on account of the extent of the disease it be thought necessary to perform *complete excision of the larynx*, the single vertical incision above described may suffice; but Hahn recommends in addition a transverse incision parallel to the cornua of the hyoid bone. All the soft parts are turned off the two sides of the larynx as far as possible with a periosteal elevator, all bleeding vessels being ligatured as they are cut. The thyro-hyoid membrane is next cut through, and the larynx being drawn forwards, it is carefully separated from the pharynx, the epiglottis usually being removed. Blunt-pointed scissors will be found more convenient than the knife at this part of the operation. They must be kept as close as possible to the cartilages, numerous short snips being made, and any wounded vessels immediately secured. The larynx is now turned downwards and carefully separated from the pharynx. Finally, the removal is completed by dividing the membrane between the cricoid cartilage and the trachea, and the opening of the latter is secured to the skin by several sutures.

When the operation is completed and all bleeding arrested, an india-rubber tube must be inserted into the œsophagus, through which the patient must be fed until healing is far advanced. The wound must be plugged with some absorbent antiseptic material, such as iodoform gauze, sufficiently firmly to prevent any discharges from passing downwards into the trachea, and this must be changed periodically. The tracheotomy tube is necessarily retained permanently. Gussenbauer invented an artificial larynx, which was improved by Foulis, containing a reed for the production of vocal sounds.

The first case in which excision of the larynx, or *laryngectomy*, was undertaken was that of a man 35 years of age affected with syphilitic stenosis of the larynx. Heron Watson in 1866 excised the larynx in this case, the patient dying three weeks afterwards of pneumonia. The first excision for carcinoma

was performed by Billroth in 1873. The patient survived the operation, but died in a few months from recurrence of the disease.

**Partial excision of the Larynx**, usually consisting in the removal of half the thyroid cartilage with the corresponding arytenoid cartilage, has been practised in cases in which the extent and situation of the growth render complete excision unnecessary. The operation must be carried out on the same lines as those described for complete excision ; but care must be taken to cut sufficiently widely around the disease to give the patient a chance of escaping recurrence.

**Results.**—During recent years a considerable number of statistics have been published dealing with the results of complete and partial excision of the larynx. In 1890 Kraus collected 240 cases of excision, 160 of which were complete and 80 partial. Of the 160 complete excisions, 142 were undertaken for carcinoma. Of these 63 died without recurrence, 57 within eight weeks, and 8 within a year ; 38 were known to have recurrence within one year, and 5 at later periods ; 24 were free from recurrence after periods of more than one year, 13 being after more than two years, and one, a case of Gussenbauer's, after eight years ; 10 had been operated upon too recently to be considered.

Of the 80 partial excisions, 66 were performed for carcinoma. Of these 25 died without recurrence, 23 within eight weeks, and 2 within a year ; 12 had recurrence within a year, and 2 later ; 16 were free from recurrence after periods of at least one year ; 11 cases had not been under observation for a year.

Of 102 operations for malignant disease of the larynx, collected by Butlin, thyrotomy was performed in 28, partial excision in 23, and complete excision in 51 cases. Of the 28 cases of thyrotomy 3 died from the operation and 3 were "cured," viz., free from recurrence after periods of more than three years. Of the 23 cases of partial excision, 7 died from the operation and 4 were cured. Of the 51 cases of complete excision, 16 died from the operation and 8 were cured.

There seems every reason to believe that the operation performed upon the lines already described will largely replace the more formidable excisions hitherto frequently practised, and that in this way, without increasing the risk of recurrence, the immediate mortality will be much lessened and the subsequent condition of the patient much improved.

Felix Semon has recently published the results of 12 operations performed in his own practice, 10 for malignant disease and 2 for disease of doubtful malignancy. Partial extirpation was performed in three cases with 2 deaths ; thyrotomy with resection of portions of cartilage in 4 cases with no deaths ; thyrotomy with removal of soft parts only in 4 cases with 2 deaths ; subhyoid pharyngotomy in one case which ended fatally. Of the 5 fatal cases 2 died of septic pneumonia, 1 of bronchitis, 1 from the effects of ether administered by the rectum, and 1 from unexplained causes. Of the 5 cases which recovered, and in which the disease was certainly malignant, 1 died from heart disease after 6½ years ; 3 were well and free from recurrence after 5½, 3½, and 2½ years respectively ; in 1 there was probable recurrence 4 months after the operation. Of the 2 cases in which the malignant nature of the disease was doubtful, 1 was free from recurrence after nearly a year and a half and the other after 7 months.

**Polypus of the Trachea.**—Solis Cohen has collected forty-five cases of this rare condition ; in some the polypus was fibrous or sarcomatous, and in others due to tubercle. L. A. Bidwell has recently recorded the case of a child aged five years in whom tracheotomy was performed for severe dyspnoea without relief. After death a fibrous polypus as large as a small marble was found blocking the trachea at a point an inch and a quarter above the bifurcation.

## CHAPTER LVIII.

## OPERATIONS ON THE AIR-TUBE AND ON THE CHEST.

## LARYNGOTOMY AND TRACHEOTOMY.

THE windpipe may require to be opened to allow the formation of a temporary breathing aperture, in consequence of obstruction of the larynx by causes that are speedily removable; or it may be necessary to establish a permanent opening in those forms of chronic laryngeal disease, in which the obstruction depends upon alterations of structure which are not remediable.

Among the conditions requiring a *temporary aperture* may be mentioned all acute inflammatory affections of the larynx that give rise to obstructive œdema of the glottis; also traumatic conditions, such as the impaction of masses of food in the gullet, inducing asphyxia, and not capable of being immediately removed; scalds of the rima glottidis; the presence of foreign bodies in the air-passage; and œdema of the glottis from wounds of the thyro-hyoid membrane. The establishment of a *permanent aperture* in the air-passage is required in chronic diseases of the larynx, attended with thickening of the mucous membrane, with abscess, or with necrosis of the cartilages, and in cases of tumour of the larynx.

**Opening the Windpipe in Membranous Laryngitis.**—By membranous laryngitis is meant any form of inflammation of the larynx, accompanied by a coagulable exudation from the mucous membrane, forming a false membrane upon it, whether diphtheritic or not. It is unnecessary here to enter into the question of the varieties of membranous inflammation of the pharynx and larynx. At the present day the presence of the bacillus described by Klebs and Löffler in the membranous exudation can alone be considered certain evidence that the condition in question is diphtheritic. Mixed infection is common, the bacillus being accompanied by streptococci and staphylococci, and it seems certain that in some instances, indistinguishable clinically from true diphtheria, the inflammation is due to streptococci and staphylococci only.

Membranous laryngitis, from whatever cause arising, is a most fatal disease in childhood, at least 90 per cent. of those attacked dying, and a considerable proportion of the minority that escape owing their lives to the performance of tracheotomy. In acute catarrhal laryngitis, unattended with membranous exudation, tracheotomy is scarcely ever needed, the disease yielding to milder methods of treatment.

Owing to the frequent failure of tracheotomy to save the life of the patient in membranous laryngitis, the propriety of the operation was at one time disputed. It is now universally acknowledged that the operation should be performed in all cases in which the obstruction is evidently in the larynx, care being taken to distinguish the *hurried* breathing and dyspnoea due to extension of the inflammation to the bronchi and lungs from the *laboured* breathing of true laryngeal obstruction. In diphtheria tracheotomy must necessarily fail to

save life in many cases, as it merely wards off the immediate danger of death from asphyxia, and the disease runs its course uninfluenced by the operation, and frequently proves fatal by extension to the bronchi and lungs, by exhaustion, or by the sequelæ of the affection. By opening the windpipe, however, as Jenner has justly observed, we save the patient from so terrible a death as that from asphyxia, and even if the disease is ultimately fatal, death occurs in a less distressing manner.

The necessity of the operation then being recognized, it remains to consider the indications for performing it. Trousseau strongly advocated early tracheotomy before collapse of the lung had taken place to any extent, or the patient had become exhausted by the struggle for breath; and nothing is more certain than that the operation is rarely successful if performed *in extremis*. It may be taken as a rule that when the voice is lost or nearly lost, and there is evident laryngeal obstruction gradually increasing, the sooner tracheotomy is performed the better. The degree of obstruction is estimated by the recession of the chest walls during inspiration. If the lower ribs and epigastrium sink in with each inspiratory effort, it is not wise to delay the operation. Jenner pointed out that implication of the larynx in diphtheria rarely occurs after the end of the first week.

Even when performed early, tracheotomy for diphtheria frequently fails to save life. In the Hospital for Sick Children in Paris it appears that the operation was performed in 215 cases during a period of five years, and of these only 47 recovered. Unless we assume that the disease, as occurring in Paris, is different from that we meet with here, it may fairly be doubted whether an operation which is in itself dangerous could have been necessary in many of these instances, and whether a large proportion of the children might not have recovered under ordinary medical treatment.

The prospect of saving life after opening the windpipe in cases of diphtheria will greatly depend upon the age of the patient. Under two or even three years of age, recovery is extremely rare; as age advances, the chance of life proportionately increases, and in adults the prospect of recovery is considerable. In many cases the patient will get great temporary benefit from the operation, and will appear to be doing well for several days, perhaps for eight, ten, or fourteen; and then, to the great disappointment of the Surgeon, he will die, not from the effects of the operation, but from blood-poisoning or from extension of the disease to the bronchi and lungs.

**In other forms of laryngeal obstruction** not dependent on membranous laryngitis, there can be no question as to the propriety of the operation. No patient ought ever to be allowed to die from simple laryngeal obstruction, whether it be spasmodic or dependent on organic disease, without an attempt being made to save life by opening the windpipe. It is as unpermissible for a Surgeon to allow a patient to die of laryngeal asphyxia without an attempt at relief by opening the windpipe, even though life appear to be extinct, as it would be to let him die of hæmorrhage without attempting to control the bleeding vessel.

**Necessity for Promptitude.**—When it has been determined to open the windpipe for acute disease, more especially supervening on chronic laryngitis, the less delay there is in having recourse to operation, the better; as the patient may at any moment be seized with fatal laryngeal spasm. The operation ought always to be completed, even though the patient have apparently

expired before the windpipe has been opened ; for resuscitation may, even in these extreme cases, be effected by artificial respiration. It has twice happened to me to operate under such circumstances, and in both cases to be fortunate enough to save the patient's life. In one case an elderly woman was apparently dying from the supervention of acute upon chronic laryngeal disease. I lost no time in making an incision into the crico-thyroid membrane, but at the first touch of the knife she sank back, apparently dead. I immediately completed the operation, and introduced a large silver tube, through which the lungs were inflated : in the course of a few minutes, respiration recommenced, and the patient recovered, but was never able to breathe without the tube. In another instance the patient, a young woman, was in the last stage of asphyxia from acute disease of the larynx. I immediately proceeded to operate. As the patient's neck was short and thick, and the veins excessively turgid, there was profuse hæmorrhage on the first incision being made ; while we were waiting a minute or two for this to cease before opening the windpipe, the patient fell back and apparently expired. I at once plunged the scalpel through the crico-thyroid membrane, and cut down through the cricoid cartilage, so as to make a free aperture into the air-passage. On endeavouring to set up artificial respiration, I found the air-passages clogged with inspissated mucus, which prevented the entrance of air into the lungs. The life of a fellow-creature being at stake, and dependent on the immediate establishment of artificial respiration, I felt that there was only one thing to be done—to empty the chest at once of the matters loading it. I accordingly applied my lips to the wound and sucked out three or four mouthfuls of blood and mucus, when I had the satisfaction to see that air could be made to enter the lungs. After artificial respiration had been kept up for some time, the heart began feebly to act, the face became less livid, and the circulation was re-established ; the patient did well, and was in good health many years afterwards.

**Operations.**—In opening the windpipe, the Surgeon has the choice of two situations in which he may make the aperture : either in the crico-thyroid membrane by **Laryngotomy**, or in some part of the trachea by **Tracheotomy**. Besides these two established operations, some Surgeons have performed a third—**Laryngo-tracheotomy**, by opening the crico-thyroid membrane, and dividing the cricoid cartilage with the upper rings of the trachea.

Whichever operation is performed, as soon as the windpipe is opened, the patient is seized with an attack of spasm and convulsive cough, often attended with much struggling and distress, during which the whistling occasioned by the passing of the air through the new opening is very marked. The patient, however, soon recovers, and breathes easily, the signs of asphyxia disappearing. In some cases the opposite condition is observed, the patient ceasing to breathe the moment the tube is inserted. This need cause no anxiety, as natural breathing speedily returns after a few movements of artificial respiration.

The windpipe may require to be opened by laryngotomy or tracheotomy for many different conditions. In the **adult laryngotomy** may be required : 1. In acute laryngitis with œdema of the glottis ; 2. In scald of the glottis by boiling water or acids ; 3. In sudden spasms of the glottis in cases of chronic laryngeal disease ; 4. In cases of extreme urgency from obstruction of air-passages by a foreign body ; 5. If the air-passage becomes obstructed by

blood during operations about the head and face. *Tracheotomy* may be required: 1. In chronic forms of laryngitis with obstruction, such as chronic laryngitis with œdema, syphilitic and tuberculous ulceration, necrosis of the cartilages, etc.; 2. In membranous laryngitis; 3. In tumours of the larynx; 4. In some cases of bilateral paralysis of the abductors of the larynx; 5. For the removal of foreign bodies from the trachea or bronchus; and, 6. As a preliminary step in certain operations about the mouth and throat, attended with much hæmorrhage.

In **children**, as a general rule, laryngotomy should not be attempted on account of the small size of the crico-thyroid space. For this reason tracheotomy is almost invariably performed in children in all cases in which it is necessary to open the windpipe, whether for acute or chronic causes of obstruction. In cases of extreme urgency, however, arising from the presence of a foreign body, laryngotomy may be performed in children, the cricoid cartilage being, if necessary, divided.

**Laryngotomy** is an easy operation. The crico-thyroid membrane is almost subcutaneous, and may readily be reached by making a vertical incision in the mesial line, between the sterno-hyoids, about an inch in length, and then a cross cut through the membrane with an ordinary scalpel. The air-passage

Fig. 762.—Laryngotomy Tube.

having thus been opened, a silver tube, curved on the flat (Fig. 762), may readily be introduced and retained by tapes round the neck. The only troublesome result that can occur in this operation is the wound of a small artery, the crico-thyroid branch of the superior thyroid, which crosses the membrane. I have never seen any trouble arise from this; but, should it occur, the hæmorrhage would readily be arrested by the application of pressure or ligature.

In cases of extreme urgency, it is recommended by some Surgeons that, in order to save time, laryngotomy be performed by a transverse instead of by a longitudinal cut through the superficial structures. In this opinion I do not agree; little if any time is saved, and peril may ensue by cutting across the branches of the anterior jugular veins—thus leading, as I have seen, to profuse hæmorrhage. There is, moreover, some risk of the formation of an aerial fistula. In all cases the longitudinal cut answers perfectly, and the crico-thyroid membrane can be opened in less than five seconds.

**Tracheotomy** consists in making an opening into some part of the trachea, by exposing the tube and cutting across two or three rings.

There are three situations in which the trachea may be opened: above, behind, and below the isthmus of the thyroid body, which usually crosses it opposite its second and third rings. Above the isthmus, the trachea is comparatively superficial, being covered merely by the skin and superficial fascia, the deep fascia, and the sterno-hyoid muscles. Beneath the muscles will be found a strong fascia, which comes downwards in front of the larynx from the hyoid bone and divides above the thyroid body, inclosing its isthmus between its two layers. This fascia is of some importance, as it is difficult to push the isthmus downwards so as to expose the upper rings of the

trachea without notching this transversely. Below the thyroid gland the trachea recedes from the surface and is overlapped by the sterno-hyoid and sterno-thyroid muscles, beneath which is some loose areolar tissue in which lies the inferior thyroid plexus of veins, which are of large size, together with some tracheal branches from the inferior thyroid artery, and in rare cases an irregular arterial branch ascends from the aorta in front of the trachea to the thyroid body—the *thyroidea ima*. Beneath the deep fascia, but superficial to the muscles on each side, lie the anterior jugular veins. These are variable in size, become larger below, and sometimes communicate by a branch crossing the line of the tracheotomy wound. The carotid arteries also are in close relation to the trachea on each side, being more especially in danger at the lower part of the neck. Opposite the episternal notch, the windpipe is crossed by the left innominate vein, which has been seen by Macilwain lying high at the very point where tracheotomy is usually performed. A glance at these important relations will suffice to indicate the difficulty that must in many cases occur in exposing and opening the trachea. This difficulty is greatly increased when the veins of the neck have become turgid in consequence of the laryngeal obstruction. It will be seen also that the trachea is less covered, and may consequently be much more readily reached above, than below, the isthmus of the thyroid gland. Though some Surgeons, as Velpeau, for instance, have recommended the opening to be made in the lower part of the tube in all cases, no advantage whatever is gained by so doing, whilst the difficulties of the operation are very seriously increased; and in practice it is almost invariably opened at its upper part, usually through the first and second rings.

Fig. 563. — Operation of Tracheotomy.

The patient should, if possible, be placed on a table in a good light. In operating on an adult, it will be found sufficient in most cases to support the patient's shoulders with pillows, while the head is thrown as much back as practicable. In children, a small firm pillow must be placed under the neck, so as to throw the trachea as much forwards as possible. A stocking stuffed tightly with towels will usually be found to answer the purpose admirably. An assistant should be seated above the head of the patient; it is his duty to hold the head steady with his wrists, while with a blunt hook in each hand he draws the wound open during the operation. At the same time he must keep the chin exactly in the middle line to serve as a guide to the Surgeon. The hooks must never be entrusted to two assistants, as they would certainly displace the wound from the middle line. If another assistant is present, he may administer the chloroform and sponge the wound. The Surgeon stands to the right side of the patient. During the operation every vessel that bleeds must immediately be seized in forcipressure forceps, which

not only arrest the bleeding, but, if allowed to hang down on each side, help to hold the wound open.

If it be intended to open the trachea *above* the isthmus of the thyroid body, the incision must be commenced at the upper border of the cricoid cartilage and carried downwards exactly in the middle line for an inch to an inch and a half, according to the age and size of the patient and the amount of subcutaneous fat. After dividing the integuments, the interval between the sternohyoid muscles must be found, and these drawn apart. Any veins that present themselves should be avoided as carefully as possible, and held on one side by the assistant, who has charge of the blunt hooks. After the muscles have been drawn apart, the isthmus of the thyroid body comes into view, and above it is the fascia that supports it and covers the trachea. The lower border of the cricoid cartilage should then be felt for; it can be recognized by its forming a slight projection above the level of the trachea, which can be readily felt with the finger-nail. If the parts are well in view, the trachea may be best exposed by the plan recommended by Bose. The layer of fascia in front of the trachea which supports the isthmus is picked up with a pair of forceps at the lower border of the cricoid cartilage, and carefully divided transversely for a distance sufficient to admit the handle of the scalpel beneath it, by means of which the isthmus is pushed downwards, and the upper three rings of the trachea clearly exposed. The trachea is then transfixd with a sharp hook and drawn forwards to steady it while the opening is made. It is usually recommended to insert the hook in the middle line, immediately below the cricoid cartilage, but the plan devised by J. Marshall will be found more convenient. In this, the hook is inserted about an eighth of an inch from the middle line parallel to the intended incision, its point being made to reappear so as to puncture the trachea in two places, and to get a firm hold on it. The opening in the trachea is then made, the knife being held by the blade about half an inch from its point, so that it is not possible to transfix the trachea and puncture the œsophagus. The incision must be made from below upwards, and should include two, or, if necessary, three rings of the trachea. The tube may now easily be inserted by drawing one lip of the opening well forwards with the hook that has been inserted parallel to it, while the other is depressed with the end of the tube. If this be done, it slips in without any difficulty. It must then be retained by tapes round the neck.

If the trachea is to be opened *below* the isthmus of the thyroid body, the incision must commence immediately below the cricoid cartilage, and be carried downwards for at least an inch and a half. The muscles are exposed and separated as in the previous operation. In this situation the sternothyroids will probably come into view after the sternohyoids have been drawn aside. The isthmus, having been exposed, must be drawn upwards with a blunt hook. At this stage of the operation, the large veins forming the inferior thyroid plexus must be carefully avoided, and if the wound be very deep it is safer to use the scalpel to a limited extent, dilating the deeper parts of the wound with its handle or with a director. In young children the thymus gland will appear in the lower part of the incision, and require to be pushed downwards.

Opening the trachea *behind* the isthmus is seldom necessary, but should it be unavoidable the tissue of the thyroid body may be divided with but little

bleeding if the knife be kept accurately to the middle line. *Laryngo-tracheotomy*, in which the cricoid cartilage is divided with one or two of the upper rings of the trachea, is occasionally performed intentionally, but more often accidentally, in young children, the cricoid being mistaken for a ring of the trachea. The accident, if such it can be called, is not productive of any injury to the patient.

The question as to the **safety of the administration of chloroform** in these operations often occurs. I believe that it may always be given safely except in cases of extreme syncopal asphyxia, where, as sensibility no longer exists, it is unnecessary. Laryngeal inflammation and obstruction are always associated with so much spasm, more particularly in children, that it will often be found that the patient breathes more easily and fully whilst under the influence of chloroform than before its inhalation was commenced; and, as the anæsthesia materially facilitates the operation, I invariably have recourse to it.

**Difficulties and Accidents.**—This operation is often attended with extreme difficulty, and not unfrequently with much danger.

The difficulties occurring in tracheotomy are chiefly referable to four heads:

Fig. 764.—Automatic Retractor.

1. Difficulty in Exposing the Trachea; 2. Profuse Hæmorrhage; 3. Difficulty in Opening the Trachea; and 4. Trouble in Introducing the Tube.

1. The **Difficulty in Exposing the Trachea** increases greatly as the incisions approach the sternum, and is especially great in stout, short-necked persons. The want of an assistant to hold the wound open adds greatly to the difficulty of the operation. This may, however, be overcome by the use of the ingenious "Automatic Retractor" devised by R. W. Parker (Fig. 764). The forcepressure forceps on the vessels will also help to hold the wound open. The accidents in this part of the operation arise very commonly from taking the guides incorrectly. In their anxiety to open the trachea above the thyroid body, young operators are apt to make the incision too high. The pomum Adami of a young child, especially when covered by much fat, is scarcely to be felt, and the hyoid bone is sometimes mistaken for it. Owing to this error I have more than once seen the thyroid cartilage partly divided, and in one case an opening made even in the thyro-hyoid space. The mistake is avoided by taking the sternal notch as the guide, and making the incision in a child reach to about a finger's breadth above it. Insufficiency of the incision is a frequent source of difficulty. Even in the smallest children it should never be less than one inch in length. Deviation from the middle line is a common cause of accident, leading to wounds of the thyroid body or even of the carotid artery, or to great difficulty in finding the trachea. It may be the fault of the assistant, who should keep the chin exactly in the middle line as a guide to the Surgeon. In very young children an inexperienced assistant may even draw the trachea on one side with the blunt hook.

2. The **Hæmorrhage** may occur either from arteries, from veins, or from the thyroid gland. Arterial hæmorrhage is less frequent and troublesome than the bleeding from other sources. When it occurs, it happens chiefly from the wound of some anomalous branch, or from that of the small tracheal vessels. Desault has, however, mentioned a fatal case, in which death arose from a wound of the carotid. The arterial anastomosis of the isthmus of the thyroid body may, if this part be enlarged, occasion some difficulty in the performance of the operation; but the main source of danger is unquestionably the *venous bleeding*. Not only are the plexuses of veins of large size, more particularly where they cover the lower part of the trachea, but they become immensely gorged by the asphyxia that necessitates the operation. Hence, when they are wounded, the bleeding may be very abundant.

It is a generally recognized rule that all bleeding must be completely arrested before the windpipe is opened, lest the blood should enter the bronchi and asphyxiate the patient, or by lodging in the tubes and decomposing, should at a later period cause septic broncho-pneumonia. The only exception to this rule is when the case is urgent, and the bleeding does not proceed from any recognizable vessel, but is rather a uniform venous oozing due to the obstruction to the circulation through the lungs. In such cases the bleeding will continue as long as the obstruction remains unrelieved. But as the respiratory process is re-established, the venous turgescence of the neck subsides, and the hæmorrhage proportionately lessens. This I have repeatedly found in asphyxia artificially induced in animals; and I have often seen it in the human subject, in cases in which it has become necessary to open the windpipe at once, without waiting to arrest hæmorrhage.

It is important to bear in mind that the risk of hæmorrhage is not entirely avoided by the use of blunt instruments. The veins are very thin-walled and easily torn, and I have seen very troublesome bleeding caused in this way by the incautious use of a director. The difficulties arising from hæmorrhage are very greatly increased by an insufficient incision. There is seldom any trouble in arresting the bleeding if the wounded vessel can be clearly seen. Spencer Wells's forcipressure forceps will be found invaluable under these circumstances, as the vessel can be seized and the forceps left attached till the operation is completed. Should blood accidentally enter the trachea in such quantities as to threaten suffocation, it must be sucked out either by the mouth applied to the tube or by an aspirator tube passed down the trachea. As in diphtheria it is extremely dangerous for the operator to suck the tube, it is advisable, when performing tracheotomy, always to have an aspirator at hand in case of need. R. W. Parker has invented a simple apparatus by which suction can be performed without danger. It consists simply of a tube to pass down the trachea, and another with a glass mouth-piece, connected by an oval glass bulb, which is plugged with carbolized cotton-wool, which thoroughly filters any air passing through it.

3. Another difficulty in tracheotomy sometimes attends the process of **Opening the Trachea** after it is exposed. In consequence of the convulsive breathing of the patient, the sterno-mastoids are put upon the stretch, thus increasing considerably the depth of the wound in the neck; and, at each short and gasping respiration, the air-tube is rapidly jerked up and down, approaching to and receding from the surface in such a way that the scalpel cannot be thrust into it with safety. This difficulty is best avoided by

thoroughly cleaning the trachea before attempting to open it, and then inserting the hook in the way already described, and drawing it well forwards. Edwards recommended that a sharp hook grooved on its convexity (Fig. 765) should be introduced under the cricoid cartilage, and the windpipe pulled up and opened by sliding the scalpel along the groove and cutting downwards. I have occasionally used the cutting hook (Fig. 766), and some Surgeons prefer, instead of the scalpel, to open the trachea with cutting forceps, or with a trochar carrying a cannula in the shape of a trachea-tube; but these instruments, though ingenious, are not so safe or easy of management as the scalpel and sharp hook.

A possible accident at this stage of the operation is wound of the œsophagus. This is avoided by steadying the wrist on the sternum while making the

Fig. 765.—Trachea-hook-Director.

incision, by drawing the trachea well forward with the sharp hook, and by holding the knife by the blade so that not more than half an inch projects beyond the finger and thumb. I have heard of a case in which, for want of these precautions, not only was the œsophagus wounded, but at the post-mortem examination the mark of the knife was found upon the bodies of three of the cervical vertebræ.

In rare cases the mucous membrane of the trachea has been pushed before the knife, but this is practically impossible if the hook be used as described on p. 744, and if the point of the knife be properly sharp. In cases of diphtheria in which the false membrane forms a distinct tube lining the trachea, it may be pushed before the point of the knife, and thus, if the tube be inserted at once, no air may enter. This accident is avoided by adopting

Fig. 766.—Cutting Trachea-hook.

the plan of holding the wound in the trachea open with a dilator, and removing all membrane that can be seen before introducing the tube.

4. After the trachea has been opened, the next point is to **Introduce a proper Tube**. In doing this, special care must be taken not to push the tube into a sort of pouch which always exists at the lower angle of the wound, between the trachea and the deep fascia of the neck. This error is not only embarrassing to the Surgeon, but dangerous to the patient by the delay it occasions, by the compression exercised on the trachea below the opening into it, and by the suction of blood into the aperture in the air-tube. It is best avoided by expanding the tracheal opening with the dilator (Fig. 769), and passing the tube between the blades of that instrument, or by adopting the method already described of inserting the sharp hook parallel to the line of incision instead of above it. In passing the tube into the trachea some difficulty may be experienced, owing to the elasticity of the sides of the

incision in the windpipe, in consequence of which one of them is apt to be doubled in under the end of the instrument. This may be avoided by introducing the sharp hook in the manner described above, or by the use of Fuller's bivalve tube introduced closed (Fig. 767), and then expanded by slipping a cannula into it (Fig. 768). If the rings of the trachea be very rigid and unyielding, the silver tube may most conveniently be introduced by expanding the incision by means of the trachea-dilator (Fig. 769), and then passing it between or under their blades.

**Trachea-tubes** should be of such a calibre throughout as to admit of respiration being carried on through them, without any effort on the part of the patient. Many of those that are to be met with in the instrument-makers' shops, though very wide at the mouth, are far too narrow and contracted at the lower aperture to allow a free and unimpeded passage for the air of respiration, being made very conical in order to admit of easy introduction

Fig. 767.—Bivalve Tube closed.

Fig. 768.—Bivalve Tube with Cannula introduced.

Fig. 769.—Trachea-dilator.

and to occlude the opening in the windpipe completely, so as to prevent the entry of any blood by the side of the tube.

It is most important after the operation to keep the tube from being clogged by mucus. The frothy mucus which the patient constantly brings up after the operation is easily removed by wiping it away with a sponge during the expiratory efforts of coughing, and by the occasional introduction of a feather moistened with a solution of carbonate of soda. It will be found, however, that after a few hours the lumen of the tube becomes narrowed by an adherent layer of dried mucus on which the feather makes no impression. This accumulates in the largest quantity at the inferior aperture and at the curve of the tube, and may seriously block up its calibre while the external opening appears quite free. Ohrsé devised a very simple means to remedy this inconvenience. It consists in the trachea-tube being made of uniform calibre throughout, and having an interior tube accurately fitted to it, and projecting about one-eighth of an inch beyond the lower extremity of the outer tube. It is in the projection of the internal tube beyond the lower end of the external one that the great utility of this contrivance consists. If the two tubes be of the same length, or still more, if the innermost tube be the shorter, a plug of mucus may be left at the end of the outer cannula, on the withdrawal of the

inner tube. But if this be the longer of the two, the end of the outer tube will be effectually cleared every time it is withdrawn, which may be done as often as any mucus collects, without in the slightest degree disturbing the patient. The two tubes are fixed by means of a button, attached to the edge of the outer one (Fig. 770).

When a trachea-tube has been worn for any length of time, it will almost

Fig. 770.—Tracheotomy-tube. The inner tube has been removed from the outer.

always be found that ulceration has taken place in the trachea at some point as the result of pressure. The discharge from this ulcerating surface, and the increased secretion caused by the accompanying irritation, add greatly to the difficulty experienced in keeping the tube from becoming blocked. R. W. Parker has pointed out that this ulceration is due to the fact that the ordinary quarter-circle tubes do not correspond with the natural direction of the trachea, and that consequently the end of the tube impinges on the anterior wall of the trachea. To overcome this difficulty Parker has devised an angular tube (Fig. 770) so shaped that the part which lies in the trachea accurately follows its direction. The tube is fitted with a movable collar, as suggested by Roger of Paris, which will be found more comfortable to the patient than a rigid shield.

With the same object Marrant Baker has employed a tube made of india-rubber, such as is used in the manufacture of the india-rubber catheter (Fig. 771). It has sufficient rigidity to prevent its collapsing, but not sufficient to give rise to irritation or to cause ulceration. It is to be introduced after the first twenty-four hours, a silver tube being used till then. The tube is single, but the ease with which it can be removed and re-introduced is so great, that there is no difficulty in keeping it clean; in fact, the irritation produced in so doing is said to be less than that caused by the removal of the inner tube of any ordinary double trachea-tube. Baker has found, from experience in a considerable number of cases, that it is worn with much greater comfort to the patient than a rigid tube.

It has sometimes happened that in consequence of the tube becoming detached from the shield, it has slipped into the trachea. Cases of this kind have been related by Walters, and by J. W. Ogle. The removal of the tubes was effected by means of forceps.

Fig. 771.—Baker's Tracheotomy-tube.

**Tracheotomy in Children** is never easy, and is at times a dangerous operation. The difficulty of the operation arises more particularly in infants and very young children from the shortness of the neck, and the depth and small size of the trachea. Before the age of puberty, this tube is usually thickly covered by a quantity of loose granular fat, containing many veins, and is of small size, so that a slight deviation of the incision to one side may readily lead the Surgeon astray, and into dangerous proximity with the carotid arteries. The danger of the operation results from the large size of the venous plexuses in connexion with the thyroid body. In performing this operation in young subjects, chloroform should always be administered. This may be done with safety, even though the most urgent dyspnoea be present; the difficulty of respiration, being in a great measure spasmodic, is relieved by the anæsthetic. If chloroform be not given, the struggles of the child will seriously embarrass the operator. The dangers and difficulties of the operation are avoided only by attention to the advice already given, to keep accurately to the middle line, to avoid operating too high, mistaking the hyoid bone for the pomum Adami, to make a sufficiently free incision, and above all, to avoid needless hurry in cases in which asphyxia is not imminent, and to do the operation by a careful process of dissection, rather than by irregular tearing with blunt instruments.

**Comparison of Tracheotomy and Laryngotomy.**—On comparing tracheotomy, as ordinarily performed, with laryngotomy, I think there can be little doubt that the Surgeon should give the preference, in all cases where it is practicable, to the latter operation, on account of its greater simplicity, safety, and rapidity. When the windpipe is to be opened for the extraction of a foreign body, tracheotomy should be performed in preference to laryngotomy, as the latter operation does not provide a sufficient opening for its expulsion or extraction. In children the larynx is so little developed, that tracheotomy should as a rule be done. In all cases in which the obstruction to respiration is produced by inflammatory effusion into the submucous areolar tissue, or œdema glottidis, whether dependent upon idiopathic or erysipelalous laryngitis, or chronic disease of the larynx, or upon the irritation and inflammation excited by swallowing boiling water or the stronger acids, in my opinion, laryngotomy is the operation that should be preferred in the adult; and this opinion is based on the following reasons:—

1. As in laryngotomy the air-tube is always opened below the seat of obstruction, there can be no necessity to make an aperture farther from the seat of disease. In laryngitis, whether acute or chronic, the obstruction to breathing depends upon swelling of the lips of the glottis causing an impediment to the entrance of air. But this loose submucous areolar tissue terminates at the true vocal cords, where the mucous membrane becomes directly applied to the subjacent fibrous structures; the swelling and consequent mechanical impediment are hence confined to the limits of the thyroid cartilage, and any opening made below this will clear the lowest limit of the disease, which is always accurately bounded below by the vocal cords. Hence an aperture in the crico-thyroid membrane is quite as effectual as one in the trachea.

2. Laryngotomy is a far safer operation than tracheotomy. On this point I need scarcely dwell: a glance at the anatomy of the parts concerned will be sufficient to establish it. The crico-thyroid membrane is nearly subcutaneous, and no parts of importance can be wounded in opening it, if we except the

small crico-thyroid artery which crosses it, and which might be cut across, but from which I have never seen any trouble arise. The trachea, on the contrary, is not only deeply seated, but covered by a large plexus of blood-vessels, which, when rendered turgid by the asphyxiated condition that exists when an operation is required, pours out a large quantity of dark blood, and thus seriously embarrasses and delays the Surgeon at a time when the life of the patient depends on the speedy admission of air to his lungs.

3. Laryngotomy can be much more quickly performed than tracheotomy. This I look upon as an inestimable advantage in many of the cases requiring operation; a few seconds more or less being sufficient to turn the balance either in favour of life or of death. The rapidity with which laryngeal obstruction—partly mechanical and partly from spasm—sets in, is sometimes so great, more particularly when an acute inflammation supervenes on chronic disease of the larynx, that life may be extinguished before the Surgeon has time to open the windpipe, if he endeavour to do so by tracheotomy. In extreme cases, in which the lungs have become slowly engorged, the action of the heart is already enfeebled, and a sudden spasm occurring at the glottis will at once place the patient beyond recovery. But even though life appear for the moment extinct, it is the imperative duty of the Surgeon to open the air-passage as speedily as possible, and to endeavour, by means of artificial respiration, to revive the flickering spark; and it is impossible to experience a greater satisfaction in the exercise of our profession, or to witness a greater triumph of art, than in thus snatching a patient out of the very jaws of death.

An objection has been urged to laryngotomy in these cases, that it does not allow the patient to wear a tube without much irritation being induced. This, however, I have not found to be the case in my practice. I have had patients who have worn silver tubes in this situation a considerable number of years, in one case as many as twelve, and in whom no special irritation has been occasioned by them.

**After-Treatment of Laryngotomy and Tracheotomy.**—In all cases after the windpipe has been opened, the patient should be placed in a well-warmed room, the air of which should be kept moist by means of steam. A thin piece of muslin folded two or three times may be laid over the opening of the tube to exclude dust. If the operation have been performed for some temporary obstruction of the glottis, such as the impaction of a foreign body, the tube may be taken out as soon as the cause is removed, and the wound allowed to heal by granulation, or as suggested by MacCormac, the wound in the trachea may be closed by cat-gut sutures.

The *after-treatment of tracheotomy for membranous laryngitis* requires special attention, as the success of the operation depends almost entirely upon it. The objects in view are, 1st, to provide a warm moist atmosphere, in order to diminish as far as possible the risk of bronchitis; 2nd, to keep the tube clean and free; 3rd, to hasten the separation of the membrane and limit its extension; and 4th, to remove the tube at the earliest possible period.

A *warm moist atmosphere* is best provided by placing the child in a bed over which a sort of tent of sheets is reared, supported by pieces of lath or iron attached to the legs of the bedstead. One side of this tent must be left open, and through this opening a current of steam must be introduced from a kettle, to the nozzle of which a tin tube is attached. The best apparatus for this purpose is the "croup kettle," invented by R. W. Parker, which supplies

a current of warm air mixed with the steam, thus efficiently maintaining ventilation as well as warmth and moisture. By its means the temperature can be easily regulated, so that there is little risk of weakening the child by over-heating. 2. *The tube must be kept clean* by frequently removing the inner part and washing it with warm water and cleaning the inside with a feather. If it is caked inside with dried mucus, this will readily be removed by a solution of carbonate of soda. After the fourth day the outer tube also may be removed and cleaned once every twenty-four hours. The patient must be constantly watched day and night, and any mucus that appears at the orifice of the tube during efforts at coughing must be wiped away with a sponge. 3. *To hasten the separation of the membrane and to prevent its extension* various substances may be administered by inhalation. Carbolic acid, creasote and eucalyptus oil may be given by adding a few drops to the water in the kettle, from which the steam is being supplied. Quinine may be administered by means of a spray from a Siegle's apparatus, the solution used containing about four grains to the ounce. Solvents may be used in the same way to soften the membrane: the best of these is carbonate of soda (gr. xx. to 3j.). Lactic acid also has been recommended, but it does not seem to be superior to the soda solution. These substances in spray may be used every two or three hours, the child being wrapped in a mackintosh cloth at the time to avoid wetting the clothes. R. W. Parker, believing that in all cases of membranous laryngitis the disease is at first local, and that the general symptoms are due to the absorption of the unhealthy products of the local process, insists very strongly on the necessity of clearing these away both at the time of the operation and afterwards. Before inserting the tube he recommends that the incision in the trachea should be held open with hooks or a dilator, while all membrane within reach is removed by means of a feather which has previously been soaked in a solution of carbonate of soda. In order to clear the larynx the feather may be passed upwards into the mouth. This apparently severe treatment has in his hands proved very successful, no fewer than 8 out of 16 cases thus treated having recovered.

The feeding of the patient must not be neglected, even if considerable persuasion be necessary to make the child swallow. Food should be given about every two hours, and soft solids will often be taken more easily than liquids.

4. *The removal of the tube* should always be accomplished as soon as possible. It is often difficult to determine when this can be done safely. Many tubes are made with an opening at the upper part, so that the patency of the glottis can be ascertained by placing the finger over the external opening, and observing the effect. The return of the voice, more or less perfectly, when the opening is closed, is usually a sign that the tube may safely be removed.

**Difficulty in establishing natural respiration after Tracheotomy.**—

In rare cases it is found impossible to dispense with the tracheotomy tube on account of the occurrence of laryngeal obstruction either at once or after an interval. Cases of this kind may be divided into two classes: those in which the obstruction is due to spasm or paralysis of the larynx, and those in which there is actual mechanical obstruction. It sometimes happens that the passage of air through the larynx, after a tube has been worn for some time, causes spasm of the glottis, which may threaten suffocation. This cause may

be suspected if the breathing is free under the influence of chloroform whilst the opening in the trachea is closed. The spasm is best overcome by removing the tube periodically for longer or shorter intervals until the patient becomes accustomed to its absence; or a tube with an opening in its upper part may be used, and the external opening may be plugged with a cork which can be at once removed should dyspnoea occur. If these methods fail, catheterization or intubation of the larynx should be tried. In a case recorded by Bilton Pollard the tracheotomy tube had been worn for nearly two years, and in spite of many kinds of treatment could not be dispensed with. A Macewen's tracheal catheter was introduced and left in for thirty-one hours, after which the breathing was easy, and in fourteen days the tracheotomy wound had healed. An O'Dwyer's intubation tube may be used with advantage in such cases. Paralysis of the abductor muscles has been recorded by Gerhardt, but it is exceedingly rare and its cause is very uncertain.

*Mechanical obstruction* after tracheotomy may arise from three causes: obstruction by masses of fungating granulation tissue, adhesion of the vocal cords, and cicatricial contraction of the glottis, consequent upon the disease for which the operation was performed. The formation of fungating granulation tissue may occur above the tube, projecting upwards into the larynx, or more rarely below the tube where its point touches the trachea. R. W. Parker has recorded a fatal case of obstruction of the tube by a mass of granulation tissue formed below it. More commonly the granulation tissue is above the tube and prevents its removal. The treatment in these cases consists in the application of nitrate of silver, either by means of a coated probe or a brush dipped in a solution of 30 grains to one ounce of water, introduced by the wound. If this fails, a tracheal catheter may be passed through the larynx, and retained for from twenty-four to thirty-six hours, or intubation may be performed. The pressure of the tube destroys the fungating mass. If this fails the parts may be carefully scraped with a sharp spoon, the head being allowed to fall backwards so that blood shall not flow down into the lungs, or as a last resource thyrotomy may be performed and the granulation tissue removed. Chloroform is, of course, required for any of these proceedings. Adhesion of the vocal cords is rare, and is treated by the passage of an instrument upwards from the wound, or by division of the adhesions followed by intubation. Cicatricial contraction commonly occurs in cases of syphilitic disease, and usually resists all simple treatment. In a case of this nature E. C. Stabb performed thyrotomy and removed the cicatricial tissue which replaced the true and false vocal cords of the right side, together with a large piece of necrosed cricoid cartilage. The patient made a complete recovery.

**Intubation of the Larynx.**—Since the latter half of the last century various attempts have been made, sometimes with success, to relieve acute or chronic laryngeal obstruction by the passage of a tube from the mouth through the larynx into the trachea. In recent years the utility of "catheterization of the larynx" has been especially demonstrated by Macewen, who, in 1880, published four cases in which this treatment was adopted. In two instances a catheter was passed through the larynx for the relief of obstruction due to œdema of the glottis; both cases recovered. In a third case the tube was used in place of preliminary tracheotomy during the removal of a carcinoma of the tongue and pharynx; it served its purpose well, the aperture of the larynx

being plugged around the tube with a sponge. In the fourth case it was intended to use the catheter during a similar operation and its introduction had been successfully practised beforehand, but the patient died during the administration of the chloroform.

A short tube which could be left in the larynx, with its larger upper end resting on the cords, was first employed by Bouchut in 1858, but the credit of devising the method of "intubation of the larynx" as at present practised is due to Joseph O'Dwyer, of New York. The gold-plated brass tube which is passed into the larynx is represented in Fig. 772. The expanded upper end of the tube rests upon the ventricular bands, and the constricted part below lies between the vocal cords. The tubes are made in different sizes. The other instruments required are an efficient gag, a specially constructed "introducer" for placing the tube in the larynx, and an "extractor" for removing it. The "introducer" is screwed on to a steel obturator which accurately fits

Fig. 772.—O'Dwyer's Intubation Tube—size for children of from five to seven years of age.

the tube. If the patient be a child it should be seated on the nurse's lap with the head against her left shoulder. An assistant standing behind steadies the head and holds the gag. The Surgeon, sitting in front of the patient, passes his left index finger to the upper aperture of the larynx, and with this as a guide, inserts the tube by means of the "introducer," which is then at once removed. A loop of thread attached to the head of the tube serves as a safeguard against leaving the tube in the oesophagus; it may be cut and withdrawn as soon as it is certain that the tube is in its right position. This is shown by an attack of coughing and the relief afforded to the breathing. After a short time the larynx becomes very tolerant of the presence of the tube and in some cases it has been worn for long periods. The interference with the act of swallowing caused by the tube varies considerably; soft solids are usually taken more easily than fluids, and it has been found that often deglutition is most easy when the child is lying on its back with the head slightly dependent.

The operation of intubation is not easy. It is far easier to pass the tube into the pharynx than into the larynx, and it is very necessary that the Surgeon should gain the required skill by practice on the cadaver.

*Indications.*—Speaking generally it may be said that intubation should be tried as a substitute for tracheotomy in cases of obstruction due to simple oedematous laryngitis or to oedema of the glottis such as follows scalds of the larynx. It has also been employed successfully in the treatment of chronic forms of laryngeal obstruction, sometimes after division of cicatricial bands, and reference has already been made to its use in cases in which difficulty is met with in establishing natural respiration after tracheotomy.

In connexion with membranous laryngitis it is impossible at the present time to speak positively of the relative merits of intubation and tracheotomy. It seems probable, however, that if the hopes entertained of the treatment of diphtheria with the antitoxin are realized, and the false membrane can be rapidly loosened and detached, intubation may be found more successful than hitherto. A large number of statistics have been brought forward to show the

relative mortality of the two methods. J. B. Ball has collected 1849 cases of intubation, and adding these to 2368 cases previously collected by Dillon Brown, of New York, the total recoveries were 1285, or 30·4 per cent. ; whilst after tracheotomy Ball finds that the recoveries, reckoned from a large number of statistics, are 27 to 28 per cent. The difference is small, but in cases under one year old the evidence afforded by statistics is certainly in favour of intubation. As objections to intubation may be mentioned the danger of detaching membrane and pushing it down in front of the tube, the impossibility of applying local treatment to the larynx and trachea, and its failure to give relief if, as Ball remarks, there is much swelling about the pharynx and tonsils. To those who have made themselves skilled in the introduction of the tube intubation is simpler than tracheotomy, and has the advantage that consent for its employment is readily obtained ; the tube can usually be dispensed with about the fifth day, and thus in successful cases the average duration of the treatment is shorter than after tracheotomy. Lastly, it must be allowed that if the tube becomes blocked and expelled by coughing, in the absence of skilled assistance, the position is more critical than any which is likely to arise after tracheotomy. On the whole the evidence is certainly in favour of its continued trial, but intubation for diphtheria should never be attempted unless the necessary means for the performance of tracheotomy are at hand.

#### SURGICAL OPERATIONS ON THE CHEST.

**TAPPING THE PLEURAL CAVITY.**—The operation of **Tapping the Pleural Cavity** is required in cases of hydrothorax, empyema, and hæmothorax. The point of selection is a spot in the fifth intercostal space on the lateral median line. This point is crossed by a line drawn horizontally round the body from the nipple to the spine.

As it is of great importance in cases of *hydrothorax* to exclude the air from the pleural sac, the operation is now almost invariably performed by the aspirator. The ordinary bottle-aspirator (Fig. 773) will usually be found the most convenient instrument. The air having been exhausted from the bottle by means of the air-pump, and the stop-cock closed, the chest is tapped in the way presently to be described with the aspirator-trochar ; and the cock in its side being turned on, the fluid rushes into the bottle to fill up the vacuum. The original aspirator, as invented by Dieulafoy (Fig. 94, Vol. I.), may be used, and can easily be converted into a siphon.

Thompson's "*Siphon-trochar*" will usually answer the purpose well enough. If it be used the fluid is allowed to run off by the elastic tube, the end of which is immersed in a vessel containing a 1 in 20 solution of carbolic acid (Fig. 774).

In the absence of all special instruments the chest may be safely tapped with a common trochar by the simple method suggested by Reybard. A piece of thick linen or cotton rag free from holes is made into a funnel, the narrow end of which is tied lightly round the cannula immediately below its expanded end. The funnel is then thoroughly soaked in carbolic oil (1 in 10). When the trochar is withdrawn the funnel of oiled rag hangs down from the end of the cannula, and serves to direct the fluid into a vessel held to receive it, and at the same time it forms an efficient valve which prevents the entrance of air during inspiration.

Whatever plan be adopted, the side of the chest, the operator's hands and

all instruments used must be carefully washed in a solution of carbolic acid (1 in 20). The *lower* border of the sixth rib is then felt for, and if a trochar is being used, a small incision may be made through the skin, parallel to it, in the mid-axillary line. The point chosen should correspond to the interval between two digitations of the serratus magnus. If the aspirator is being used no incision is required. The skin is then drawn upwards till the point chosen in the skin corresponds to the *upper* border of the rib, and the point of the trochar is then slipped over its margin and thrust sharply and firmly into the pleural sac, so as to make sure of penetrating the thickened pleura, and any layer of false membrane, which if the instrument were pushed

Fig. 773.—Tapping the Chest by the Bottle-Aspirator.

slowly on, might be thrust before it. By thus passing the trochar immediately above the rib any risk of wounding the intercostal artery or nerve is avoided, while by drawing up the skin before so doing the superficial opening and that in the intercostal muscles and pleura do not correspond and thus the track of the trochar is efficiently closed. After the withdrawal of the cannula the puncture is covered with some dry cotton-wool and collodion, or by a piece of adhesive plaster, and will usually unite without trouble.

If the aspirator is used the details described in Vol. I., p. 245, must be attended to. It must be remembered that when the vacuum is moderately perfect the lung is being expanded by the pressure of the atmosphere with a force equal to fifteen pounds to the square inch. This may possibly cause some injury by rupture of adhesions, and even cause hæmorrhage from the lung. If therefore the patient complains of severe pain after a certain amount of fluid has been withdrawn, or if the fluid becomes blood-stained, the

operation must at once be brought to an end, and repeated after an interval of a day or two, if necessary.

The importance of antiseptic precautions such as have been described above is very great even in a simple case of hydrothorax. If they are rigidly carried out, tapping may be repeated several times without evil result, but should they be neglected the hydrothorax is very prone to become converted into empyema.

**Surgical Treatment of Empyema.**—When the fluid in the chest is purulent it is generally acknowledged that the patient's chance of recovery is but small, except by surgical interference. The consideration of general

Fig. 774.—Tapping the Chest by the Siphon-Trochar.

symptoms indicating the presence of pus in the pleura belongs to medicine rather than to surgery, and need not be discussed here. In all cases of doubt the diagnosis may be readily made by means of the aspirator. The presence of pus having been determined, there should be no delay in removing it. The longer it is left, the more firmly the lung becomes bound down by adhesions, and the probability of its perfect expansion becomes less. Moreover, the pus may burrow beyond the limits of the pleural cavity, finding its way downwards into the iliac fossa, or more rarely into the abdominal cavity, and thus add greatly to the gravity of the case. The proportion of cases of empyema which are cured by simple aspiration is so small that valuable time should not be lost in attempting this before proceeding to drain the cavity.

The operation of opening the pleura for empyema, though one of the most ancient in surgery, was until recently so unsatisfactory in its results that it was resorted to only in the last extremity. The fatal result that so frequently

followed was due to septic fever and prolonged suppuration consequent upon imperfect drainage and decomposition of the retained fluid. With the view of preventing the accumulation of pus and diminishing the risk of septic poisoning Goodfellow and De Morgan adopted the use of Chassaignac's drainage-tubes with considerable advantage; but it was not until the introduction of efficient antiseptic treatment that the operation became really safe and successful. In discussing the operation the following points have to be considered:—1. The best point for making the opening; 2. The method of making it; 3. The form of tube; 4. The dressing and after-treatment; 5. The removal of the tube; 6. The results; and 7. The subsequent treatment of the cavity should the lung fail to expand.

1. **The best point for the opening** is the subject of considerable difference of opinion. When the Surgeon is free to choose the position of the opening, he may either select a point in the sixth intercostal space in front of the posterior axillary line, or a point slightly below and outside the angle of the scapula. Objection has been raised to the latter position on account of the closer proximity of the ribs here than further forward, and the greater thickness of the overlying muscles. It has further been pointed out that as the patient usually lies on the affected side, an opening in the axilla is more dependent than one further back, and again, that an opening made too far back is liable to become early overlapped by the expanding lung, and drainage thus interfered with, or a sinus difficult to heal may be left running forwards towards the anterior part of the chest. Notwithstanding these theoretical considerations, it is found that, in practice, an opening below and external to the angle of the scapula is very efficient, and if, as is usually advisable, a piece of rib is excised, the narrowness of the intercostal spaces is no objection. If, however, the Surgeon is called upon to operate without assistance, or in a case in which the administration of an anæsthetic is thought inadvisable, the removal of a piece of rib may be dispensed with, and the opening best made in the axilla at the point above described.

It was pointed out by John Marshall that, immediately outside and below the junction of the fifth rib with its cartilage, there is a point in the chest wall at which, from the comparative absence of superjacent muscles, the pleura is but slightly supported externally, and through this he believed that an empyema tends naturally to point. This point is above the origin of the external oblique, external to the insertion of the rectus and internal to the origin of the serratus magnus. It is covered by the outer edge of the pectoralis major, and is beyond the anterior limit of the external intercostal muscle. That an empyema may perforate the chest at this point is undoubted, but according to most authorities it tends to point higher up in the second or third space. Marshall, arguing from the excellent results that usually follow the opening of an empyema pointing in front, suggested that the opening should always be made at the thin point above mentioned, but subsequent experience has not shown that this method presents any practical advantages.

When an empyema is pointing subcutaneously, the superficial collection of pus should be opened and, as a rule, a second opening will be required in a more convenient position. In a case of localized empyema the incision must, of course, be made over the collection of pus.

2. **The method of operating.**—Chloroform should always be used in preference to ether, and the operation should be performed with the strictest

antiseptic precautions. The patient should be drawn well to the edge of the table so that it may not be necessary to roll him on to the sound side, a position which is apt seriously to interfere with the breathing. A point on the ninth rib is chosen which is slightly external to the angle of the scapula when the arm is by the side.

An incision from two to three inches in length is made directly upon the rib, the periosteum of which must be divided in the long axis of the bone. The wound is then held widely open with the blunt hooks and the periosteum stripped from the exposed part of the rib with an elevator, which must not be too sharp. No difficulty will be found in turning the intercostal artery out of its groove at the lower border. A curved elevator is then passed completely under the rib and the bone divided in two places with a saw or bone-forceps, and about an inch and a half of its length removed. The pleura should not be wounded up to this stage in the operation. All bleeding having been arrested, the pleura may be opened and the tube inserted. If it be preferred the operation may be performed by a T-shaped incision, but this usually presents no advantage over the simple longitudinal. The removal of a piece of rib is not accompanied by any difficulty or danger. Necrosis rarely follows, not more often apparently than after the simple insertion of a tube between the ribs. New bone rapidly forms from the periosteum, and after a time the continuity of the rib is restored, and sometimes a mass of bone fills the intercostal spaces.

The advantage of removing a piece of rib is that a larger opening can be made, which facilitates the escape of the masses of lymph which are often present in the pus, permits the introduction of the finger to investigate the condition of the cavity, and allows the use of a large drainage-tube.

If the removal of the rib is not practised the opening is best made, as before said, in the sixth intercostal space about an inch in front of the posterior axillary line. An incision should be made about an inch and a half in length parallel to the upper border of the sixth rib and exposing it clearly. Any superficial vessel that bleeds may then be secured. The intercostal muscles and pleura are next punctured with the scalpel, guided by the left forefinger in the wound, immediately above the rib, so as to avoid the intercostal artery. The blade of the knife must be parallel to the rib. A pair of dressing-forceps may then be introduced and the wound stretched by expanding the blades, after which the tube may be at once inserted.

3. The **Tube**.—The ordinary india-rubber drainage-tube should be used, but care must be taken that there is no hole in the part corresponding to the chest wall, as granulations are apt to sprout up into it and obstruct the lumen. It must be provided with a shield, lest it slip into the pleural cavity. The best form is that suggested by E. B. Baxter. It is thus prepared: In the middle of a piece of sheet india-rubber, about a sixteenth of an inch thick, and one inch and a half to two inches square, a round hole is cut of the same size as the drainage-tube. The tube is then passed through for a sufficient distance, and split into four pieces sufficiently long to reach to the four corners of the shield, to which they are attached by silver wire. The remainder of the tube on the other side of the shield must have holes cut in it at intervals, as in an ordinary drainage-tube. The tube must vary in diameter with the size of the cavity, and, as the discharge lessens, a smaller one may be substituted. It need never be more than two or three inches in length. Nothing is gained by

putting eight or nine inches of tube into the pleura ; it cannot suck the fluid out, and only causes needless irritation.

4. The **dressing and after-treatment.** The deep part of the dressing should consist of cyanide or alembroth gauze, over which it is well to place a piece of oiled silk or some other impermeable material, to prevent the discharge soaking directly through opposite the wound. The outer part of the dressing should consist of an absorbent mass of antiseptic wool, sublimate wood-wool, carded oakum, or carbolized jute. For the first few days the dressing should be changed at least daily, but the intervals may be gradually increased. When the dressing is removed, the entrance of impure air should be prevented by immediately covering the wound with a piece of rag soaked in some antiseptic solution. In ordinary cases nothing is gained by washing out the cavity with antiseptic solutions, a proceeding which has been known to cause sudden death in more than one case, an accident the cause of which is quite unknown. If, however, it is thought necessary to wash out a cavity, the discharge from which is profuse and offensive, two tubes of unequal size should be inserted as recommended by Godlee and the fluid slowly injected through the smaller one. In this way a free escape for the fluid is ensured.

5. The **removal of the tube.** The time at which the tube should be removed is often a difficult point to determine. When the discharge becomes purely serous and very small in amount, the tube may at first be shortened till it is just long enough to retain its position. It is then often forced out by the granulations, or by the expanding lung. It is well to examine the cavity carefully with a probe before removing the tube, as the space unclosed may be larger than would be supposed from the amount of discharge. So long as a distinct cavity remains the tube should be retained. In young children, especially if the opening has been made early, the tube may sometimes be removed after a week or ten days, and often need not be retained after a fortnight. In adults, in whom expansion of the lung is often less perfect, and whose chest-walls are too rigid to sink in, many months usually elapse before the cavity is closed, and in some cases complete recovery never takes place. Long sinuses, very troublesome to heal, are occasionally left. These commonly arise from opening too far back or too low down, or from the prolonged retention of tubes of needless length.

In some cases in which a small cavity remains and refuses to heal, Godlee has obtained good results by removing the tube and passing a small catheter along the track daily, so as to give exit to any discharge which may have accumulated.

6. The **results** of the operation for empyema are usually as satisfactory now as they were formerly unsatisfactory. In children, especially if the health is otherwise good, recovery is the rule. The temperature falls immediately after the operation, and unless some complication occur, seldom rises again. If the operation be not too long delayed, complete expansion of the lung usually takes place. This is effected by the gradual adhesion of the two pleural surfaces to each other, commencing in the angle of reflexion from the chest walls to the lung.

Operation for *empyema without antiseptic precautions* may occasionally be necessary when the means of proper treatment are not obtainable. The Surgeon must then rely on freedom of drainage, by which it may be possible so far to reduce the quantity of decomposable matter in the chest, that the dose of septic products absorbed by the patient shall not be sufficient to cause

serious constitutional disturbance. This object is best attained either by making a free incision some inches in length between two ribs, or by the insertion of two tubes, one in the ordinary situation, and one at the lowest possible point in the pleura. The second opening may be made upon a curved probe passed in at the upper wound.

In cases of *tuberculous empyema* operation should, if possible, be avoided. In cases in which drainage is necessary it may be advisable very carefully to wash out the cavity with two tubes in the way above described.

7. **Estlander's Operation.**—In cases in which the cavity of the empyema continues to discharge after many months, or even years, showing no signs of diminishing either by contraction of the chest-walls or expansion of the lung, the patient's condition becomes very serious. If the cavity be very small it is possible the sinus may remain discharging a small quantity of pus without causing much inconvenience, but if it be of any size it is almost impossible to keep it clean, and the health is gradually impaired by the constant absorption of small quantities of septic matter, and finally death will almost inevitably occur from albumenoid degeneration of the viscera. In such cases Estlander proposed the removal of the bony wall of the chest corresponding to the cavity, so that the soft parts of the chest-wall should come in direct contact with the surface of the lung. This operation has now been performed in a large number of cases with a very considerable measure of success. The area of the cavity must first be accurately ascertained by careful probing. The ribs are then exposed by a free incision. This may be done by raising a large flap, or by a single vertical incision. In whichever way it is done the whole area from which the ribs are to be removed must be fully exposed, so that the thickened pleura can be cut away as well as the bones, and any bleeding vessel easily secured. The ribs having been exposed are removed separately to the required extent by the method already described. The thickened pleura with the periosteum which has been stripped from the ribs is then cut away with a strong pair of scissors. The intercostal vessels lying in this dense tissue are usually obliterated, so that there is singularly little bleeding. Unless the thickened pleura be removed as well as the ribs, the operation is certain to fail, as it is almost as unyielding as the bony wall. The wound is then cleaned with some efficient antiseptic solution and closed by sutures, a drainage-tube being inserted at the most dependent part, and an antiseptic dressing applied.

Estlander's operation is only applicable to cases in which the patient is otherwise in good health and free from tuberculous disease of the lungs. It can scarcely ever be required except in adults, as the soft walls of a child's thorax readily fall in, even if the lung fails to expand.

**Pneumothorax.**—In some cases an accumulation of air in the pleural cavity gives rise to so much interference with respiration that it is necessary to remove it by aspiration. This has been practised in traumatic pneumothorax, and also in cases of spontaneous origin. Aspiration should, however, never be performed for tuberculous pneumothorax.

#### TAPPING PULMONARY CAVITIES.

The operation of tapping vomicae in the lungs in phthisical patients could not be done with certainty until the existence and precise seat of such cavities could be accurately determined by auscultation; for, prior

to Laennec's time, the physician could not diagnose a pulmonary cavity from a circumscribed empyema communicating with the lung. Hence the accounts of such an operation given by the older writers on medicine from the days of Hippocrates down to the present century must be received with scepticism. But that the idea of treating pulmonary cavities by incision or tapping had suggested itself at an early period to medical practitioners, there can be no doubt; for, without going back to the earlier medical writers, we find Barry in 1726 recommending that phthisical cavities should be opened, with the view of giving a direct exit to the contained matters, thus, by avoiding violent paroxysms of cough, making it possible for the parts to be kept at rest, so as to be more likely to undergo a cure. The proposal received little attention, and the practice died out, until, in 1836, it was revived by an empiric of the name of Ramadge, who appears to have tapped the chest on several occasions in order to let out pus from cavities in the lungs. In 1845, Storks performed this operation with success, in a case under the care of Hastings. He operated by making a long incision upon the upper border of a rib, and then opening up the cavity by means of a pair of forceps, and inserting a cannula to allow of the escape of the contents. This case attracted little attention at the time, and the operation again died out, until it was revived by Mosler of Greifswald, who not only tapped, but injected the cavities with disinfectant solutions.

Pepper of Philadelphia, who has published an exhaustive article on this subject, adopts a different procedure. He taps the vomica with a small cannula and trochar fitted to a syringe, and injects the cavity with dilated tincture of iodine. Shingleton Smith instead of iodine has used a solution of one grain of iodoform in five minims of ether injected by means of a Pravaz's syringe. Although in some cases the fœtor of the expectoration was diminished but little curative result was obtained.

During the last few years cavities of the lung of various kinds have been opened by Marshall, Godlee, Gould, and others, but the limits of the operation and the best cases for its performance have yet to be determined. The state of opinion at the present time is thus summed up by Godlee: 1. Gangrenous cavities should always be sought, and if possible, opened, and the prognosis, if the operation be successful, is not bad. 2. The same may be said in regard to abscesses caused by rupture of purulent collections from other parts into the lung, at least as regards the pulmonary complication. 3. Abscesses connected with foreign bodies must be opened, and, if the body be not found, it must be remembered that if of any size, it probably lies in one of the larger bronchial tubes not more than three inches from the middle line. 4. Bronchiectatic cavities when single (a very rare condition) will be cured by operation. When multiple (a very common condition), they offer but small chance of relief. 5. Tuberculous cavities should be opened only when the cough is harassing and the cavity single. Injections may be used to relieve symptoms, but cannot be expected to cure.

The **operation** is more safely done by carefully incising the lung than by the use of a trochar and cannula. Chloroform should be administered with great care, and the presence of pus ascertained by thrusting an aspirator needle through the intercostal space over the position of the supposed abscess. A portion of one or two ribs should be excised in the way already described (p. 761), and the parietal layer of the pleura fully exposed. If there is reason to believe that the two layers of the pleura are adherent, the lung may be at

once incised with a long straight scalpel, passed along the aspirator needle which serves as a guide to the cavity. Should it be necessary to open up the lung substance more freely, this may best be done by means of dressing forceps, as in Hilton's plan of opening deep abscesses. Free drainage must be secured by introducing a flanged drainage-tube well into the cavity. The Surgeon must be prepared for somewhat profuse hæmorrhage, the blood escaping from the wound or through the mouth. As a rule the bleeding quickly ceases, but sometimes it is necessary to arrest it by gently plugging the cavity with strips of gauze.

If, after the pleura has been exposed, the Surgeon be doubtful as to the existence of adhesions, there is grave danger in proceeding at once to incise the lung. In the absence of adhesions the lung will at once retract when the parietal pleura is divided, and all further attempts to draw up the lung and open the abscess will fail or be attended with almost certain infection of the pleural cavity. Under these circumstances the Surgeon should follow Godlee's advice and endeavour to stitch up the lung to the parietal pleura without opening the latter, and postpone incising the lung for at least a week.

No antiseptics are needed when the contents of the cavity are already decomposing; free drainage is all that is required; and all antiseptics, if injected, irritate the bronchi and lung.

If there is any reason to think that the abscess is the result of the presence of a foreign body in the lung it may be advisable to keep the wound open with a tube for a considerable period in the hope that the foreign body may work its way out. In a case of pulmonary abscess recently under the care of Godlee in University College Hospital, the iron peg of a top escaped from the wound many months after it had entered the air-passages.

**Hydatids of the Lung.**—Hydatid disease of the chest, affecting chiefly the lung substance or the pleura, is so rare in this country that for our knowledge of the subject we are largely indebted to Australian writers, among whom may be mentioned Dougau Bird of Melbourne, and Thomas and Gardner of Adelaide. Although, in some instances, successful results have followed the simple operation of tapping or aspiration, the dangers attending this treatment are so great that it should not be practised in a case in which hydatid disease of the lung is suspected. The danger consists in suffocation, due to the sudden flooding of the lung tissue with fluid from the cyst. A case in which a fatal result was thus caused has recently been recorded in this country by Bristowe. The safer plan to adopt is to expose the lung after the removal of a portion of one or more ribs in the way recommended for the treatment of abscess in the lung. The cyst should then be exposed and opened by incising the lung-substance and the cavity drained, or if possible, the parasitic cyst completely removed, as advocated by Gardner and others.

**TAPPING THE PERICARDIUM.**—In hydrops pericardii, attended with imminent danger of death from pressure, it will be necessary to **tap the pericardium**. The operation is most safely done with the aspirator. From experiments made on the dead body, Dicuafey concludes that it may be performed in the fourth or fifth left interspace, the fifth being perhaps preferable, as it is nearer the apex of the heart and is a more dependent situation. The puncture may be made from 2 to 2½ inches from the left margin of the sternum. The

spot having been selected should be marked with ink. If the patient be anasarcaous, the interspace must be determined by carefully pressing away the œdema. The needle to be employed should vary with the case. If the diagnosis be certain, No. 2 (one millimetre, or roughly  $\frac{1}{16}$  inch in diameter), should be used ; but if the diagnosis be uncertain, No. 1, half this size, should be chosen, as with this needle, it is said, the heart may be punctured with impunity. The best form of aspirator to use is one such as is represented in Fig. 94, Vol. I., as needles of such small size are apt to be plugged with small flakes of lymph, and if such an accident occur, they may be cleared again by reversing the syringe and forcing a small quantity of fluid back into the pericardium. Before using the aspirator, it should be carefully tested with some carbolized water to render it aseptic, and to see that the needle is pervious, and the whole apparatus in working order. A vacuum having been created in the aspirator by drawing back and fixing the piston, the needle is to be inserted at the spot determined on. As soon as the opening at the point of the needle is covered, the stop-cock leading to it is to be opened, so that the vacuum extends into the needle ; and " we now advance, vacuum in hand, in search of the effusion." The needle must be pushed slowly and carefully onwards in a direction upwards and inwards till the fluid appears in the glass tube of the aspirator. The moment this occurs all movement of the needle must cease, and it must be held steadily as long as the fluid continues to flow. Any unnecessary movement may scratch and injure the surface of the heart. If the flow cease suddenly, as if from some obstruction, a little fluid may be forced back as above stated, to clear the needle. After withdrawing the needle the puncture should be covered with wool and collodion. Over a pint of fluid has been removed by this means at one operation. In inserting the needle, care must be taken not to force it through a costal cartilage, or a small plug of cartilage may be cut out which would effectually close its canal.

**Drainage of the Pericardium** may be required for purulent pericarditis. The incision should be made in the fourth or fifth intercostal space, and should commence at a point at least an inch from the edge of the sternum, in order that the internal mammary artery, which lies half an inch from the bone, may not be wounded. When the pericardium is reached it should be carefully punctured, and the opening sufficiently enlarged with sinus-forceps to admit a drainage tube.

## CHAPTER LIX.

## DISEASES OF THE BREAST.

**Diseases of the Breast** may occur in either sex, but they are necessarily more frequent as well as more important in the highly developed and active organ in the female than in the rudimentary gland of the male.

Diseases of the female breast are of much interest to the Surgeon ; not only on account of their great variety, but from the difficulties attending their diagnosis, and from the importance attaching to the question of operative interference in connexion with them.

Diseases of the breast seldom occur before puberty, being most frequent either during lactation, when the functions of the gland are in a high degree of development ; or towards the termination of menstrual life, when the organ is necessarily influenced by the changes that are taking place in the uterine system. But there is this important difference between the diseases at these different periods of life, viz., that in the young they are of a simple, in the older woman frequently, if not generally, of a malignant nature. Just before or at puberty, the breast occasionally becomes the seat of inflammation and abscess ; in all probability owing to changes taking place in it in connexion with the general development of the reproductive system. As the period of puberty approaches, the breasts often swell, become hard, knotty, and somewhat painful, indicative of some commencing change in the generative system. In other cases again, a precocious hypertrophy may take place, frequently attended with severe neuralgia in the part. When puberty occurs, the breasts naturally enlarge, and often become tender ; and occasionally one undergoes a certain degree of hypertrophy, increasing greatly in bulk beyond the other. These various changes, though exciting alarm, cannot be regarded as of any very serious importance.

## ANOMALIES OF DEVELOPMENT.

**Complete Absence of the Mamma or Amasia** is very rare. Froriep records the case of a woman, aged thirty, in whom the right breast was completely wanting. The third and fourth ribs were also absent from the scapula forwards. A few similar cases are also on record, but Birkett states that he could find only one authentic case of the absence of the breast without malformation of the chest-walls. A rudimentary condition of the breast, in which it resembles that of the male, has been noted in a few cases of congenital absence of the ovaries.

**Supernumerary Breasts or Polymasia.**—This condition is far more frequent than absence of the gland. Klebs divides the abnormality into three forms, according as the supernumerary glands are situated in the pectoral region, in the axilla, or in other parts of the body. In the pectoral region as many as five breasts, each with a nipple, have been observed. When the

number is even the glands are arranged one above the other in the normal line on each side. These glands usually secrete milk during lactation.

According to Klebs axillary breasts are of two kinds. In one a genuine supernumerary breast, with nipple and areola, is found at the anterior border of the axilla; the other variety consists in a more or less complete separation of a piece of the normal mamma from the rest of the gland. The true axillary breast is smaller than the natural gland, but secretes milk after pregnancy. The importance of the second variety is in connexion with the occasional development of simple or malignant glandular tumours at a distance from the main gland.

Supernumerary glands in distant situations have been described on the outer side of the thigh, in the groin and on the back. The most celebrated case is that recorded by Robert. The accessory mamma was situated on the outer part of the thigh about four inches below the great trochanter. Until the patient's first pregnancy it was supposed to be a nevus, but at this time it enlarged with the normal breasts, and reached the size of half a citron. After delivery it secreted milk, and the child was suckled at it. The mother of the woman had three breasts, all on the chest.

**Congenital Absence of the Nipple** is extremely rare; in fact it is doubtful if it has ever been met with except in conjunction with absence of the mamma.

**Multiple Nipples** are extremely rare; two to each breast have been met with, each with ducts opening into it.

#### NEURALGIA.

**Neuralgia of the Breast or Mastodynia.**—The term "neuralgia of the breast" is properly applied only to those cases in which no inflammatory induration or morbid growth can be recognised as the source of the pain. Such cases are not common, at least in this country and in Germany, but from the large number recorded by Velpeau it would seem to be of more frequent occurrence in France.

The only *symptom* is the pain. This is severe and paroxysmal, radiating in all directions from the breast; sometimes extending to the neck and head, the shoulder and arm, and even, it is said, as far as the hip and lower extremity. The pain is usually aggravated during the menstrual period; it is sometimes distinctly periodic, more rarely persistent. There is generally marked cutaneous hyperæsthesia over the affected breast, and deep pressure is less painful than a light pinch of the skin. There may be slight heat and fulness of the gland, but this is never a marked symptom. The severe pain and the mental anxiety caused by the dread of cancer may seriously impair the patient's health.

Neuralgia of the breast is usually met with during the period of activity of the uterine organs, but Velpeau states that he has seen it as early as the twelfth year and as late as the sixtieth. It is not definitely associated with any constitutional condition, but it is most common in nervous or hysterical subjects. It is sometimes connected with some uterine disorder, but the relation between the two is not sufficiently constant to justify a vaginal examination unless there are manifest symptoms of functional or organic disease of the uterus. Sometimes the neuralgia seems to be dependent on anæmia, and

may be associated with intercostal neuralgia and spinal tenderness. Habitual constipation is occasionally a predisposing cause. Amongst the various local conditions to which the pain has been attributed are injury, the pressure of badly-fitting stays, and the dragging weight of an unusually large breast.

*Treatment.*—It is necessary first to relieve the patient's mind from the fear of cancer. Any uterine affection that may be present must receive suitable treatment. Constipation must be relieved by diet and purgatives; anæmia by iron and a sufficiency of meat food. Change of air to a dry, bracing climate may be of service. Locally, the application of a belladonna plaster is most likely to be of service; it not only protects the tender skin and acts as a sedative, but prevents the frequent examination and manipulation of the breast. Velpeau recommends that the breast should be supported and drawn slightly inwards. Hypodermic injections of morphine should only be given as a last resource in the most extreme cases. Partial removal or complete excision of the gland is not justifiable, as it is rarely productive of any real benefit.

#### HYPERTROPHY.

**True Hypertrophy of the Breast** is a rare condition. It consists simply in an overgrowth of the mammary tissue.

*Causation.*—No definite cause of the disease is known, but in different cases, often without much evidence, it has been attributed to menstrual irregularity, excessive sexual excitement, blows, &c. In most cases the hypertrophy has commenced about the period of the establishment of the menstrual function, but in other cases it has appeared at a later time. Of 26 cases collected by Labarraque only 5 occurred in women above twenty-six years of age. In some few instances the enlargement has been merely an exaggeration of the normal process of evolution of the breast during pregnancy. Labarraque quotes two such cases, in one of which, a woman of twenty, the breasts had reached such an enormous size at the second month of pregnancy, that the patient was entirely confined to the recumbent position. At the time of the patient's death from typhoid fever two months after her confinement, the right breast was one-fifth, and the left about one-half, its former size.

*Symptoms.*—True hypertrophy of the breast is characterized by the steady increase in size, which sometimes goes on rapidly, but as a rule is gradual and continues for years. Pain is an uncommon symptom, and the chief discomfort arises from the weight of the enlarged breasts. In some cases this has been so great that the patient has been unable to maintain the erect position and respiration has been seriously interfered with. In the early stages the breast maintains its normal form, but as the size increases it tends to become flask-shaped and pendulous. The nipple becomes flattened and the areola expanded, but the skin remains non-adherent and the axillary glands are not enlarged. The general nutrition is usually somewhat impaired and the patient becomes thin and anæmic. In the large majority of cases there has been disturbance of the menstrual function, usually in the direction of amenorrhœa. The tendency of the disease is for the breast to reach a certain size and then to become stationary; but in that variety which arises in connexion with pregnancy a great diminution, and in some cases a return to a reasonable size, has constantly occurred after delivery. In some cases this has been preceded by a very profuse and continuous flow of milk.

*Pathology.*—Many of the cases recorded as "hypertrophy of the breast" appear to have been examples of large glandular tumours. In the few cases of typical hypertrophy that have been examined—that is to say, of cases in which both breasts were affected in young subjects independently of lactation—there seems to have been an increase of all the normal constituents of the gland but not in equal proportion—the chief growth being in the interstitial fibrous tissue.

*Diagnosis.*—The only condition with which hypertrophy of the breast is likely to be confounded is the development of a large cysto-adenoma. In this case, the affection of one breast only, the excentric position of the nipple, the greater firmness, and the presence of cysts, would enable the Surgeon to arrive at a correct diagnosis. A large fatty tumour in the neighbourhood of the breast might also somewhat resemble hypertrophy.

*Prognosis.*—So far as life is concerned the disease is free from danger; on the other hand, cure is almost hopeless in those cases that arise in young girls about the period of the first menstruation. When distinctly connected with pregnancy the prognosis is much more hopeful.

*Treatment.*—Iodine, iodide of potassium, and iodide of mercury internally, and iodine, lead lotion, belladonna, and many other remedies, externally have been tried without material benefit. If the menses are arrested an attempt should be made to restore them by the administration of iron. Pressure has been tried in several cases, but without success. When all other means have failed

Fig. 775.—Simple Hypertrophy of Breast in a girl fifteen years old.

removal of the enlarged glands becomes justifiable. Only one gland should be removed at a time, partly to avoid shock and excessive loss of blood, and partly because improvement in the remaining breast has been noticed in one or two cases. If the base of the tumour is pedunculated it may be surrounded during the operation by an india-rubber band, or secured by a screw-clamp specially made for the case. The operation has been performed several times, and the success attending it has been very satisfactory when the size of the mass removed is considered.

#### ABNORMALITIES OF SECRETION.

**Appearance of Milk at Unnatural Times.**—The secretion of milk unconnected with pregnancy is of extremely rare occurrence. The two best known cases are those recorded by Baudelocque and by Carganico. In the former the secretion occurred in a girl aged eight, and in the latter in a woman aged fifty-nine who had borne eight children, the youngest being seventeen years old. In both cases the secretion was stimulated by allowing a child to suck at the nipple.

**Agalactia**, or total absence of the secretion of milk after child-birth at the

full time, is very rare. But few such cases have been recorded. Should the milk not appear the child may be applied to the breast and hot fomentations put on, but it is useless to persevere in such means if no secretion takes place in the first two days.

**Excessive Secretion of Milk, or Galactorrhœa.**—Galactorrhœa may occur at an early period of lactation, or consist rather in a persistent secretion in spite of the withdrawal of the child from the breast. In the former condition there may be considerable swelling and distension of the breasts, with a constant flow of milk from the nipple. Birkett quotes a case recorded by Riesenberg, in which this condition occurred in a woman of thirty in three successive pregnancies. In the last the child was not even put to the breast, but at the end of two weeks the secretion was so abundant that it soaked the clothes and even filled her shoes to such an extent that it was necessary to empty them periodically. In the second class of cases the secretion of milk has been known to continue for from two to five years after weaning the child. Birkett states that this is usually associated with some uterine disease, and in some cases it is due to prolonged suckling.

The *Treatment* of galactorrhœa consists in the external application of glycerine of belladonna, and in the internal administration of saline purgatives. In some extremely severe cases iodine or iodide of potassium has been found to produce a rapid and marked effect. In extreme cases the patient may be considerably reduced in strength before the discharge is arrested.

**Galactocèle.**—The term "galactocèle" has been applied to three pathological conditions, of the existence of two of which grave doubts must be entertained. The true galactocèle is caused by the obstruction of a duct during lactation; the obstructed duct becoming dilated behind the point at which the flow of milk is arrested, and thus forming a cyst of considerable size. It fluctuates distinctly, and is usually seated superficially near the nipple. The tumour appears during the first few weeks of lactation, without the signs of inflammation and without pain. It continues to increase slowly, and may reach an enormous size, as in the well known case recorded by Scarpa, which in two months attained such a magnitude that the mamma rested on the knee when the patient was in the sitting position. Ten pints of pure milk were removed in this case by tapping. Suppuration followed the treatment, but the patient ultimately recovered, and afterwards bore another child and nursed it without any return of the disease. As Billroth points out, this condition is very rare, most authors quoting the same cases, and few adding to the number.

The second form of galactocèle rests upon the authority of Velpeau. The patient, aged thirty-four, had been confined fifteen months before, and had weaned the child for six weeks. At the end of this time the right breast became swollen to double its natural size, without redness. There was some pain, and the whole gland felt spongy. On puncturing it with a bistoury, milk escaped "which evidently came from the meshes of the connective tissue." The evidence here is evidently insufficient to establish the existence of such a condition.

In the third form of galactocèle the milk is said to have undergone various changes, becoming butter-like, cheese-like, or inspissated. These tumours have been met with late in lactation, or even independently of it, and there seems little doubt that many such cases were really chronic abscesses.

The true galactocoele is to be treated by aspiration, repeated till the bulk of the tumour is greatly diminished. It may then be opened and drained.

#### ACUTE INFLAMMATION OF THE BREAST.

**Acute Inflammation of the Breast** may take place at any time of life, but the most common periods are within a few days of birth, at puberty, and during lactation in the adult, especially in feeble and anæmic women. Inflammation may affect any one of the parts of which the breast is composed, and may be limited to this: thus, it may take place in the nipple; in the subcutaneous areolar tissue lying between the skin and the gland; in the gland itself; or in that extensive plane of areolar tissue upon which the gland rests, and which intervenes between it and the pectoral muscle. But, although inflammation commonly affects these different parts, in many cases the whole of the breast appears to be involved, and no distinct implication of any special tissue can be made out.

**Inflammation of the Nipple and Areola.**—When the nipple and areola are inflamed, these parts become conical, red, and swollen, with much pain, owing to the density of the subcutaneous tissue in this situation. This affection, “the cracked nipple” of nurses, usually occurs at an early period of lactation in delicate women, and especially with the first child. It commences in the follicles of the part, being accompanied by superficial ulceration, abrasion, and fissures, with oozing of a small quantity of thin sero-puriform fluid. There is great pain during suckling, and usually a good deal of constitutional irritation. In wet-nurses the possibility of the occurrence of a primary syphilitic sore communicated by an infant suffering from the congenital form of the disease must always be borne in mind.

The *Treatment* of sore nipple should in the first instance consist in strict attention to cleanliness. After each suckling the nipple should be sponged with boric acid lotion and carefully dried, and during the act protected with an india-rubber shield. If the nipple be actually fissured or ulcerated, the child must be taken from the affected breast and the milk drawn off with a breast pump. Locally, the part may be painted once or twice a day with carbolic acid lotion (1 in 20), or a solution of nitrate of silver (one grain to the ounce), and then dried and covered with flexible collodion.

A weak lead and spirit lotion is often useful, and in the earliest stages a dusting powder of oxide of zinc and starch may be used. If actual ulceration be present, or deep fissures have formed, the application of the solid nitrate of silver, although painful, will be found the most effectual treatment.

The immediate treatment of a sore nipple is most important, for if neglected it is not unfrequently followed by abscess of the breast.

**Abscess of the Areola** not unfrequently occurs in nursing women, and is not uncommonly the result of a sore nipple. The abscess is usually very circumscribed, and shows little tendency to spread. The *Treatment* should consist in endeavouring to prevent suppuration by the application of glycerine of belladonna and hot fomentations. As soon as fluctuation is detected the abscess must be opened, care being taken that the cut be made from the centre of the nipple towards the circumference of the areola, so as not to divide the lacteal ducts.

The child must be taken from the breast and the milk drawn off with a pump.

Small follicular inflammations and abscesses, varying in size from a pin's head to a cherry, are common in middle-aged women, independently of lactation. They often excite alarm, and cause some pain. They are usually readily relieved by belladonna and glycerine or warm lead lotion, followed by the touch of the point of a lancet.

**True Eczema of the Nipple** is rare, and must be carefully distinguished from a very intractable form of inflammation which occasionally attacks the nipple and areola, and has been shown by Paget to be an occasional precursor of carcinoma of the breast (see p. 801). Eczema may affect one or both nipples; it usually occurs during lactation, and is attended with much itching and uneasiness. At first there is simple redness, but soon crops of small vesicles appear which discharge a serous fluid and leave a raw surface. Among the many local remedies which may be tried for this condition are glycerine of borax, boric acid ointment with one drachm of extract of belladonna to each ounce, carbonate of lead ointment, lead lotion, and calamine lotion. Painting the inflamed area with a strong solution of nitrate of silver may sometimes prove beneficial.

PARENCHYMATOUS INFLAMMATION OF THE BREAST may be met with in the following varieties: 1. Puerperal Mastitis; 2. Mastitis neonatorum; 3. Mastitis of Puberty; and 4. Mastitis of Adults not connected with Pregnancy.

1. **Puerperal Mastitis** includes more than 80 per cent. of all cases of acute abscess of the breast. Suppuration is by no means a necessary result, but in a considerable proportion of cases—according to Winkel in 33 per cent.—it occurs, the abscess being commonly known as a **milk abscess**. Puerperal mastitis is most common in primiparæ, and generally commences during the first four weeks after labour, or if that period be passed, towards the end of prolonged lactation, especially in weakly women. Hence it is common among the poorer classes, who not rarely suckle their children until they are nearly two years old. It is rare in mothers who do not nurse their own children, a fact which, as Billroth has pointed out, is somewhat opposed to the theory that its common cause is obstruction to the flow of milk.

The first *symptom* of puerperal mastitis is pain during suckling and a sense of heaviness in the breast, relieved by supporting it. As a rule only one lobule is first affected, most commonly at the lower and outer part of the breast, and this will be found to be hard and tender. In rare cases the whole gland is affected. As the inflammation advances the skin becomes reddened and oedematous, and at the same time the pain becomes more severe and lancinating and the constitutional disturbance more marked. The temperature often reaches 102° or 103° F., and there may be a rigor. The occurrence of suppuration may be indicated by a sense of fluctuation or elasticity, but this is often absent if the abscess is small and deeply seated. Velpeau has pointed out that one lobule after another may become inflamed, so that a succession of abscesses forms in different parts of the gland. Both breasts are rarely affected.

*Pathology.*—As the name "milk abscess" suggests, it has very generally been supposed that puerperal mastitis arises from retention of milk due to some obstruction of the lacteal ducts. The evidence of such obstruction is,

however, not obtainable, and as an objection to the retention theory it has been pointed out that mastitis is rare in women who have to give up nursing suddenly on account of the death of the child. In many cases, on the other hand, the abscess is preceded by a sore nipple, and it is probable that in the majority of cases the infection occurs from this through the lymphatics or ducts.

The pus of an acute mammary abscess is always found to contain staphylococci or streptococci. According to Cheyne the former are associated with abscesses deeply seated in the gland, and the latter with superficial inflammations extending from some crack or fissure of the nipple. In the wall of a mammary abscess Bumm demonstrated the presence of staphylococci in the acini, the infection having taken place by way of the ducts. This partly explains the fact that the infiltration with leucocytes is most marked around the acini; but the appearance is also due to the abundance of lymphatics and vessels in this position, for Billroth produced exactly the same condition by passing a seton through the breast of a bitch.

*Treatment.*—The child must not be put to the affected breast, and should be weaned if the patient is feeble. The arm should be fixed to the side, the breast supported in a sling, and the milk drawn off with a proper breast-pump or sucker. Great relief will be afforded by the application of glycerine and belladonna, with hot flannel fomentations. Cold applications and leeches are never of any use. An occasional saline purgative, such as sulphate of magnesium, should be given.

If, in spite of this treatment, suppuration occur, the pus should be let out as soon as possible by an incision into the most dependent part of the abscess, and made in a direction radiating from the nipple, so as to avoid needlessly damaging the ducts. A good-sized drainage-tube should then be inserted, and an antiseptic dressing applied. When suppuration is going on, the patient's strength must be supported with tonics, the mineral acids, bark, or quinine. Stimulants may be given as required, and plenty of nourishment supplied. Should sinuses form in a case of mammary abscess, they will usually close if the child be weaned, and lactation stopped. Should they not do so, the employment of pressure and the use of stimulating injections, with attention to the general health, will usually in time bring about a cure. Lacteal fistula is a very rare consequence of a mammary abscess. It closes readily when lactation has ceased.

## **2. Inflammation of the Breast in Infants. Mastitis Neonatorum.**

—In new-born children of both sexes the rudimentary breast becomes slightly swollen about the third or fourth day after birth, and on squeezing it a small quantity of milky fluid containing colostrum corpuscles can be made to exude. The secretion is most abundant about the tenth day, and completely disappears before a month. According to Filatow this phenomenon is absent completely only once in about every 65 children. Inflammation of the breast may occur during this period in weakly children, especially if the tender breast has been squeezed or otherwise injured by an ignorant nurse. There are the usual signs of redness, increased swelling, heat, pain, and acute tenderness. Suppuration occasionally follows, and the pus may burrow widely in the subcutaneous tissue unless let out early, and death may ensue. Erysipelas is an occasional and very fatal complication. In females, mastitis neonatorum may lead to imperfect development or deformity of the nipple in after life. The *Treatment*

consists in the application of warmth and moisture, and of belladonna. Should suppuration occur, the pus must be let out early by an incision radiating from the nipple.

3. **Inflammation of the Breast at Puberty** is not uncommon in boys as well as girls. It is subacute in character, accompanied by some pain, swelling, and slight induration. It scarcely ever ends in suppuration, and is of little importance. It is best treated by the application of a belladonna plaster.

4. **Non-puerperal Mastitis of Adults.**—This is rare. It results most commonly from blows. It agrees in its symptoms and course with puerperal mastitis, but runs as a rule a less acute course. The treatment is the same.

**ACUTE SUBMAMMARY ABSCESS.**—This consists in an accumulation of pus in the loose areolar tissue between the breast and the fascia covering the pectoral muscle. It arises in some cases apparently independently of any affection of the gland itself; but in most cases, as Billroth suggests, it is probably due to inflammation and suppuration of a deep lobule of the mamma. The inflammation diffuses itself over the whole of the areolar layer, and almost invariably abscess forms with considerable rapidity, giving rise to severe pain, of a deep, heavy, and throbbing character, much increased by moving the arm and shoulder, and attended with swelling, œdema, and a slight red blush upon the skin. The breast becomes prominent, and is conical and projecting, the whole organ being pushed forwards by the pressure from behind. It is not always easy in these cases to determine whether suppuration has taken place or not, the depth at which the pus forms rendering it impossible in the early stages to detect fluctuation; its presence may, however, be suspected on the occurrence of deep-seated throbbing pain, subcutaneous œdema, and some superficial redness. The abscess at last points at some part of the margin of the gland, usually at its lower and outer side, to which point the matter seems to gravitate; after a time, however, it will commonly appear at other points of the circumference of the gland, beyond which it always extends, seldom, if ever, perforating the structure. A series of four or five apertures, forming a circle round the breast, may thus form, and it very commonly happens that these contract into sinuses, which are by no means easily closed.

**Treatment.**—The occurrence of suppuration should, if possible, be prevented by the means adopted in other forms of inflammation of the breast. Great care must be taken to prevent movement of the arm. When once pus has formed it should be evacuated without delay by an incision at the border of the breast, and if possible at its lower and outer part. A large drainage-tube should be used and an antiseptic dressing applied. Troublesome sinuses more often follow this than any other form of mammary abscess. It has been proposed to slit these up by free incisions directed towards the nipple; but this is unnecessarily severe practice, and may, I believe, in all cases be avoided. It will often be found that the delay in healing is due to the existence of a cavity beneath the mamma which is imperfectly drained by the sinuses. Under these circumstances, the orifices of the sinuses should be enlarged with a knife, and the tracks dilated with the finger. They should then be scraped with a sharp spoon to remove the unhealthy granulation tissue, after which they should be cleaned with a piece of sponge soaked in chloride of zinc solution (gr. 40 to 3j), held in a pair of sinus-forceps. A drainage-tube should then be inserted into each, and

gradually shortened at each dressing. In some cases healing is promoted by the introduction of a small quantity of iodoform. The worst submammary sinuses may usually be speedily made to close by this treatment.

#### CHRONIC INFLAMMATION OF THE BREAST.

A form of chronic interstitial inflammation of the breast, affecting usually only a limited part of the gland, is not uncommonly met with in women past middle life, and is of great importance from the resemblance it bears in its clinical features to scirrhus cancer. The condition was first accurately described by Cruveilhier, under the name of "fibrous bodies" (*corps fibreux*) in the breast; and since his time it has received many other names, such as Diffuse Fibroma or Hard Elephantiasis (Virchow), Lobular Hypertrophy (Astley Cooper), Knotty or Nodular Induration (Billroth), Cirrhosis of the Mamma, Benign Induration, &c. "**Chronic lobular interstitial mastitis**" is, however, the best name that can be applied to it, as it correctly indicates the nature of the affection.

The **pathological appearances** are very minutely described by Virchow. In the earliest stage, which is evidently inflammatory, the acini and ducts of the gland show no change beyond a slight increase in the epithelium. The connective tissue of the affected lobule is infiltrated with small round cells, which are most numerous in the immediate neighbourhood of the acini. In the second stage the new cells undergo development into dense fibrous tissue like that of a cicatrix. This is accompanied, as in similar processes elsewhere, by shrinking of the tissue. The acini and ducts in the affected area are thus pressed upon. The epithelium undergoes fatty degeneration, and is for the most part absorbed, and thus a number of the acini are finally obliterated. Here and there, however, small retention-cysts form, chiefly from the ducts which have been constricted in places by the contracting fibroid tissue, while at the same time there has been a slight increase of secretion owing to the chronic inflammatory process going on in the surrounding areolar tissue. These cysts seldom reach a size larger than that of a mustard-seed owing to the density of the tissue by which they are surrounded. The disease is very commonly limited to a single lobule of the mamma. Occasionally, however, it may be more diffused, and in such cases when the stage of shrinking is reached, the gland may become shrivelled and considerably reduced in size. The nipple may be retracted as the breast shrinks, thus still further increasing the resemblance to atrophic scirrhus.

There is some reason for believing that carcinoma of the breast may actually take origin in a lobule of the gland indurated by chronic inflammation. In this connexion it is of interest that although atrophy of the glandular epithelium is the usual result of the interstitial inflammation, yet in some cases a very marked epithelial proliferation has been observed.

The **Causes** of the condition are very obscure. It is frequently associated with some menstrual disturbance, and is not uncommonly met with at the change of life. It is most common in women who have borne children. In some cases it is attributed to an injury.

The **Symptoms** consist in the gradual formation of a tough, hard nodule in the breast, usually situated in the peripheral part, tolerably clearly circumscribed, and of rounded form. In size it may vary from a marble to a

pigeon's egg, seldom being larger. It may distinctly increase in size at the menstrual periods, and diminish in the intervals. Its surface is often slightly nodular, the nodules being formed by the small, tense cysts already mentioned. If it be grasped and gently pulled upon with one hand while the nipple is held with the other, so as to make the ducts passing from it tense, it can easily be recognized that it is part of the mamma, and not an isolated tumour. On pinching up the skin over it, a dimple may form, as the areolar tissue of the subcutaneous fat is continuous with that penetrating between the lobules of the mamma, which is involved in the interstitial inflammation. A similar nodule may not unfrequently be found either in another part of the same breast or on the opposite side. The disease may be painless, or may be associated with severe neuralgia, worse during the menstrual period. In the early stages there may be slight tenderness, but this is seldom marked, and is often wanting when shrinking is far advanced. There may in some cases be a slight enlargement of the axillary glands.

The **Diagnosis** will be considered with reference to chronic abscess, cysts, adenoma, and carcinoma.

From *chronic abscess* it differs in not arising in connexion with pregnancy or lactation, and in the absence of œdema over it. The dimpling of the skin in a chronic abscess is more marked, and the centre of the swelling is often softer than the periphery. From a *cyst* it is distinguished by the absence of elasticity, but it has already been pointed out that cysts are often present in the indurated lobule. From an *adenoma* it can usually be readily distinguished by its ill-defined outline, and its connexion with the nipple, showing that it is an altered piece of the mammary gland and not an encapsuled tumour. If more than one lobule is affected the diagnosis is more easy, as true tumours of the breast are usually single. From *scirrhus* the diagnosis may be impossible. The long duration of the induration may sometimes prove its simple nature, and if there are several lobules affected, or similar nodules in the opposite breast, it is very improbable that the disease is cancerous. If the nodule is single the following points may serve to make a diagnosis. The simple induration is tough rather than hard, whilst scirrhus cancer is stony; the simple induration is usually less defined and less rounded. In both diseases the surface of the induration may be nodular. In lobular mastitis the skin is not distinctly implicated, and only in exceptional cases can any dimpling be obtained by pinching up the skin over the affected part. In scirrhus the dimpling of the skin is always an early symptom. The simple induration does not cause retraction of the nipple. The absence of enlargement of the axillary glands is of little value, for it should be the object of the Surgeon to make the diagnosis of cancer before any implication of the glands has taken place. In some cases it is impossible to determine with any certainty the nature of the disease. Under these circumstances it is not justifiable to advise the patient to wait until time has cleared up the doubt. By so doing she is robbed of her last chance of cure if the disease be cancerous. It is much wiser to cut out the indurated lobule and investigate its nature by microscopic examination.

The **Treatment** of chronic interstitial mastitis is unsatisfactory. Blistering, prolonged painting with iodine, and other forms of counter-irritation, produce little or no effect. Belladonna may be applied to relieve the pain. Pressure may possibly be of service in some instances, and probably the cases of

supposed adenoma or cancer cured by pressure were in reality merely chronically inflamed lobules. Should it seriously annoy the patient, the affected lobule may be removed. If the breast is widely affected, no operative interference should be undertaken. In operating in doubtful cases the incision should be placed so that if the disease prove to be cancerous the whole mamma may be removed by enlarging the wound.

**Calcification of the Breast.**—Bryk has recorded a case in which an indurated lobule underwent subsequent calcification. The disease was mistaken for scirrhus, and the whole breast removed. The calcification was found to have taken place in the interstitial connective tissue.

**General Diffuse Inflammation of the Breast.**—Klebs describes a general chronic inflammation of the breast, at first causing some tough enlargement, but finally ending in shrinking and atrophy of the gland. Billroth also mentions a similar condition, and gives a figure of a breast which has become shrivelled and atrophied from this process. Such a condition is extremely rare. It must not be confounded with the atrophic scirrhus of old people.

**CHRONIC ABSCESS OF THE BREAST** may assume two forms : the *Mammary* and the *Submammary*.

**Chronic Encysted Abscess of the Breast** is a disease of great importance, inasmuch as it closely simulates scirrhus carcinoma. The breast has indeed in numerous instances been amputated on the supposition of its being the seat of a cancer, when the disease was merely a very chronic thick-walled abscess. This form of abscess usually, but not invariably, commences as the result of pregnancy, whether complete parturition or miscarriage take place ; sometimes as a consequence of lacteal inflammation, but usually without any injury or other direct local cause. An indurated indolent swelling forms, and this may gradually soften in the centre ; but fluctuation may for a long time be very indistinct, and even absent, being obscured by the thick wall of indurated tissue surrounding the collection of pus. It is owing to the dense inflammatory induration of the surrounding tissues that the chronic encysted abscess is so commonly mistaken for a solid tumour. It is in general not very distinctly circumscribed, and of but moderate magnitude ; after a time it remains stationary during a space of many months, or but slowly increases with but little pain ; it is not unfrequently attended with retraction of the nipple.

**Diagnosis.**—The error of mistaking a chronic abscess for a tumour may commonly be avoided by attention to the following points : 1, that the existence of an abscess is almost invariably preceded by parturition or miscarriage ; 2, that there is more or less œdema of the subcutaneous areolar tissue covering it ; 3, that, although it is of slow formation and often painless, it is not distinctly circumscribed, but gradually fuses in an irregular manner with the neighbouring tissues ; 4, that it is not freely movable, but rather incorporated with adjacent parts ; 5, that elasticity, or even deep fluctuation, may be commonly felt at one part of it ; and 6, that in hard cancer, which it most closely resembles, the circumference is softer than the centre. In a chronic abscess or any fluid tumour, the centre gives the least sense of resistance. Should there be the least doubt in the case, the introduction of an exploring trochar, by giving issue to a drop of pus, will always determine its true nature ; indeed, this simple means of diagnosis should never be neglected in

any case in which there is reason even to suspect the possibility of the apparent tumour of the breast being in reality an abscess.

*Treatment.*—The abscess should be opened as soon as recognized, and if of sufficient size a drainage-tube should be inserted. Should the mass of indurated tissue surrounding the pus be very large and dense, a free incision carried through it will usually hasten its disappearance, or in some cases the diseased lobule may be completely excised.

**Chronic Submammary Abscess** has also been described under the name of “diffused abscess.” It consists of an ordinary chronic abscess containing curdy pus, and is probably in all cases due to necrosis of a rib. It is not therefore properly to be considered a disease of the breast, its relation to that gland being purely accidental.

**TUBERCULOSIS OF THE BREAST.**—Although tubercle of the udder of the cow is of comparatively common occurrence, and of great importance on account of

Fig. 776.—Tuberculous Disease of Breast. Inter-acinous tubercle (65 diams.). *a*, Breast acini; *b*, tubercle system; *c*, fibrous stroma; *d*, blood-vessel.

Fig. 777.—Tuberculous Disease of Breast. Intra-acinous tubercle (67 diams.).

the liability to infection of the milk, tuberculous disease of the human breast had received but little attention until recent years, and was regarded as an extremely rare affection. It seems certain, however, that the disease is by no means so rare as was at one time supposed, and this is readily explained by the fact that a chronic inflammatory condition of the breast often presents no clinical features which indicate its tuberculous nature, certain evidence only being afforded by microscopic examination.

**Symptoms.**—Tubercle of the breast may occur in two clinical varieties: first, as a chronic induration in the gland, and secondly, as a chronic abscess. Each form is most common in young women, and may be associated with evidences of tubercle in the lungs or elsewhere. Enlarged glands may be present in the axilla, especially when the disease in the breast assumes the form of a chronic tuberculous abscess. Should the abscess burst spontaneously, or be simply opened, an intractable sinus is likely to remain.

Speaking generally, it may be said that the tuberculous nature of a chronic inflammatory condition of the breast, with or without suppuration, should be suspected when such a condition occurs in a young woman independently of the ordinary causes of mastitis. The diagnosis of tubercle is strengthened by an inherited tendency to the disease, and by the presence of evidences of tubercle in the lungs or elsewhere, but it can rarely be made with certainty by the clinical features alone.

**Pathological Anatomy.**—The microscopic examination of a considerable number of cases has shown that the disease presents the characteristic features of tubercle elsewhere, and the bacillus has been demonstrated by Habermaas and others. The case from which Figs. 776, 777 were prepared was a good example of tuberculous mastitis.

The patient, a woman aged about twenty, was under treatment in the Brompton Hospital for early pulmonary phthisis. A painful and indurated lobule in the breast was excised by Godlee. To the naked eye it presented a dense fibrous structure thickly studded with small soft greyish-yellow points. The microscope showed a typical tuberculous structure, the tubercle being most abundant in the interacinous tissue, and taking the form of definite tubercle-systems (Fig. 776). In other parts, however, the tubercle occupied the interior of the dilated acini (Fig. 777). In its relation to the glandular elements the specimen exactly resembled the appearances usually seen in tuberculosis of the testis.

In the majority of the recorded cases a definite chronic abscess has been present, the cavity of which was surrounded by a layer of tuberculous granulation tissue. A specimen of this kind is preserved in the Museum of University College. A chronic abscess in the upper and outer quadrant of the left breast opened on the surface by a small sinus near the nipple. From the abscess cavity an enlarged lymphatic, lined with granulation tissue, leads to a caseous lymphatic gland, which was removed from the axilla.

**Treatment.**—No operation should be undertaken if the patient is the subject of advanced tuberculosis of other organs. In favourable cases the treatment should consist in the excision of the affected part of the breast, together with any enlarged glands which may be present in the axilla. If a chronic abscess exists, this should be opened and thoroughly scraped, but as a rule a more certain result will probably be obtained by the removal of the surrounding breast tissue.

**SYPHILITIC DISEASE OF THE BREAST.**—**Primary sores** on the nipple have already been mentioned on p. 770. The secondary eruptions are often well marked in the skin covering the breast, and **mucous tubercles** may occur on the nipple and areola as well as in the fold between the lower border of the gland and the chest wall. Two forms of tertiary syphilitic affections of the breast have been described by Lancereaux—the diffuse and the gummatus. The existence of a **diffuse induration** of the breast as a result of syphilis is somewhat doubtful, but in a few recorded cases the diagnosis is said to have been confirmed by the disappearance of the swelling under iodide of potassium. **Gummata** in the breast are also extremely rare, but their occasional occurrence cannot be doubted. They form painless swellings in the gland, which, if untreated, run the same course as gummata elsewhere.

## TUMOURS OF THE BREAST.

The study of the various tumours of the female breast, more especially from a diagnostic point of view, is of the first importance to the practical Surgeon ; for though it might be supposed that it would be easy, if not to recognize the minuter shades of pathological difference between morbid growths so superficially situated, at all events to diagnose the malignant from the non-malignant affections, yet in practice nothing is more difficult in many cases; and it not only requires great experience, but a most intimate acquaintance with the special course and symptoms of each particular disease, to come to a correct conclusion as to its nature. Even with all the light which experience and a careful examination of the characters of the tumour may throw upon the nature of the disease, it will be impossible for the Surgeon to avoid occasional errors in diagnosis.

The first thorough classification of the different varieties of simple tumours that develop in the mammary gland was made by Astley Cooper, and this important department of surgical pathology was subsequently much extended by the researches of Velpeau, Birkett, and Paget. Since the improvements in the methods of investigation have led to a more perfect anatomical classification of tumours, the confusion that formerly surrounded this very intricate subject has been to a great extent cleared up by the labours of Virchow, Billroth, Gross, and others. The microscopic characters of the various tumours of the breast are now accurately determined and generally agreed upon, but confusion still remains in the nomenclature which time alone can remove. In describing the various tumours of the breast I shall follow the order adopted in the chapter on tumours in general.

## CYSTS OF THE BREAST.

Cystic formations are met with in the breast under a great variety of different conditions, and the difficulty of the subject has been much increased by the unnecessary complications of an unsatisfactory nomenclature. Only those conditions will be here described in which the formation of one or more cysts is the essential part of the disease. Cysts are often met with in certain tumours of the breast, forming in some cases an essential part of their structure, and in others being accidentally present, but these cannot correctly be looked upon as examples of cystic disease of the breast, and they will be mentioned subsequently in connexion with the different tumours in which they occur.

Cysts of the breast may be divided primarily into two classes: first, those which arise by distension of some part of the glandular apparatus; and secondly, cysts formed in the breast independently of the gland tissue.

CYSTS ARISING IN THE GLAND TISSUE.—Under this heading are included all those cysts which are due to distension of the ducts or secreting acini. They are often spoken of collectively as “retention cysts,” but with the single exception of galactoceles, it is doubtful whether simple obstruction resulting from retention of secretion is their chief cause. Except in the case of galactocoele, or milk cyst, which forms during lactation, cysts of the breast never contain milk. The fluid that distends them varies much in appearance: sometimes it is thin and almost colourless, but more often it is thick, sometimes

almost mucous in character, and of a brownish-yellow or brown colour. It may indeed be assumed that abnormal secretion is an important factor in the production of the disease, associated no doubt in many instances with an obstruction to the ducts such as is caused by an overgrowth of connective tissue around them. The walls of these cysts are composed of a layer of condensed connective tissue of variable thickness, containing usually an abundant supply of capillary vessels. They are lined internally by a layer of epithelium, either cubical or spheroidal like that of the acini, or columnar like that of the ducts. In many instances the cysts merely contain fluid, but not unfrequently the cavity is occupied by an intracystic growth sprouting into it from the wall. In such cases the cyst is called a *proliferous cyst*.

**Single Cysts** of this class are of three varieties : 1. Galactocoele. 2. True Glandular Cyst. 3. Duct Cyst.

1. **Galactocoele** or **Milk-Cyst** has already been described at page 769.

2. The **True Glandular Cyst** is not uncommon, and may attain a considerable size. These cysts form rounded or slightly lobulated tumours, usually imperfectly defined and painless, or nearly so. They may be deeply seated in the substance of the breast, but often project on its surface or at one of its borders. The position of these cysts in the breast, and the fact that they are usually lined with a more or less perfect layer of cubical or spheroidal epithelium, make it almost certain that they arise in the glandular acini or small ducts. In some cases they contain intracystic growths covered with a similar epithelium, and containing spaces lined with the same. Sometimes their fluid contents can be partly squeezed out from the nipple, and the cyst is soft and fluctuating. Should the duct become completely or partially blocked, either from inflammatory induration of the surrounding tissue, or, as in a case recorded by Rogeau, by a small papillary growth springing up in its interior, the cyst increases more rapidly in size, and becomes so tense as to be easily mistaken for a solid tumour. The causes of these cysts are uncertain. They seem usually to arise from some injury or irritation of the breast. Butlin, who has published some interesting observations on these cysts, states that they most commonly occur after thirty-five, in women who have borne children, and in several cases appear to have arisen as the result of a blow. In some cases they may possibly be associated with some uterine affection.

3. **Duct Cyst**.—This variety of cyst undoubtedly arises in distension of one of the large ducts of the breast. It is situated towards the central part of the gland, often projecting prominently beneath the areola. In many instances the first symptom observed by the patient is the occasional escape of a yellowish fluid from the nipple, and pressure on the cyst may greatly increase this.

The chief importance of the duct cyst is that it is often the seat of a delicate branching intracystic growth, the vascular papillæ of which are covered with columnar epithelium similar to that lining the cyst. Such a growth is known as a Duct Papilloma. The vascularity of the growth is often so great that hæmorrhage from the nipple may be a marked symptom. In the case from which the breast represented in Fig. 778 was removed there was a constant clear discharge from the nipple, which rapidly became bloody when the small cyst was pressed upon. It is extremely probable that this simple duct papilloma may in some instances be the starting-point of a columnar carcinoma (see p. 799).

It occasionally happens that if a glandular or duct cyst projects prominently beneath the skin, the latter, together with the subjacent cyst wall, may give way and expose its interior. If the cyst contains an intracystic growth this may rapidly protrude through the opening and form a fungating mass, with an appearance of considerable malignancy.

**Multiple Cysts** arising in the breast are met with: 1. In connexion with chronic interstitial mastitis; 2. During involution of the gland; and 3. As a true cystic degeneration of the mamma.

1. The cysts which are so frequently met with in lobules of the breast affected by chronic interstitial inflammation seldom reach any large size. They have been described at page 775.

2. **Involution Cysts** are not uncommon in the indurated and atrophied breasts of old women. They are of no great practical importance, and doubtless result from constriction of the gland tissue by the overgrowth of fibrous tissue around it.

3. **Cystic Degeneration of the Mamma** is characterized by a wide-spread tendency to the formation of cysts in the glandular tissue, which may, in advanced cases, reach such a degree that the whole breast is converted into a mass of cysts bound together by connective tissue. In the majority of cases the disease begins in a single lobule, but sooner or later it tends to affect other parts of the same breast, and often the opposite one. This remarkable disease has received considerable attention at the hands of French pathologists, and Reclus has especially insisted upon its tendency to become bilateral. In the early stages the cysts appear as hard rounded tumours in a lobule of the breast substance, and around these a coarsely granular sensation is produced by the minute cysts with which the gland is infiltrated. Gradually other lobules undergo similar changes, until the whole breast presents similar characters, and may be considerably enlarged. Discharge from the nipple is not uncommon; this may be blood-stained, probably from the presence of vascular intracystic growths in some of the cysts.

Nothing definite is known concerning the causation of this disease, but in some instances it appears to be connected with uterine disorders or other affections of the generative organs. A well-marked specimen of the disease, which is preserved in the museum of University College, was removed *post mortem* from a woman on whom ovariectomy had been performed.

As a good example of the disease the following case may be given. A young unmarried woman, in order to quiet a baby she had charge of, put it occasionally to her breast. This was followed by some pain and swelling, and a thin yellowish discharge from the nipple. Some months after, on examining the breast, a number of small fluctuating swellings, the largest about the size of a hazel nut, could be felt scattered through both breasts. They were most

Fig. 778.—Duct Papilloma of Breast. An incision has been made into the deep surface of the gland.

distinct in the neighbourhood of the areola. The discharge continued, and was a source of considerable annoyance. On pressing the cysts their contents were easily squeezed out through the nipple. The condition remained unchanged for about two years, in spite of belladonna and other external remedies. She then married and became pregnant. As the breasts enlarged, the abnormal discharge gradually ceased, and after her confinement she was able to nurse her child without difficulty.

The remarkable persistence of the disease was well illustrated by a case in University College Hospital. The left breast was excised for cystic disease by Marshall in 1877, and the right breast for a similar condition in 1882. In 1889 a small mass of cysts was excised by Beek from the neighbourhood of the scar in the left mammary region, and microscopic examination showed that these had arisen in a fragment of breast tissue which had escaped removal twelve years previously.

Hæmorrhage may take place into the cavity of a cyst, especially if this contains a vascular intracystic papilloma. This may be the result of an injury. The term "blood-cyst of the breast," has, indeed, no pathological meaning, for blood-cysts may arise from hæmorrhage into the substance of a soft sarcoma, and they are also found in certain forms of carcinoma.

CYSTS ARISING INDEPENDENTLY OF THE GLANDULAR TISSUE comprise two forms, the serous and the hydatid.

1. **Serous Cysts of the Breast.**—These are believed to be formed, as elsewhere, by dilatation of the lymph-spaces of the areolar tissue, the wall of the cyst being formed of the surrounding connective tissue pressed together and subsequently thickened by new growth. The evidence of this mode of growth is not by any means perfect, but it seems the only possible explanation of their structure. Their walls are composed of delicate areolar tissue, lined internally with flattened endothelial cells like those of a lymphatic vessel. The contents are usually clear yellowish serous fluid, but may sometimes be brownish or turbid, from the admixture of blood, and in some cases cholesterine is present. These cysts are usually single, sometimes they are loculated, and in other cases multiple. They are usually about the size of a filbert when first noticed, and may remain small for a great length of time, but in other cases they gradually increase until they may contain several ounces of fluid. They then become very tense, so much so, in fact, that fluctuation is no longer present. The true serous cyst is almost invariably seated in the submammary areolar tissue, or at one margin of the breast, very rarely in the glandular substance.

Unilocular cysts of the breast occasionally attain an immense size, at the same time that their walls remain thin and supple. In these cases the skin covering them may become thinned and translucent, constituting the condition which has been termed *hydrocele of the breast*.

The simple serous cysts never develop intracystic growths. In some rare cases calcification of the cyst-wall has been observed.

2. The true **Hydatid Cyst** is extremely rare, but has been met with in the mamma. The simple serous cyst was described by Astley Cooper under this name.

The **Diagnosis of a cyst of the breast** may usually be effected by feeling the globular elastic tumour under the skin; the mammary gland being movable, and not adherent to any of the adjacent structures. Cysts being connected

with the mammary tissue drag upon the nipple when moved away from it. This is recognized by holding the nipple lightly while the tumour is drawn away with the other hand, when the connexion between them will be clearly perceptible. In those cases, however, in which the tumour lies deeply, the diagnosis may not so readily be made, more especially from tumours containing cysts or from carcinoma. In fact, nothing is more easy than to diagnose the nature of a superficial lax cyst; nothing is more difficult than to recognize it when tense and deeply seated towards the under surface of the mammary gland (Fig. 779); for, the whole thickness of the gland intervening between

Fig. 779.—Breast laid open after removal, showing Cysts deeply seated in Mammary Gland, mistaken for Scirrhus.

the cyst and the finger, the sense of elasticity is lost and a solid feel communicated, which may readily mislead even the most experienced Surgeon. In a cyst, if elasticity can be recognized, it will be most distinct in the centre; in solid tumours the centre is the densest part. In examining the tumour the patient should be placed on her back, so that the mamma is flattened out and supported by the ribs. Elasticity and fluctuation are then more easily distinguished. Many errors in diagnosis arise from neglecting this simple precaution. Whenever the Surgeon has any doubt about the existence of fluid in a tumour of the breast, he should introduce an exploring trochar. If the tumour prove to be solid, no ill consequences will result from the simple puncture. I have known several instances in which, from the want of this precaution, Surgeons have mistaken cystic tumours of the breast for cancer.

It may be impossible to distinguish with any certainty between the different varieties of cysts. One or more cysts deeply seated in the substance of the breast are probably duct or glandular cysts; whilst a serous cyst is usually

single and thin-walled, and lies either beneath the breast or at one of its borders. The presence of a discharge from the nipple excludes the serous cyst; whilst a blood-stained discharge suggests the presence of an intracystic growth in a glandular or duct cyst. The true hydatid cyst is so rare that it may practically be excluded in making the diagnosis. It may be recognized by the character of the fluid withdrawn on puncture. This is clear, containing merely the faintest trace of albumen, and has a specific gravity of 1003 to 1004. Hooklets may possibly be found in it. Without puncture these cysts cannot be distinguished from the other forms.

Cystic degeneration of the mamma may be mistaken for a cysto-adenoma, but in the latter case careful examination will show that the cysts are in an encapsuled tumour and not in the breast itself. The bilateral distribution of cystic degeneration will often indicate its nature.

The **treatment of cysts of the breast** varies according to their number and size and the presence or absence of intracystic growths. Small multiple retention-cysts which can be emptied through the nipple sometimes require no further treatment. Belladonna or some form of counter-irritation may be applied externally in the hope of arresting the abnormal secretion, but these means are seldom of much use. If the cyst is larger and cannot be emptied by pressure, the fluid contents may be let out by puncturing with a small trochar; but a cure cannot usually be effected in this way, as the fluid re-accumulates. Occasionally it will suppurate spontaneously, and is thus got rid of. If the tumour be single, it may usually be cured by opening it by a small incision, wiping it out with a strong solution of chloride of zinc or tincture of iodine, and inserting a drainage-tube under an antiseptic dressing for a few days. If it seem to be surrounded by indurated mammary tissue, it is best to dissect it out and to remove it with the lobule of the mamma to which it is attached. On doing this it will often be found that the cyst is not single, as was at first supposed, but that several smaller sacs are present which have been concealed by the larger one. If the cyst contain intracystic growths, it should be completely removed with the neighbouring part of the mammary gland. If the cysts are multiple they must be treated according to circumstances. If there are but two or three they may be treated as if single, but if very numerous there is nothing to be done but to remove the breast if operative interference is demanded.

#### SIMPLE TUMOURS OF THE BREAST.

**Lipoma.**—Fatty tumours have occasionally been met with in close proximity to the mamma, so as to simulate a tumour of the gland itself. A little careful examination will usually enable the Surgeon to ascertain that the gland is not implicated. The *Treatment* of these tumours presents nothing peculiar.

**Fibroma.**—Pure fibroma of the mamma is very rare. Two cases only have occurred in University College Hospital in the last fifteen years. One was a middle-aged woman, and the tumour, which was about the size of a hen's egg, was of stony hardness. It was thought to be a scirrhus, but as there was some doubt, a deep incision was made into it before removing the breast. It was found to be exceedingly dense, creaked under the knife, and no capsule was recognized. After removal of the breast, it was found to

be clearly defined and surrounded by a distinct but dense capsule, from which it could be dissected out, leaving the mammary tissue untouched. Microscopic examination showed it to be composed of dense fibrous tissue, without a trace of glandular structure.

In the second case a very lobulated pure fibroma was removed from the centre of the breast of an unmarried woman aged twenty-four. The tumour was easily shelled out of its capsule, and had probably arisen as a growth into a lacteal duct.

**Chondroma and Osteoma.**—Tumours of the breast containing cartilage have been recorded, but are of extreme rarity. Billroth mentions a case of a large sarcoma of the mamma in which small nodules of true bone were found, and W. H. Battle has recorded a case in which an osteo-chondro-sarcoma was removed from the breast of a woman aged seventy-three.

**ADENOMATA OF SIMPLE GLANDULAR TUMOURS.**—To this group belong the large majority of the simple tumours of the breast. The general characters of the adenomata have already been described in Vol. I., p. 1034, but it will be necessary here to consider the anatomical characters of the different varieties which occur in the breast. An important feature, which is common to them all, is that they are perfectly encapsuled, and are not intimately connected with the breast substance itself.

**Structure.**—The type of the simple glandular tumours of the breast is the **True Adenoma**. Microscopic examination of this rare tumour shows acini lined with abundant epithelium, presenting much the appearance of the normal gland during lactation. Small ducts connecting several acini may be present, but there are no large collecting ducts, as in the normal mamma. In some cases cysts, formed by the dilatation of the acini, have been present.

From this single type it is easy to pass by a gradual transition to several other tumours, which, although they may differ widely from one another in their superficial characters, have this essential feature in common, that they consist of epithelium-lined glandular spaces lying in a connective tissue stroma.

Thus, if the bulk of the tumour consists of dense fibrous tissue in which the glandular spaces are more or less abundantly scattered (Vol. I., Fig. 374), the growth is termed a **Fibro-adenoma**. The glandular spaces may retain their resemblance to normal acini, but often they are dilated into small cysts, or form flattened slit-like spaces which branch irregularly through the fibrous stroma.

In another common modification the tumour presents a minute structure exactly corresponding to that last described, with the single exception that the stroma, instead of being represented by dense fibrous tissue, is richly cellular, and may indeed be almost entirely embryonic, every variation between the two extremes being met with (Vol. I., Fig. 375). Thus, it may be composed of small spindle-cells with numerous fibres between them; of imperfectly developed fibrous tissue infiltrated with small round or large spindle-cells; of delicate fibres with stellate cells and mucous intercellular substance; or of various modifications of these structures. Such a tumour may most correctly be called a **Soft Fibro-adenoma**. Much confusion has arisen from the use of the name *Adeno-sarcoma* for this tumour, which is only a rapidly growing fibro-adenoma.

The last variety of the adenomatous tumours of the breast is characterized

by the conversion of the glandular spaces into cysts, which frequently reach a large size, and often present intracystic growths which form the most marked feature of the tumour. These growths are formed of processes of the interstitial tissue of the tumour projecting into the cyst, and are covered with a layer of epithelium. They are often branched, and may in some cases completely fill the cavity into which they grow. They may sprout from all sides at once, and then form a closely-packed foliated mass, without any clear evidence of the mode of growth remaining. In other cases a pedunculated mass springs up from a single point in the cyst-wall, and may project into it, still surrounded by a certain amount of fluid, or may completely fill it, displacing the fluid, and being surrounded by the cyst-wall as by a capsule. The stroma of the growth varies, but is generally more or less richly cellular. A tumour of this structure is generally known as a *Cysto-sarcoma*, but the same objections may be raised to this name as to that of *Adeno-sarcoma*, and all confusion may be avoided by calling it a **Cysto-adenoma**.

In describing the clinical features of these tumours, it will be found that they differ greatly in their superficial characters. They agree, however, in being perfectly encapsuled and distinct from the breast itself, and in showing no tendency to infiltrate the neighbouring parts or to recur in internal organs. The chief difference between them consists in their rate of growth and the size which they tend to assume. If the stroma is dense and fibrous, the tumour is usually small and of slow growth. If the stroma is richly cellular or embryonic, the rate of growth is relatively rapid, and the size of the tumour may be considerable. If large cysts develop from the glandular spaces, the rate of increase may be very rapid, and the size of the tumour eventually enormous. The close relationship of these different tumours is further shown by the fact that the same growth may in different parts present all the varieties of structure above described, and further, that there is strong reason for believing that a growth of one variety may, in the course of its development, gradually assume the characters of another.

It is impossible here to enter into the question of the supposed origin of the adenomatous tumours of the breast. Billroth states that they commence by an overgrowth of the connective tissue surrounding the acini and ducts. But in whatever point they commence, it is evident that in their subsequent development the growth of the epithelium is as essential a part of the process as is that of the interstitial tissue. The presence of the epithelium-lined spaces is not a mere accident of the growth, but an essential feature of it. A view which seems very probable, at least in many cases, is that they arise in small outlying lobules of the breast, which have failed to become connected up with the proper glandular apparatus. In some instances the relation of the tumour to the breast is in favour of Paget's view, that it arises as an intracystic growth, which gradually fills the cyst in which it lies, and thus appears as a solid encapsuled tumour.

The **True Adenoma** is extremely rare. In the Museum of University College is a specimen of this kind of tumour, five inches in diameter and weighing four pounds. It was removed by R. Quain from a lady, aged 26, after about 18 months' growth. At the time of the operation the patient was in the sixth month of pregnancy. The tumour was loosely encapsuled, and not adherent to the gland or to the skin. Its section much resembles that of the pancreas to the naked eye, and microscopic examination shows the

structure above described. It is distinguished from normal mammary tissue by the total absence of fat from the inter-acinous tissue. It contains one small cyst about half an inch in diameter, with some fine papillary intracystic growths projecting into it.

The **Hard Fibro-adenoma** is the most common simple tumour of the breast. It is identical with the *Chronic Mammary Tumour* of Astley Cooper, the *Pancreatic Sarcoma* of Abernethy, and the *Partial or Lobular Hypertrophy of the Mamma* of Vidal. It is often attributed to blows, squeezes, or lacteal irritation, and is most commonly met with in young women under thirty years of age: usually in women otherwise healthy. Bryant states that of 100 consecutive cases observed by himself, 27 were first discovered between puberty and 20; 35 between 20 and 30; 22 between 30 and 40; 13 between 40 and 50; and 3 after 50. Forty-six occurred in single women, 37 in the married and prolific, and 15 in the married and sterile. It is often associated with the hysterical temperament, and connected with, if not dependent on, uterine irritation and sexual excitement of an irregular kind. This tumour is generally of small size when first perceived, and may remain stationary for many years; or it may slowly increase, and at last attain a considerable bulk. In other cases it may very rapidly grow to a great size. In a case on which I operated some years ago, the tumour had continued for eighteen years about the size of a walnut, but in the course of six months it increased to an enormous magnitude, and on removal weighed nearly five pounds.

This tumour usually commences as a small, movable, finely nodulated growth, attached by a pedicle to one side of the mammary gland; it is hard and incompressible, often appears isolated, and is not generally painful, but in anæmic women may be the seat of intense neuralgic pain; it increases slowly, without discolouring the skin or becoming attached to it, and is frequently many years in attaining a moderate size. It is often floating, as it were, in the substance of the gland, into which it can be pushed back.

On examination after removal, a fibro-adenoma appears to be irregularly lobulated, is enclosed in a capsule of areolar tissue, and its cut surface is found to present a bluish- or greyish-white colour, which, after exposure to the air, assumes a rosy tint; and on pressure, drops of a thick mucous or serous fluid are often seen to exude. On examination with a lens, its foliated structure is often very apparent, so much so that it has been compared by Virchow to the section of a cabbage. This is more clearly seen after it has been a few days in spirit.

It occasionally happens that a fibro-adenoma becomes the seat of very severe and paroxysmal neuralgic pains attended with very considerable cutaneous sensibility, and it has then been termed the *painful mammary tumour*. This condition most frequently occurs in early life, and in women of an irritable and delicate constitution; it is commonly associated with disorder of the uterine functions, the pain increasing at the catamenial periods.

The **Soft Fibro-adenoma** is frequently known by the name of *Adeno-sarcoma*. It often develops from a slowly growing hard fibro-adenoma which has remained more or less quiescent up to about the middle of life.

In cases in which the disease develops for the first time between the ages of 35 and 40 it may grow quickly from the first. In these cases it will grow with great rapidity, attaining in a few months a size equal to that of a cocoa-nut, or even larger, and simulating in this respect the progress of a

soft sarcoma. These rapidly growing fibro-adenomata are painless, and however large, continue perfectly movable, free from deep adhesion, and from glandular implication; the skin covering them is healthy, thinned, and unadherent, the nipple projecting usually very prominently. The tumour

Fig. 780.—Adenomatous Tumour of Breast. In the left half the tumour has the character of a soft fibro-adenoma, and in the right half of a cysto-adenoma.

itself will be felt to be nodulated, semi-elastic, and always rounded in outline. After removal its section is lobulated and glistening, something resembling a mass of sago-jelly, often having cysts interspersed through its substance.

Fig. 781.—Cysto-Adenoma of Breast.

The **Cysto-adenoma** is identical with the *cysto-sarcoma* of J. Müller, the *glandular proliferous cysts* of Paget, and the *sero-cystic sarcoma* of Brodie.

These tumours are composed of dense white lobulated or foliated structure, resembling that of the fibro-adenoma. This mass is studded throughout with

a number of small cysts, varying in size from a pin's head to an inch and a half in diameter, and usually containing clear fluid. The larger cysts contain lobulated, branching, intracystic growths, most commonly sprouting from one side only, and forming pedunculated projections into the cavities. These intracystic growths are not always present. This form of tumour is usually met with in women of from thirty to thirty-five years of age, and is often attributed to injury. It occurs most frequently in women who have borne children, and is possibly a remote consequence of some inflammatory process occurring during lactation. On examining a breast affected in this way, it will be found that the tumour is hard, heavy, and solid to the feel; on careful examination, however, its surface may be felt to be finely nodulated;

Fig. 782.—Cysto-Adenoma of mamma, showing large cysts with intracystic growths.

and, occasionally, a larger cyst than usual, recognised by its elastic feel and globular shape, may be found projecting. The disease is slow in its growth, and does not implicate the adjacent cutaneous or areolar structures; hence, the tumour is movable on the pectoral muscles, and the skin is unattached to it. The axillary glands, also, are not enlarged. The nipple will usually be found to be normal in its shape, and not depressed. If one of the larger cysts be laid open, or if the pressure of the intracystic growth causes inflammation and ulceration of its capsule, this may at last be perforated, and a fungous mass will sprout through it, presenting many of the ordinary symptoms of a malignant growth; being irregular, dark-coloured, bleeding readily, and increasing rapidly in size. When such changes as these have taken place, the tumour assumes a formidable character, and will rapidly prove fatal by exhaustion. A cysto-adenoma may attain an immense size and

weight. They have been met with of six, eight, or even twelve pounds weight; but by far the largest is one described by Velpeau, which weighed forty pounds.

In the case from which the drawings (Figs. 783, 784) were taken the tumour had existed for more than twenty years before removal, it commenced at the age of twenty-eight; and after extirpation soft fungous growths were found at the bottom of some of the cysts. The constitution was uncontaminated throughout.

**Diagnosis.**—A small hard fibro-adenoma may be mistaken for a chronic lobular mastitis, or early scirrhus. From all these conditions fibro-adenoma is distinguished by its perfect circumscription and free mobility and in not being, as are these other conditions, an intimate part of the tissue. A cyst further differs in the absence of lobulation, and in the softness of its central part as compared with the periphery; lobular

Fig. 783.—Ulcerated Cysto-Adenoma of Breast, of 20 years' duration.

Fig. 784.—The same Tumour, six months with fungating sarcomatous growth.

in the ill-defined outline of the induration and its flattened irregular surface and early scirrhus in the more stony hardness and the dimpling of the skin over it. The patient's age and the duration of the disease may also help in deciding between fibro-adenoma and an early stage of scirrhus, but in a case of great doubt no time should be lost in making an exploratory incision.

A soft and rapidly growing fibro-adenoma may resemble somewhat closely a sarcoma or a soft carcinoma. The distinction will turn chiefly on the relation of the tumour to the breast—the soft adenoma being quite independent and movable, the carcinoma being intimately connected with the breast, and a sarcoma being in this respect intermediate between the other two. The history may be helpful, for the soft fibro-adenoma often develops from a small tumour of long duration. The chief importance of the accurate diagnosis is as a guide in deciding between removal of the tumour only and excision of the whole breast. An exploratory incision is often the only means of removing the doubt.

A cysto-adenoma may be distinguished from cystic degeneration of the mamma

fact that in the former the cysts occupy the substance of an encapsulated ; and in the latter case occupy the substance of the breast itself. From c sarcoma the distinction may be difficult, and will depend chiefly on fact circumscription of the cysto-adenoma, and often the long duration growth.

**tment.**—The probable explanation of recorded cases in which supposed adenomata have been cured by the application of counter-irritants, ab- a, or pressure, is that the tumour was in reality an indurated lobule of ast, and the same may probably be true of tumours which have dis- ead after marriage or during pregnancy. Removal of the tumour is the ficient treatment, and this should, as a general rule, be recommended ough the growth be small and stationary, on the ground that at any time rapidly increase in size and assume serious proportions. The tumour e exposed by a single incision radiating from the nipple, so as to injure mmary tissue as little as possible. The loose capsule of areolar tissue iding it should be thoroughly opened, after which it can often be shelled hout further use of the knife. There are usually few vessels to tie. In onal cases the growth may be adherent to the breast by a pedicle, ating the removal of a small lobe of the gland. As these tumours lie at the margin of the breast, or sometimes deeply beneath it, the abmammary areolar tissue is often opened up. When the tumour is ore superficially this may possibly be avoided by keeping the knife it in dissecting it out. When the submammary tissue is opened up it important to prevent extravasation of blood into it, or the occurrence uration. These accidents are avoided by the strictest attention to hic precautions during the operation, by the perfect arrest of all bleeding closing the wound, and by the application of an absorbent antiseptic g exerting uniform elastic pressure on the part.

fibro-adenomata and cysto-adenomata can, as a rule, be removed with en though they have reached some pounds in weight. In some cases, lly when a cysto-adenoma has burst through the skin, it is found neces- remove the whole breast with the tumour. The operation should be out in the same way as for malignant tumours, except that only such is actually attached to the growth need be sacrificed.

#### MALIGNANT TUMOURS OF THE BREAST.

**SARCOMA OF THE BREAST.**—The mammary gland or its immediate neigh- od is a not unfrequent seat of sarcoma. By far the most common form spindle-celled sarcoma, usually of the large-celled variety. Sometimes mer form of spindle-celled sarcoma, with small cells and a varying t of fibrous stroma—the old “recurrent fibroid”—is met with in this

Small round-celled sarcoma, alveolar sarcoma, and giant-celled sar- may also occur, but are all rare. The structure of these various forms oma has already been fully described in the Chapter on Tumours , p. 1035 *et seq.*).

t sarcomata of the breast are distinctly encapsuled by a layer of fibrous in the early stages of their growth, but later on they tend to spread this, and infiltrate the surrounding structures.

r usually develop in women after thirty, and form soft, elastic tumours,

weight. They have been met with of six, eight, or even twelve pounds' weight; but by far the largest is one described by Velpeau, which weighed forty pounds.

In the case from which the drawings (Figs. 783, 784) were taken, the tumour had existed for more than twenty years before removal, having commenced at the age of twenty-eight; and after extirpation soft fungating growths were found at the bottom of some of the cysts. The constitution was uncontaminated throughout.

**Diagnosis.**—A small hard fibro-adenoma may be mistaken for a cyst, chronic lobular mastitis, or early scirrhus. From all these conditions the fibro-adenoma is distinguished by its perfect circumscription and free mobility, and in not being, as are these other conditions, an intimate part of the breast tissue. A cyst further differs in the absence of lobulation, and in the greater softness of its central part as compared with the periphery; lobular mastitis

in the ill-defined outline of the induration and its flattened irregular shape; and early scirrhus in the more stony hardness and the dimpling of the skin over it. The patient's age and the duration of the disease may also be of help in deciding between fibro-adenoma and an early stage of scirrhus, but in a case of great doubt no time should be lost in making an exploratory incision.

A soft and rapidly growing fibro-adenoma may resemble somewhat closely a sarcoma or a soft carcinoma. The distinction will turn chiefly on the relation of the tumour to the breast—the soft adenoma being quite independently movable, the carcinoma being intimately connected with the breast, and the sarcoma being in this respect intermediate between the other two. The history may be helpful, for the soft fibro-adenoma often develops from a small hard tumour of long duration. The chief importance of the accurate diagnosis is as a guide in deciding between removal of the tumour only and excision of the whole breast. An exploratory incision is often the only means of removing the doubt.

A cysto-adenoma may be distinguished from cystic degeneration of the mamma

by the fact that in the former the cysts occupy the substance of an encapsuled tumour, and in the latter case occupy the substance of the breast itself. From a cystic sarcoma the distinction may be difficult, and will depend chiefly on the perfect circumscription of the cysto-adenoma, and often the long duration of the growth.

**Treatment.**—The probable explanation of recorded cases in which supposed fibro-adenomata have been cured by the application of counter-irritants, absorbents, or pressure, is that the tumour was in reality an indurated lobule of the breast, and the same may probably be true of tumours which have disappeared after marriage or during pregnancy. Removal of the tumour is the only efficient treatment, and this should, as a general rule, be recommended even though the growth be small and stationary, on the ground that at any time it may rapidly increase in size and assume serious proportions. The tumour must be exposed by a single incision radiating from the nipple, so as to injure the mammary tissue as little as possible. The loose capsule of areolar tissue surrounding it should be thoroughly opened, after which it can often be shelled out without further use of the knife. There are usually few vessels to tie. In exceptional cases the growth may be adherent to the breast by a pedicle, necessitating the removal of a small lobe of the gland. As these tumours usually lie at the margin of the breast, or sometimes deeply beneath it, the loose submammary areolar tissue is often opened up. When the tumour is seated more superficially this may possibly be avoided by keeping the knife close to it in dissecting it out. When the submammary tissue is opened up it is very important to prevent extravasation of blood into it, or the occurrence of suppuration. These accidents are avoided by the strictest attention to antiseptic precautions during the operation, by the perfect arrest of all bleeding before closing the wound, and by the application of an absorbent antiseptic dressing exerting uniform elastic pressure on the part.

Soft fibro-adenomata and cysto-adenomata can, as a rule, be removed with ease, even though they have reached some pounds in weight. In some cases, especially when a cysto-adenoma has burst through the skin, it is found necessary to remove the whole breast with the tumour. The operation should be carried out in the same way as for malignant tumours, except that only such skin as is actually attached to the growth need be sacrificed.

#### MALIGNANT TUMOURS OF THE BREAST.

**SARCOMA OF THE BREAST.**—The mammary gland or its immediate neighbourhood is a not unfrequent seat of sarcoma. By far the most common form is the spindle-celled sarcoma, usually of the large-celled variety. Sometimes the firmer form of spindle-celled sarcoma, with small cells and a varying amount of fibrous stroma—the old “recurrent fibroid”—is met with in this region. Small round-celled sarcoma, alveolar sarcoma, and giant-celled sarcoma may also occur, but are all rare. The structure of these various forms of sarcoma has already been fully described in the Chapter on Tumours (Vol. I., p. 1035 *et seq.*).

Most sarcomata of the breast are distinctly encapsuled by a layer of fibrous tissue in the early stages of their growth, but later on they tend to spread beyond this, and infiltrate the surrounding structures.

They usually develop in women after thirty, and form soft, elastic tumours,

by a distinct pedicle. As it increases in size it becomes hard, knotted, and irregular, or perhaps finely granular on its surface. It more definitely implicates the substance of the gland and forms adhesions to the skin covering it, and later on to the structures beneath it.

2. **Infiltrating or Diffuse Scirrhus** commences as a diffused induration of a considerable portion of the breast. Occasionally it may begin as a number of separate nodules, which quickly coalesce. In this way a mass is formed of irregular shape, hard, rugged, nodulated, and heavy. It quickly increases in size, and forms adhesions to the skin and deeper structures.

3. **Atrophying, Withering or Cicatricial Scirrhus** is more common in old women, but may occur at any age. The tumour is of slow growth, and is characterized by a peculiar tendency to shrink from atrophy of its central parts. In this way the affected breast, in spite of the presence of the tumour, may be greatly reduced in size, and may apparently almost completely shrink and disappear. The adherent nipple and skin are deeply drawn in.

**Cysts** occasionally form in scirrhus tumours in consequence of softening of the central parts of the growth. This is most common in the infiltrating form, and is never met with in the atrophic. In a woman whose breast I once removed for what was supposed to be a cystic sarcoma, but which proved after the operation to be a cancer, the tumour contained several cysts as large as cherries, filled with dark greenish fluid, and projecting from its surface; and in another case of scirrhus of the breast, a cyst as large as a pigeon's egg, containing sanguinolent fluid, formed on its surface.

**The Symptoms of Cancer of the Breast** will best be considered by describing the usual course of a case of circumscribed scirrhus. Three stages of the disease are usually recognized, as suggested by Gross: 1, Disease limited to the breast; 2, Implication of skin and lymphatic glands; 3, Ulceration and general infection.

*First Stage.*—The first symptom of cancer of the breast is usually the accidental discovery of a lump in the mamma, often whilst the patient is washing herself. In rare cases pain is the first indication of the disease, but generally this is absent during the first stage. Inspection of the breast shows no enlargement, and the only visible change is **retraction of the nipple**, which is common towards the end of the first stage. Retraction of the nipple usually occurs early, and is well marked when the tumour occupies the central part of the breast, and on the other hand it occurs later, and may be absent if the tumour is situated peripherally. A thin serous discharge from the nipple is an exceptional symptom. On palpation the tumour is felt as a hard nodule in some part of the breast. It often lies in the upper and outer segment near the margin, but may be situated more centrally near the nipple. The tumour forms an intimate part of the breast tissue; it cannot be moved about independently of the gland, and if the nipple and the tumour are drawn apart the ducts can easily be felt passing between them. Even at this early stage the skin is loosely held to the tumour, and distinctly dimples if it be pinched from the surface of the tumour with the finger and thumb.

The average duration of the first stage of cancer of the breast is, according to Gross, 14·1 months, and the general health is usually unimpaired throughout.

*Second Stage.*—The tumour slowly invades the surrounding breast tissue, but on account of the shrinking which is constantly going on in the older central part of the growth, the increase in size is not great. In this stage of

the disease gradual **implication of the skin** takes place. The skin becomes more and more fixed to the tumour, and finally invaded by it. The adherent portion now becomes smooth and thickened; it acquires a reddish or purplish colour, and is permeated by a number of small ramifying vessels. The nipple becomes more retracted, and the depression may be increased by the projection forwards of the general mass of breast, so that the nipple may become completely buried. At this stage **pain** is almost invariably present; it is acute and lancinating, and is greatly aggravated by handling the diseased part. It is often particularly severe at night, and may radiate to the shoulder and down the arm. The pain is chiefly caused by the infiltration of the skin, and often gradually becomes less in the more advanced stages, owing probably to destruction of the cutaneous nerves.

The average period at which the **enlargement of the axillary glands** becomes sufficiently marked to be recognizable to the touch is the fifteenth month. The period at which glandular implication occurs seems to bear no definite relation to the position or size of the primary tumour. The glands first affected are usually those in the lower and anterior part of the axilla, and sometimes an indurated lymphatic vessel can be felt passing to them from the breast. In examining the axilla the patient's arm should be kept by the side, so that the axillary fascia may be relaxed. Some loss of flesh is usually the only constitutional symptom during the second stage of the disease, which has an average duration of six months.

**Third Stage.—Ulceration of the skin** usually begins as a small crack or fissure, surrounded by scaly epidermic desquamation, in the area which is already infiltrated by the tumour. A small exudation of serous fluid takes place, which dries into a scab, and under this, ulceration sets in, which speedily assumes the ordinary characters of a cancerous ulcer, having hard, elevated, and everted edges, a greyish-green surface, and discharging a quantity of very fetid pus.

Whilst the disease is extending superficially it is also invading the deep parts, and becomes adherent to, and finally implicates, the pectoral muscle. This is evidenced by fixation of the breast when the muscle is brought into action. By its further spread the growth may invade the sternum and ribs, and even reach the pleura, causing pleural effusion. Meanwhile the glandular enlargement progresses, and the supraclavicular glands may become affected. Edema of the upper limb and severe neuralgic pain shooting down it are often caused by the pressure of the enlarged glands on the axillary vein and nerves.

Fig. 786.—Ulcerating Scirrhus Cancer of Breast.

At this stage of the disease the symptoms usually described as those of the **cancerous cachexia** become marked. There is progressive emaciation and loss of strength; the complexion is sallow and the appetite lost. In some cases the patient dies from gradual exhaustion produced by the extensive ulceration, the general condition being largely due to septic poisoning, and death being sometimes hastened by repeated hæmorrhage from the ulcerated growth. In other cases **secondary deposits** make their appearance in the viscera and other parts. The period at which this takes place varies in different cases. As a rule it may be stated that the softer the tumour and the younger the patient the earlier will the viscera be implicated. The most common seat of the visceral tumours is the liver; after that, but at a considerable interval, comes the lung, and then the bones. In the brain, kidneys, and other organs secondary growths are occasionally met with, but are less common. Among the bones, the femur, the ribs, and the vertebræ are perhaps the most frequently affected. In the last situation the disease causes death by development of angular curvature, with pressure on the spinal cord and nerves. In the long bones it gives rise to spontaneous fracture.

Only a short description of the clinical features of the less common varieties of hard glandular cancer need be given.

*Infiltrating scirrhus* may spread from a single centre or several small nodules may become confluent, until the whole gland is hardened and enlarged. The nipple is deeply retracted and the skin extensively adherent. The axillary glands are affected at an early stage, and extensive deep ulceration of the growth usually occurs.

*Scirrhus "en cuirasse"* is characterized by the extensive implication of the cutaneous structures. The tumour of the gland is small, atrophic, and implicates the nipple. The cancerous infiltration rapidly spreads into the surrounding integument, which early becomes contaminated, assuming a hard, leathery character, or feeling brawny and infiltrated; often without discoloration, but presenting a hypertrophied appearance, the pores being enlarged, and the interspaces between them increased. In other cases, the infiltrated skin assumes a brownish or purplish colour, and is covered by rough desquamating crusts, so as to resemble the bark of an old tree. This diseased state of the integuments will extend very widely, without ulceration or further development of the tumour situated in the gland. I have in this way seen the integuments of the whole front of the chest, from the clavicles to below the mammae, and from one axilla to the other, infiltrated, hard, and leathery, of a brownish-red colour, forming a stiff cuirass, as it were, but without ulceration. This condition, to which the name cancer "*en cuirasse*" has been given, is very chronic; and it is remarkable that in it the axillary glands are not infiltrated, or the constitution rendered cachectic, at nearly so early a period as when the disease more extensively implicates the mammary gland.

Another way in which the skin becomes involved is by the formation of a cancerous tubercle or nodule in it towards the outer or axillary border of the mamma, the gland beneath being implicated to but a limited extent. It is probable that in these cases the disease commences in an outlying lobule of the gland situated immediately beneath the skin. Occasionally small isolated tubercles spring up in the skin around the spot first implicated. They are of a reddish-brown colour, slightly elevated, smooth on the surface, and very

hard. By the coalescence of these the condition above described of wide-spreading implication of the skin may arise.

*Atrophying scirrhus* often runs an extremely slow course, but eventually the glands and other parts may be infected. The growth shows a remarkable tendency to shrink, and thus the size of the breast is often diminished. The nipple is deeply retracted, and the skin very puckered and adherent to the tumour, which is itself firmly fixed to the chest wall. In advanced stages the appearance of the part may be most remarkable. For instance, in one case, a woman of forty-six, the disease was of more than seven years' duration. The left breast was moderately large, but the right one had almost entirely disappeared, and was replaced by a puckered scar-like mass about two inches in diameter, with a small superficial ulcer in the position of the nipple. The patient's general health was excellent, and there was no pain.

The **Duration of Life** in untreated cases of scirrhus of the breast varies greatly, the disease sometimes proving fatal in a few months, and in others not for many years. As a general rule, to which there are many exceptions, the younger the patient the more rapidly fatal is the disease. The occurrence of pregnancy often leads to a rapid increase in the rate of growth. Astley Cooper states that the disease, on an average, is from two to three years in growing, and from six months to two years in destroying life after being fully formed. In this estimate, which is probably correct, Walshe agrees. Paget states that the average duration of life in cases in which the disease is allowed to run its course without operation is four years; but the statistics of Sibley and Von Winiwarter give a period of only from thirty-two to thirty-three months, and those of Gross about twenty-seven months. The average duration of life in cancer of the breast may therefore probably be estimated at about three years.

In the atrophying variety, as already stated, the duration of the disease may be very prolonged, and extend to ten or even twenty years; the average duration, according to Gross, being eighty-two months.

**Pathological Structure.**—After removal, scirrhus of the mamma presents considerable variety in appearance. In the majority of instances it occurs as a peculiarly hard, knobbed, and irregular mass, creaking under the knife, when cut, and presenting on section a greyish or bluish-grey, semi-transparent surface, traversed in various directions by bands of a more opaque character, and exuding on pressure a thin milky juice. The section has been very aptly compared to that of an unripe pear. In all slow-growing hard cancers the cut surface becomes distinctly concave, a peculiarity which distinguishes them from all other tumours. In many specimens spots and streaks of an opaque yellowish appearance may be seen in the midst of the tumour; they are the result of fatty degeneration. In other cases, again, on pressing the tumour, small drops of a thick creamy fluid will appear to exude at various points. This seems to be the inspissated and altered secretion of the gland retained in the ducts. Cysts are occasionally, though rarely, met with in scirrhus of the breast; these are usually small, and contain clear fluid, being deeply imbedded in the substance of the tumour; in other cases they may be large and globular, and filled with a bloody or dark-green liquid. The microscopical characters of scirrhus of the breast are represented in Figs. 389, 390, and 392, Vol. I., pp. 1065, 1066.

The examination of the surrounding tissues with the naked eye and

microscope frequently shows that they are infected widely beyond the limits of the actual tumour through the lymphatic channels. This subject has recently been carefully investigated by L. Heidenhain and by Harold Stiles of Edinburgh. Heidenhain has made the important observation that microscopic deposits of cancer cells can frequently be demonstrated in the lymphatics of the fascia covering the pectoral muscle, and in the fat which is present in varying amount between this fascia and the breast itself. Similarly, small masses of cancer cells can often be demonstrated in the lymphatics of the breast in parts which to the naked eye appear normal. The importance of these observations in connexion with the question of operation is obvious, and they will again be referred to later.

**Soft Glandular Carcinoma or Encephaloid.**—Formerly, when all soft sarcomata were classed as cancers, encephaloid of the breast was described as a disease of moderately frequent occurrence. Now that the term is strictly limited to the softer and more rapidly growing forms of glandular cancer the disease cannot be said to be common. No sharp line can be drawn between scirrhus and encephaloid; what one Surgeon would term a soft form of scirrhus another would class as encephaloid. Pathologically the difference between the two forms consists in the relative proportion of the stroma and cells. The greater the proportion of stroma, the harder the tumour. In the softer forms the cells are, as a rule, larger. (Fig. 392, Vol. I., p. 1067.) In rare instances the growth becomes extensively broken down by hæmorrhage, which takes place from vascular processes projecting from the stroma into the alveoli.

Soft glandular cancer usually begins deeply in the substance of the breast as a soft globular tumour, which rapidly increases in bulk and infiltrates the whole gland; the integuments covering it are not at first adherent, but are usually pushed before it, and speedily become permeated by a largely ramified network of veins. In some cases I have seen the integuments, early in the disease, œdematous and inflamed, so as to mask the subjacent tumour. The mass at first feels as if composed of several soft and rounded tumours, which may communicate an obscurely fluctuating sensation, perhaps causing the Surgeon to mistake the growth for a cystic formation or an abscess; with which it is especially apt to be confounded in those cases (rare, it is true), in which the skin is inflamed and œdematous. The breast now rapidly assumes a very prominent and conical form; the skin covering it at its most projecting part becomes thinned and reddened, and at last gives way, leaving a large circular ulcer, from which a fungous mass of greyish or reddish-brown colour speedily sprouts up, with a good deal of foul, bloody discharge. From this disintegrated masses are occasionally detached by sloughing. Implication of the glandular structures in the vicinity of the tumour, followed by cachexia, occurs in this as in scirrhus, but somewhat earlier. The progress of the disease is always extremely rapid, especially in patients below middle life and otherwise healthy; the average duration of life in untreated cases is less than one year.

**Colloid Carcinoma** of the breast is of very rare occurrence. Most commonly only a part of the tumour has undergone degeneration, the remainder presenting the ordinary appearances of soft or hard glandular cancer. In two typical cases of this disease I observed the peculiar feature that though the tumour had implicated the skin and formed a prominence

about an inch and a half in diameter and projecting nearly an inch above the surface, no deep ulceration had taken place, nor were the glands affected. A section of the breast showed, in the greater part of the tumour, a coarse alveolar structure, the alveoli being distended with colloid matter. The growing margin of the tumour presented the ordinary appearance of a rather soft scirrhus cancer, and between this and the colloid part every intermediate gradation was recognizable. The absence of contraction in a colloid cancer is shown by the absence of retraction of the nipple. When secondary deposits occur in the glands or elsewhere the deposits may exhibit the colloid change, or they may have the ordinary structure of glandular cancer. The duration of life in colloid cancer is longer than in any other form, the average, according to Gross, being 144 months in untreated cases.

**Columnar Carcinoma** may take its origin in the epithelium lining the lacteal ducts, and is generally known as **Duct Cancer** or **Villous Cancer**. Its structure was fully described by Cornil and Ranvier, and a considerable number of cases have been recorded in this country by Butlin, Bowlby, Robinson, and others.

From a consideration of the published cases of duct cancer it may be stated that the tumour is usually situated in the central part of the breast near the nipple, and is firm or elastic in consistence. The rate of growth is slow, and it is unattended with retraction of the nipple or adhesion to the skin. In some instances more than one growth has been met with in the same breast. A very frequent symptom is the occurrence of a blood-stained discharge from the nipple, which may be the first indication of the disease, and was present in five out of seven cases observed by Bowlby. The malignancy of the growth is low as compared with glandular carcinoma, and glandular infection is very rare. Local recurrence after removal has, however, been observed by Butlin, glandular infection by Godlee, and a secondary tumour in the ribs by Shattock. Of ten cases collected by Bowlby in which the age was mentioned, one occurred between 20 and 30, two between 30 and 40, two between 40 and 50, two between 50 and 60, and three between 60 and 70.

*Pathological Anatomy.*—The structure of villous cancer has been very fully described by Cornil and Ranvier. To the naked eye it may resemble encephaloid cancer, and its section yields an abundant milky juice, but it differs from ordinary cancer in presenting numerous small cysts, some only just visible to the naked eye, and others an eighth of an inch or even more in diameter. In some specimens these cysts are filled with blood. Microscopic examination shows it to be composed of a well-formed fibrous stroma, containing spaces lined with an epithelium tending to assume a columnar form. Delicate villous processes covered with epithelium project from this stroma into the spaces. These villi contain loops of capillary vessels which yield the blood so often found filling the spaces. It thus seems clear that the tumour may correctly be defined as a columnar carcinoma commencing in the epithelium of the ducts. The relation between duct cancer and duct papilloma (p. 780) is the same as that between papilloma and carcinoma of the rectum. The papilloma is a simple pedunculated tumour springing from the wall of a dilated duct and occupying its lumen; the duct cancer is no longer bounded by the duct wall, but invades the tissues around it. Clinically the two conditions are very similar, and it cannot be doubted that some cases described as duct cancers were in reality simple papillomata. In a case recently in University College

Hospital a typical duct cancer and a small duct papilloma were found in different parts of the same breast.

The *Treatment* of duct cancer consists in the excision of the whole breast, but considering the rarity of glandular infection in the cases hitherto observed, the routine removal of the contents of the axilla can hardly be required. In view of the close resemblance, both clinical and pathological, between duct cancer and certain simple intracystic papillomata, the tumour should be carefully examined through an exploratory incision before the Surgeon decides between removal of the affected lobule and excision of the whole breast.

**Causes of Cancer of the Breast.**—These are usually extremely obscure.

**Sex** is certainly the circumstance that has the most marked influence on the occurrence of mammary cancer, the disease being, as is well known, almost entirely confined to women; yet instances of this affection in the male breast occasionally occur. R. W. Williams found that of 1,879 cases of cancer of the breast only 16 were males. Its peculiar frequency in the female may possibly be connected with the sudden alternations of the functional activity of the breast. The changes impressed upon this organ at puberty and during pregnancy, the inflammatory affections to which it is subject during lactation, the frequent irritation to which it is exposed by sympathizing with uterine derangement, and the diminution in its vital activity that takes place at the menopause, are sufficient to explain the great liability of this organ to disease generally; and may not improbably give a clue to the reason why it is peculiarly the seat of cancer in women.

**Age.**—An analysis of 600 cases observed by Bryant gives the following result: 4 per cent. occurred before 30; 27 per cent. between 30 and 40; 36 per cent. between 40 and 50; 25 per cent. between 50 and 60; 7 per cent. between 60 and 70. Two cases only were over 70. These results correspond almost exactly with an analysis of 642 cases by Gross. The earliest case confirmed by microscopic examination is recorded by Henry of Breslau as occurring in a young woman aged 21. I have removed a scirrhus breast from an unmarried woman 23 years of age, and Bryant has seen it at 25, 26, and 28. In young subjects the tumour is apt to grow rapidly and to assume the form of encephaloid, but most of the recorded cases have been of the scirrhus variety. In elderly women also scirrhus is the prevalent form, though I have seen several instances of encephaloid at an advanced age.

**Social Condition.**—Bryant states that of the 600 cases observed by himself, 80 per cent. were or had been married; and Gross made the proportion 88 per cent. in his cases. According to the Registrar-General's returns, 84 per cent. of the women in London over 35 years of age are or have been married. It would seem probable, therefore, that cancer occurs proportionally with equal frequency in married and single women. Of the married women in Bryant's cases, no fewer than 26 per cent. were sterile; while Gross makes the proportion only 16 per cent. Both Bryant and Von Winiwarter observe that a large proportion of the prolific women had borne many children. The menstrual function is persistent at the time the disease appears in 70 per cent. according to Birkett, and 61 per cent. according to Gross.

**Injuries** inflicted upon the breast, such as blows, squeezes, &c., are commonly referred to, and are greatly dreaded by women, as the causes of cancer. That they might be so in constitutions otherwise predisposed to the affection does not appear improbable; and that they are so in reality in many cases, I

have not the least doubt. The number of instances that have fallen under my observation, in which a blow or squeeze of the breast has speedily been followed by the appearance of a cancerous tumour in it, leaves no doubt whatever in my mind of the truth of the popular belief that associates the injury with the disease, in the relation of cause and effect.

**Disease of the Nipple**, resembling eczema, has been described by Paget as an occasional precursor of cancer of the breast, and is commonly known as "*Paget's disease*." The disease begins with slight desquamation and discharge from the surface of the nipple or areola. When the condition is fully developed the affected area, which may include the whole areola or extend beyond it, is in most cases intensely red, raw, and granular, and there is an abundant yellowish discharge which forms scabs as it dries. It is accompanied by itching. In other cases the surface is dry and scaly. The outline of the patch is well defined, and its shape is more or less circular, with the nipple in the centre. Occasionally ulceration takes place by which the nipple may be destroyed. The disease differs from eczema in its intensely red colour, the sharply defined outline, the presence of slight induration, and the absence of vesicles and pustules. When cancer occurs it is usually situated immediately beneath the diseased nipple, but it may be more deeply situated.

The microscopic appearances of the diseased tissue were first described by Butlin, and his observations have been confirmed by others. Butlin found proliferation of the deeper layers of the epithelium, and small-cell infiltration of the corium of the areola, dilatation of the galactophorous ducts, with proliferation of the epithelium, sometimes completely choking them, and small-cell infiltration around the diseased ducts. Deeper down, the epithelium of the acini was seen to be proliferating, and finally to be invading the tissues around. With the exception of four specimens examined by Thin, which were described as duct-cancers, the form of cancer invariably met with has been the spheroidal-celled variety.

It has been suggested as a possible explanation of the relation between the condition of the skin and the cancer that the former is the result of irritating discharges from the ducts due to presence of the morbid growth. Apart from the absence of any evidence of such discharge, it may be pointed out that Paget's disease may exist independently of a tumour, and in many instances has been present for many years before the presence of a tumour was detected. It seems, therefore, almost certain that the affection of the nipple stands in some definite causal relation to the development of the cancer, probably by the production of proliferative epithelial changes in the ducts and acini.

Lastly, it must be mentioned that Darier and Wickham attribute the disease to the presence of psorosperms in the epithelium of the skin (Vol. I., p. 1056). Bowlby has examined a considerable number of specimens, and is also of opinion that the bodies seen in the cells are in all probability parasitic, but at present no actual proof of this view is forthcoming, and similar appearances have been ascribed by other observers to endogenous cell division (Vol. I., p. 1057).

The *Treatment* of this disease is very unsatisfactory. In the earliest stages, when the distinction from simple eczema may be doubtful, soothing applications, such as calamine lotion, should be used. When, however, the nature of the condition is certain, the case must be regarded as serious, and the

question of excision of the breast, even though no actual tumour be present, must be considered.

**Chronic indurations** in the breast following puerperal mastitis are generally regarded as sometimes being the starting-point of carcinoma. Actual proof of any real connexion between the two is necessarily difficult to obtain, but it is quite conceivable that the epithelial overgrowth sometimes present in chronic inflammatory conditions of the gland may favour the development of cancer. Among 365 cases of cancer of the breast occurring in women who had borne children, Gross found that "there was antecedent mastitis in 71, but in only 30 of these did an induration remain from which carcinoma originated."

The influence of **Heredity** and the **Geographical Distribution of the Disease** have already been sufficiently discussed in the chapter on cancer in general (Vol. I., pp. 1052 and 1057).

**DIAGNOSIS.**—No subject in connexion with diseases of the breast is of greater practical importance than the diagnosis of carcinoma, for upon the early recognition of the disease depends very largely the hope of cure by operation. The difficulties of the subject cannot be better exemplified than by the fact that after removal of the disease Surgeons of equal experience will differ as to its nature; and, indeed, in many of these cases nothing but microscopical examination will clear up the doubt. In advanced cases, where perhaps the tumour is invading the skin, and has become adherent to the deep structures, and the axillary glands are implicated, the diagnosis is as easy as the prognosis is grave. The Surgeon must endeavour to recognize the disease before any single characteristic sign of the malignancy of the growth has yet manifested itself, and when there is a fair prospect of completely eradicating the disease by operation. The different varieties of carcinoma differ so much in their clinical characters that no general rules can be laid down for their recognition, and it is necessary to consider the chief forms separately.

A **hard carcinoma** or **scirrhus** in its early stages,—that is to say, when there is no implication of skin, no retraction of the nipple, and no enlargement of the lymphatic glands—may resemble chronic induration of a lobule, a cyst, a chronic abscess, or a hard fibro-adenoma.

From *chronic interstitial mastitis* the distinction has already been considered at page 776. A small tense *cyst*, especially if deeply seated or surrounded by indurated breast tissue, may closely resemble an early stage of scirrhus. The points of distinction have been considered at page 784, the most important being that the softest part of a tense cyst is the centre, and of a scirrhus the periphery. The diagnosis from *chronic abscess* has been discussed at page 777, and from *fibro-adenoma* at page 790.

The diagnosis from fibro-adenoma is rarely so difficult as from the other conditions, because it is generally easy to make out that the tumour is distinctly circumscribed, and has a certain amount of mobility independently of the breast itself. In all cases the age of the patient, the rapidity of growth of the tumour, and the presence or absence of spontaneous pain or tenderness on examination, must be taken into account. Such evidence may be useful, but the cases of real difficulty are just those in which, as often happens, none of these points is opposed to or supports any particular diagnosis. It cannot be too strongly insisted that no affection of the breast is more often painless than cancer in its early stages.

When in doubt the Surgeon should not hesitate to lay the state of the case before the patient, and strongly urge the necessity of making an exploratory incision. Consent should, if possible, be obtained to remove the whole breast if the doubtful tumour prove malignant. An incision is far more useful than a simple puncture, and the only one of the four conditions which may possibly not be distinguished with certainty in this way is chronic interstitial mastitis. If this be so, a small slice should be excised, and only a few minutes will be necessary, if the materials be at hand, to cut a section with a freezing microtome and examine it under the microscope.

A **soft glandular carcinoma** or **encephaloid** must, if possible, be distinguished from a soft fibro-adenoma (adeno-sarcoma) and from a sarcoma. The *soft fibro-adenoma* differs essentially in its perfectly circumscribed outline, and often the history shows that the tumour has somewhat rapidly developed from a smaller and harder one, perhaps of several years' duration. The distinction between soft carcinoma and *sarcoma* may be impossible until a microscopic examination has been made, and from the point of view of the treatment is of no great moment, as in either case excision of the whole breast is required. The sarcoma is more clearly defined than the carcinoma; it implicates the skin less early, and is not associated with glandular enlargement. Although the nipple is not retracted in cases of soft carcinoma, yet it is sometimes buried by the projection of the tumour around it. In some instances in which a soft carcinoma is of unusually rapid growth, and the skin at an early stage is red and oedematous, the resemblance to an *abscess* may be close.

The diagnosis between *cystic sarcoma* and some forms of *cystic carcinoma* of the breast is not always easy, and may be impossible without microscopic examination. In a case under my care, a woman fifty-nine years of age, a hard tumour, as large as half an orange, had existed in the breast for five years. It was freely movable, unconnected in any way with the skin, and there was no retraction of the nipple. On its upper side several large cysts could be felt, and seen through the skin. On examination after removal, it was found to be a cystic scirrhus, with large cysts of the size of cherries, containing bloody and yellow fluid. The only very suspicious circumstances here were the age of the patient, and the existence of one small indurated gland in the axilla.

The true nature of a carcinoma of the breast which has ulcerated through the skin is usually easily recognized; the deep foul ulcer, the infiltrated condition of the surrounding skin, and, in almost all cases, the presence of enlarged glands, producing a very characteristic appearance. A sarcoma projecting through the skin forms a prominent vascular mass, with usually little invasion of the skin around and no glandular enlargement. As a rule no difficulty will be met with in recognizing the nature of a case in which an intracystic growth in a cysto-adenoma or in a cyst of the breast has burst through the overlying skin.

**TREATMENT.**—In the consideration of the important subject of the treatment of cancer of the breast the only method which needs our attention here is removal of the disease by the knife. The palliative measures which may be adopted in cases unfit for operative interference have already been considered in Vol. I., pp. 1077 *et seq.*, and in the same place mention has been made of the treatment by compression, which was at one time recommended. It has there been pointed out that cases of supposed cancer of the breast cured by compression were probably in reality simple inflammatory indurations, the

close resemblance of which to the early stages of carcinoma has several times been insisted upon. The destruction of the growth by caustics needs mention only that it may be condemned. In a case which can be treated by excision of the growth the use of caustics is altogether unjustifiable, and cases unfit for operation are far better let alone.

**Operation for Carcinoma of the Breast.**—In the consideration of this important subject, the questions which present themselves to the Surgeon are : 1. The selection of cases for operation ; 2. The objects aimed at ; 3. The extent and performance of the operation ; and 4. The results.

**Selection of Cases.**—Nothing can be more unsurgical than the indiscriminate removal of cancerous tumours of the breast from all patients who may present themselves, in whatever stage of the disease. The question as to the advisability of operation in any given case of cancer of the breast cannot be determined by abstract pathological reasoning, by reference to scientific principles, or by calculations founded on statistical results. Whatever the value of statistics may be in determining the question whether in cases of cancer of the breast generally the operation will effect a cure or prolong life, they are not equally valuable in their application to individual cases. When a Surgeon is called on for his opinion respecting the propriety of amputating the breast of the patient before him, it is not sufficient for him to be able to state what the general result of the operation may be, but he must be able to satisfy himself whether the particular instance under consideration may or may not be one of those cases in which there is a possibility of extirpating the disease entirely from the system, or at all events of prolonging the patient's existence. In order to do this, it is necessary to endeavour to lay down some rules that may guide us in selecting those cases in which the operation may be advantageously done, and in setting aside others in which we know that it will almost to a certainty hasten the patient's death. And, indeed, it is the absence of all such considerations in general statistical investigations into the results of operation for cancer, that deprives them of their value as guides in actual practice.

With reference to operation, cancerous diseases of the breast may be divided into three classes :—1. Those in which it is the duty of the Surgeon to recommend operation ; 2. Those in which it is the duty of the Surgeon to discountenance it ; and 3. Those in which the operation is of doubtful expediency.

**1. Cases favourable for Operation.**—Those cases of carcinoma of the breast are most favourable for operation in which the disease is recognized in its early stage when it is apparently limited to the mamma, unconnected with the skin or deep structures, and not associated with glandular infection ; and in which the patient is middle-aged, not too fat, and free from any constitutional condition which renders operations of any kind inadvisable. The small nodular scirrhus, and the atrophying and colloid varieties, are more hopeful than the infiltrating scirrhus or the encephaloid variety.

**2. Cases unfit for Operation.**—This class includes cases presenting the following conditions : *a.* Strongly marked constitutional cachexia ; *b.* Secondary deposits in internal organs ; *c.* Enlargement of the glands above the clavicle ; *d.* Edema of the hand and arm from pressure on the axillary vein ; *e.* Adhesion of the tumour to the ribs and intercostal muscles ; *f.* Widespread infiltration of skin ; *g.* An extensively ulcerated and fungating tumour, with marked constitutional cachexia.

**3. Doubtful Cases.**—This class includes a large proportion of cases in which the disease has already advanced beyond the first stage, or in which the general condition of the patient is in some respect unfavourable to operation, although not sufficiently altogether to contraindicate it. *a.* If the tumour be adherent to the skin, and possibly slightly fixed to the pectoral muscle, and if there be but moderate enlargement of axillary glands, which are so situated as to admit of removal, the operation may be performed. *b.* When the tumour has ulcerated operation may still be undertaken if the other conditions are favourable, and the extent of the implication of the skin does not render complete removal impossible. *c.* An atrophic scirrhus of long standing, and presenting the characters described at p. 797, had better be left alone, for experience has shown that operation is soon followed by recurrence, and shortens rather than prolongs life. In its early stages this form of the disease should be removed, for it is impossible to predict a chronic course with any certainty. *d.* A rapidly growing tumour in a young patient with a strong hereditary taint should be removed, but the chance of speedy recurrence is great. *e.* Affection of both breasts is very rare, and will usually be a contra-indication to operation. If, however, the general condition of the patient is favourable, and the disease on each side seems suitable for operation, removal of both breasts may be practised either simultaneously or with an interval between the two operations. *f.* If the patient be aged, weak, anæmic, or very fat, and the tumour large, it is seldom expedient to operate, as the shock may prove fatal. As a general rule, I do not think it advisable to operate after seventy years of age, unless the distress from pain or the discomfort from ulceration is so great as to render removal at any risk justifiable. The progress of cancer in advanced age is often so slow that it is doubtful whether the expectancy of life is materially increased by operation. It must, however, be allowed that absolute rules as to age are of little practical value, for in excision of the breast, as in other operations, the general condition of the patient rather than the age in years must influence the Surgeon in his decision. *g.* Pregnancy is not a bar to the performance of any necessary operation, even of amputation of the breast. In pregnant women cancer of the breast becomes very active, hence its removal should not be delayed, if all other circumstances are favourable.

**Objects of Operation.**—The objects proposed are, in the first place, to prevent constitutional infection by the removal of the local disease, and thus permanently to free the patient from an otherwise necessarily fatal affection; or failing this, to retard the progress of the constitutional infection, and thus, at least, to prolong life.

In connexion with the question of the possibility of permanent cure, it must be pointed out that all old statistics are valueless, because many cases of sarcoma and inflammatory induration were mistaken for carcinoma, and because, until recently, most Surgeons contented themselves with the removal of the mamma, leaving the axillary glands untouched unless they were obviously affected. In speaking of the cure of cancer of the breast it must be remembered that at no period, however long after the operation, can the patient be pronounced absolutely free from risk of recurrence. It has, however, been found that if three years have elapsed, the chance of subsequent recurrence is relatively so small that for statistical purposes cases which have passed this limit without a return of the disease are classed as "cured." Of 455 cases

collected by Gross, in which the patients were traced after the operation, 47, or about 10 per cent., had passed the period of three years, and Butlin, from an analysis of 311 cases, came to a very similar conclusion.

In recent years the chance of cure has undoubtedly been considerably increased, as the result of the more extensive removal of the affected parts practised by Lister, Banks, Billroth, Küster, Volkmann, Gross, and many other Surgeons. Thus Banks has published the records of 46 cases, ten of whom were alive and free from recurrence at periods varying from two to ten years after the operation, and in five more no recurrence had taken place from one to two years after the operation. Küster states, that in 26 per cent. of the patients operated on by him, no recurrence had taken place three years after the removal of the breast. Billroth had under observation 13 cases, in which no recurrence had taken place within two years of the operation, 5 of which had remained free for four years and upwards, and 4 more for more than three years. Further statistics alone can show in what proportion of cases freedom from recurrence may be expected after operations performed on the lines presently to be indicated. In such records it is very essential that the cases should be arranged according to the stage of the disease at the time of operation.

The second reason for recommending operation in suitable cases of carcinoma of the breast is, that life may be prolonged even if permanent freedom from the disease be not obtained. Among the most trustworthy statistics that we possess on the relative duration of life in cancer of the breast, with or without operation, are those of Paget, Marrant Baker, and Sibley; but even these probably include some cases of sarcoma under the name of encephaloid cancer. Paget states that, of 113 cases, 66 were not submitted to operation; of these the average duration of life was a little more than 48 months. Of 47 operated on, the corresponding average was also a little more than 49 months. In the first two years of the disease the proportion of deaths was much smaller in those operated on than in those who were left—being in the former 24 per cent., in the latter 36 per cent. The longest duration of life in cases not operated on was 18 years; in those operated on, a little more than 12 years. Marrant Baker found that in 84 cases in which no operation was performed, the average duration of life was 43 months; in 62 cases operated on, the average was 56½ months. Sibley found that the average duration of life in cases not operated on was about 32 months; whilst in those subjected to amputation of the breast it reached 54 months. Gross found that in scirrhus the average duration of life in untreated cases was 27 months, and in those operated upon 39 months; whilst Roger Williams, founding his conclusions on cases in the Middlesex Hospital, gives 44·8 months and 60·8 months respectively.

Thus, it appears that, independently of the chances of a complete cure, the operation holds out the prospect of a gain of between a year and a year and a half, but on this point also further statistics are required.

There is, however, another point of view from which these operations may be considered; for, even if they do not prolong life, they may greatly improve the patient's condition. Thus, she may be suffering so much pain from the local affection, or, if the cancer be ulcerated, may be so much annoyed by the fœtor of the discharges, that she may be placed in a position of far greater comfort by having the local disease removed; and though she die eventually

of cachexia with secondary growths in the lungs or liver, it will be with much less suffering than if she were worn out by the pain, discharge, and hæmorrhages of a slowly progressive ulcerating cancer.

**Extent of Operation.**—No fact in connexion with the operative treatment of carcinoma of the breast seems more certain than that in any given case the chance of cure depends upon the freedom with which the tumour and the surrounding tissues are removed. It may be laid down as a general rule that in all cases *the whole breast should be removed*. When the tumour is large and central this is obviously necessary, but when a small tumour is situated at the extreme periphery of a large and apparently healthy mamma, the Surgeon may be tempted to remove only the tumour with a free margin of tissue around it. Such cases should, however, prove no exception to the rule, which is strongly supported by clinical experience and pathological observations. Reference has already been made to the fact that even in the case of small peripheral tumours masses of cancer-cells can sometimes be demonstrated in the lymphatics of distant parts of the breast (p. 798). Heidenhain has further shown, and his observations have been in the main confirmed by C. F. Beadles and Raymond Johnson, that a condition of epithelial proliferation is not uncommon in parts of the breast which to the naked eye appear normal. The exact relation of these changes to the presence of the carcinoma is doubtful, but their existence strongly supports the complete removal of the whole gland in all cases.

Secondly, *the skin over the breast should be freely removed*. This is very advisable, especially in thin subjects, on account of the impossibility of reflecting the skin from the surface of the breast without leaving fragments of the latter attached to it. This free removal of skin should not be confined to those cases in which the tumour is adherent to it; in them, however, it is especially necessary.

Thirdly, *the fascia covering the pectoralis major should be completely removed*, on account of the frequency with which secondary deposits are found in this situation (p. 798). If the fascia is thin it is better to remove the superficial fibres of the muscle with it.

Lastly, *the axillary glands and the lymphatics passing to them from the breast should be removed* as a routine measure, even though no evidence of glandular disease be discoverable before the operation. This necessarily adds to the length and severity of the operation; but at the present day the mortality following the complete operation is very low. The cases in which this rule should be departed from are few, and include those in which, after the removal of the breast itself, the patient's condition forbids further prolongation of the operation, and those cases of extensive disease, in which the breast is excised mainly to rid the patient of a constant source of suffering and annoyance. The failure to detect enlarged glands by examination is no proof of their absence, and for this reason alone it is useless to reserve opening the axilla for those cases in which the glands can be felt.

**Excision of the Breast.**—The question of excision of the breast should always be raised with more than ordinary regard to the feelings of the patient. A woman looks upon her breast as alike the emblem and the ornament of her womanhood. She shrinks from the idea of its being affected by disease. She suffers acutely in mind when it is invaded by tumour of any kind: the horrid dread of that disease being cancer ever haunts her thoughts, not so much from the fear of the possibly impending operation, as from the distress of mind, in

many cases amounting to a sense of humiliation, at the idea of the mutilation of which she is about to become the victim.

The preparation for the operation should consist in shaving the axilla, thoroughly washing the whole breast, side, and axilla with 1 in 20 carbolic lotion, and applying a wet carbolized towel to the part for some hours previously.

The patient should lie upon a table of convenient height, and the arm must be raised and secured with a bandage or held by an assistant (Fig. 787). The direction of the incision must be made to vary according to the situation and size of the tumour and the amount of integument which requires removal. In all cases the nipple should be included. The method most commonly employed consists in making two curved incisions in the line of the pectoral fibres, including between them a broad elliptical piece of the skin covering the breast. The flaps are raised with a thin layer of subcutaneous fat, and the dissection continued until the pectoral muscle is everywhere exposed around the edge of the breast. Bleeding vessels are at once seized by an

Fig. 787.—Position of Patient in Amputation of Breast.

assistant with forcipressure forceps, of which there should be a free supply. The flaps being held aside by the assistant, the breast is detached, with the cellular bed in which it lies, by carrying the knife along the pectoral muscle in the direction of its fibres so as to leave its surface quite free from the fascia which covers it. The breast is thus left attached only at the upper angle of the wound by a thick mass of fat, which contains the lymphatics passing to the axilla. After all bleeding has been thoroughly arrested by ligature or torsion, the wound is covered with a large "guard," and an incision carried from its upper angle to the arm. Through this the fat and glands of the axilla are completely removed.

The edge of the pectoralis major may be cleaned with the scalpel, care being taken to expose and clean the lower part of the pectoralis minor also, as a few glands often lie concealed between the two muscles, and may easily be overlooked. In doing this the external mammary artery will be divided. The contents of the axilla are then turned carefully over to the posterior side of the space. In the lower part this may safely be done with the edge of the knife, but at the upper part the handle of the scalpel and the fingers should be used, and any bands which are met with, and appear to contain vessels, should be

isolated, and a ligature passed round them, after which they may be divided with scissors. By thus working carefully at the upper part of the axilla, the fat and the glands contained in it may be safely separated from the great vessels, which are left exposed often for one or two inches. Finally, the whole mass is drawn downwards, and separated from the posterior border of the axilla so that it is completely removed together with the breast, care being taken not to wound the subscapular artery and vein to which the enlarged glands are sometimes adherent. Should it be necessary to divide these vessels, they must not be cut too close to the main trunks. The complete extirpation of the axillary glands is the most difficult part of the operation, but by careful dissection it can be safely accomplished. If the enlarged glands that are readily perceptible are alone removed without the fat surrounding them, a number of smaller glands are sure to be left behind. Wound of the axillary vein is the most likely accident to occur in removing glands seated high up. It usually arises from tearing through some small branch just as it enters the main trunk. If the opening be very small, it is easily secured by pinching it up, and applying a ligature round it without occluding the whole vein. Should the wound be more extensive, the whole vein should be tied. Billroth states that he has had occasion to do this more than once, and that no evil consequences followed, rarely even œdema of the arm. The safety of the patient depends very much, however, on the successful prevention of decomposition in the wound. Should the injured vessel be bathed in decomposing discharges, the patient would be exposed to the imminent danger of septic thrombosis and pyæmia, which formerly made Surgeons hesitate to apply a ligature to a vein. Entry of air into the vein is a danger which must be borne in mind while removing glands in close proximity to it. It is best avoided by careful dissection, but should the vein be unavoidably in danger, an assistant should place his finger on it, if possible, on the cardiac side of the exposed part. Wound of the artery is much less common. It is most likely to occur from shaving the subscapular branch away so closely as to leave a circular aperture in the side of the main trunk. It can only be avoided by not using sharp instruments in this region. Should it happen, the main trunk must be tied on each side of the wound.

Instead of the incisions described above, a very convenient method is represented in Fig. 787. The curved incisions are disposed transversely instead of obliquely, and the axilla is opened by drawing the skin over it well forward, and making an incision from near the outer end of the wound along the anterior border of the axilla. This incision lies over the middle of the space when the traction on the skin is removed, and by turning the small flaps backwards and forwards a very free exposure of the axilla is obtained (Fig. 788).

In all cases the parts removed must be carefully examined in order to make certain that the incisions are very wide of the disease, and that the whole breast has been removed. For this purpose the nitric acid test introduced by Stiles, of Edinburgh, will be found useful. This depends upon the fact that the acid renders any fragments of new growth or breast tissue of an opaque white colour, and thus easily discernible. "The breast immediately after its removal is placed (after washing off all the blood), in from one to two pints of a five per cent. nitric acid solution for about ten minutes; and then washed in running water for three or four minutes. By this means the characteristic reaction is produced upon the surface, so that outlying portions

of breast tissue, portions of the carcinoma itself, or small locally disseminated cancerous foci can, if here present, readily be detected. The examination can easily be completed before the time arrives for suturing the wound." A further removal of tissue should be made in any suspicious situations. When it is found that the tumour is adherent to or invading the pectoral muscle, a free removal of the latter may be required.

The *dressing* of the wound is of great consequence. All bleeding must be very carefully arrested, and provision for drainage should be made. If the oblique incisions have been used a short tube may be introduced through a puncture in the skin of the lower flap; if transverse incisions have been made the tube should be placed in the outer angle of the wound. The skin is now relaxed by bringing the arm to the side, and the edges of the wound supported with several stout sutures of silver wire or silkworm gut, and adjusted with interrupted sutures of horsehair or silk, or a continuous suture of fine silk. If there is much strain on the skin, one or two deep button-sutures of thick silver wire may be used. If in any part approximation of the

Fig. 755.—Incisions required for thoroughly clearing Axilla.

edges is found impossible, the exposed surface may be left to granulate, or it may be covered at once by skin grafts (Vol. I., p. 278). A large dressing of antiseptic gauze and wool, or wool only, should be applied; the inner part of the dressing reaching well up into the axilla, and the outer sheet of wool enveloping the shoulder and upper limb, which lies with the arm by the side, and the elbow flexed to a right angle. The whole is firmly secured by a bandage. The dressing may be left undisturbed for a week, unless there is a rise of temperature, or pain is complained of, or any discharge soaks through.

At the first dressing the drainage tube and the deep sutures can usually be removed, the superficial stitches being left until about the tenth day. Primary union usually occurs throughout the whole wound, and apart from the occurrence of suppuration, it is only likely to be interfered with by an accumulation of blood in the axilla or beneath the flaps, or by sloughing of the edges of the skin in places.

**Results.**—The questions of permanent cure and of prolongation of life have already been discussed at p. 805, *et seq.*

• The mortality from excision of the breast for carcinoma was never very

considerable, and notwithstanding the more extensive character of the operations now performed, the death-rate at the present time is very low. The removal of the fat and glands from the axilla necessarily adds to the severity of the operation, but of the three risks—hæmorrhage, entrance of air into a vein, and deep cellulitis—the two first are extremely rare, and the last is almost certainly preventible if the axilla is thoroughly cleaned out, proper drainage provided, and strict asepsis maintained. Erysipelas and septicæmia have almost been abolished from the causes of death after excision of the breast. The danger of the operation increases in proportion as the patient's general health has become undermined by the continuance of the malignant disease. Women who have small mammæ with little fat bear the operation better than those with large breasts, in whom the areolar tissue is loaded with soft yellow fat.

The older statistics concerning the mortality of the operation cannot be applied to the present day. From 16 and 20 per cent. the death-rate has been reduced to 5 per cent. and less. At University College Hospital, during the years 1881 and 1890 inclusive, the breast alone was excised in 34 cases without a death, and of 117 cases in which the axillary glands were simultaneously removed, 13, or 11·1 per cent., died, by far the larger number being in the first half of that period. In the four years 1891 to 1894, 76 operations were performed, in almost all of which the axilla was cleared, with 5 deaths, giving a mortality of 6·5 per cent. Many long series of cases without a death have been recorded by different Surgeons, and at the present day the complete operation cannot be condemned on the ground of increased mortality.

There are two dangers which attend excision of the breast rather more frequently than other operations: viz., 1st, a congestive form of pneumonia, not dependent on any blood-poisoning, but arising from defective aëration occasioned by the breathing being shallow and restrained either by tight bandaging of the chest, or by the pain induced by the movement of the chest-walls in respiration; and 2nd, cardiac thrombosis extending into the pulmonary artery. I have known several instances of death from each of these causes. The first danger can obviously be guarded against; the second cannot.

The operation, especially when portions of the pectoral muscles are removed, is usually followed by some impairment in the use of the limb, which can rarely be raised above the horizontal position. Neuralgic pains in the arm and slight œdema of the hand are occasionally met with.

**Recurrence of the Disease after Operation** may take place in three situations: in the mammary region; in the neighbouring lymphatic glands; or in some internal organ or distant part. Local recurrence is doubtless due, in the majority of cases, to the presence of cancer-cells in the lymphatics which escaped removal at the time of the operation. It is, however, possible that in some instances the return of the disease takes place in fragments of breast-tissue which were already in process of development into cancer when the breast was incompletely removed. The recurrent growth may occur in the scar, in the surrounding skin, or in the deeper structures, and in cases in which primary union fails it may spring up in the granulating surface. When the cicatrix itself is affected it assumes a dusky-red or purplish tinge, becoming hard, stony, and nodulated at points; these nodules being round or

oval, often very numerous, and varying in size from a pin's head to a pigeon's egg, studding the whole length of the cicatrix, and at last running into ulceration. Nodules in the skin may form very slowly, or they may rapidly coalesce and form an extensive ulcerated mass adherent to the chest-wall.

Recurrence in axillary glands may be secondary to recurrent growths in the mammary region, or it may arise independently of these even after long intervals. The time at which recurrence takes place varies greatly, but it has already been pointed out that in the majority of cases it occurs within three years of the operation.

Operation may, in favourable cases, be undertaken for recurrent growths, whether in the chest or in the glands. The prognosis is much more favourable in cases in which a long period has elapsed since the primary operation. In many cases the rapid spread of the disease forbids repeated attempts to remove it, but in some cases numerous isolated deposits may be successively excised and a permanent cure obtained.

**Axillo-mammary Carcinoma** presents some peculiarities that deserve special consideration. It develops at the outer and upper border of the mammary gland, so that, instead of growing into its substance, it tends to push in the direction of least resistance, and thus to extend into the areolar space at the lower border of the axillary edge of the pectoralis major, and lie between it and the latissimus dorsi muscle. The tumour is hard and nodulated, and rounded in shape. Sometimes it appears to be scarcely attached to the breast. But on closer manipulation it will be found to extend deeply into its substance, which towards the base of the tumour feels hard and thickened. The greater portion of the gland, the median half and much of the lower part, will continue long unaffected by cancerous infiltration. The nipple is not retracted until a very late period in this form of the disease. It and the areola preserve their normal appearance long after the skin above them has become involved and the axillary glands enlarged. The manner in which the skin is implicated and the appearance it presents are peculiar and characteristic. It becomes involved early by dimpling from below in a transverse direction at the upper and outer border of the mamma, where there is naturally a tendency to a fold in the integument. There the skin becomes infiltrated in a transverse line of hard scirrhus, red, depressed, and puckered in, with much feeling of constriction and difficulty in raising the arm from the side. The disease, when once it has reached this stage, will, of course, make rapid progress, both locally and constitutionally.

That these axillo-mammary cancers arise primarily in the breast gland there can be no doubt, although their rapid development beyond its limits may, at first, lead to the suspicion that they have commenced outside it.

It is only towards the upper and outer border of the mamma that these out-growing cancers seem to develop. I have never seen them at the inner or lower part of the gland, unless the whole of its structure had previously been infiltrated. The operation in these cases should be complete and thorough, the whole organ being removed, however healthy the nipple, areola, and some portions of its gland-structure may appear to be. The skin also should be widely removed where implicated, and the dissection carried as high into the axilla as can safely be done. Unless thorough extirpation be practised, speedy and rapid recurrence will ensue.<sup>3</sup>

## DISEASES OF THE MALE BREAST.

The **Male Breast**, though rarely the seat of disease, may occasionally become affected in a somewhat similar manner to the mammary gland of the female. Cases have been recorded in which it was *hypertrophied*, and in others it has been the seat of an *abnormal secretion of milk*. In boys about the age of puberty it occasionally becomes the seat of *subacute inflammation*, often attributed to a blow. This is best treated by the application of a belladonna plaster spread on soft leather with a hole cut through it for the nipple.

Fig. 789.—Scirrhus Cancer of the Male Breast.

*Chronic interstitial inflammation*, with enlargement and induration of the rudimentary mamma, is occasionally met with, and if a source of much annoyance, may justify the removal of the diseased gland. *Cysts and sarcomata* are more rare. *Scirrhus carcinoma* is occasionally met with. The accompanying drawing (Fig. 789) represents a case of this kind under the care of C. Heath. Of 100 cases of carcinoma of the male breast collected by Roger Williams the mean age was 50. In 91 the cancer was glandular, in 6 of the duct variety, and in 3 squamous. These growths require removal by the same kind of procedure that is adopted when they affect the female breast.

## AXILLARY TUMOURS.

**TUBERCULOUS DISEASE** of the axillary glands is occasionally met with, forming a large lobed mass under the pectoral muscle. Such a tumour may be safely enucleated, and should be removed if it have resisted all ordinary topical and constitutional treatment.

SIMPLE TUMOURS of various kinds are met with in the axilla. The most common are lymphadenoma of the axillary glands, fatty, and fibrous tumour.

**Lymphadenoma of the Axillary Glands** is met with chiefly in young

Fig. 790.—Fibrous Tumour in Axilla of a Woman.

Fig. 791.—Same Tumour, Front View.

women, forming a smooth, lobed mass, often reaching a great size. It is usually associated with similar tumours elsewhere, but occasionally the glands

Fig. 792.—Sarcoma in Axilla of a Man.

of the axilla are alone affected. The enlarged glands form no attachment to surrounding parts, and may be readily removed by enucleation.

**Fibromata** are sometimes met with in this region, and may attain great size. A fibroma forms a large, smooth, rounded mass, stretching the muscles and displacing the vessels and nerves, as in Figs. 790 and 791.

this case the tumour, which was of very slow growth, developed between the serratus and the ribs, stretching the muscle over it so as to form a species of capsule to it, drawing the scapula forwards, depressing the chest-wall, and drawing the axillary vessels down to about three inches below the clavicle. In removing it I was obliged to take away a piece of the stretched serratus as large as the hand. The patient made an excellent recovery, and experienced no difficulty in breathing afterwards.

SARCOMATA of various kinds are met with in the axilla (Figs. 792, 793).

Fig. 793.—Large Sarcoma in Axilla of a Man.

Such tumours might, in their early stages, be dissected out; but if they extend high up to the clavicle, or implicate the skin widely by infiltration, they should, I think, be left, as was necessary in the patient from whom Fig. 793 was taken, where the size of the tumour and its connexions precluded the possibility of operation. Their removal cannot, indeed, at any stage, be undertaken without much danger. In dissections requisite for the extirpation of such masses, as in Fig. 792, I have had to expose the axillary and sub-scapular vessels and their accompanying nerves. The growth being usually somewhat widely disseminated, it is difficult to be certain that the whole is fairly extirpated: hence, recurrence is likely speedily to take place.

## DISEASES OF THE ABDOMEN.

## CHAPTER LX.

## HERNIA.

IN no department of Surgery has there been a greater advance during recent years than in the **Operative Treatment of Diseases of the Abdominal and Pelvic Viscera**. A wound of the peritoneum, whether accidental or intentional, was once regarded as being inevitably accompanied by grave danger to life. The perfection of the operation of ovariectomy, with which the name of Spencer Wells must ever be inseparably associated, led to a more thorough understanding of the causes of death, and established the principles which alone can guide us to success in operative procedures affecting the peritoneal cavity. The systematic use of antiseptics further put at our command the best means of preventing the most common and most fatal complications of peritoneal wounds, so that at the present time operations on the abdominal viscera are undertaken with little more hesitation, and are attended with as good results, as those of equal magnitude in any other part of the body. Before proceeding to the description of the surgical diseases of the abdomen and their treatment, it will be well to consider briefly the special dangers common to all abdominal operations, and the principles which guide us in avoiding them.

Operations on the abdominal cavity, with wound of the peritoneum, should they prove fatal, usually do so from one of three causes—septic peritonitis and septicæmia, shock, or hæmorrhage.

**Septic or Diffuse Peritonitis and Septicæmia.**—These conditions are so closely associated that it is most convenient to consider them together. Until recently the peritoneum was believed to possess some peculiar tendency to inflammation which rendered a wound of it specially dangerous; the inflammation spreading, as was said, by continuity of tissue. There is nothing to justify such an assumption. The peritoneum becomes inflamed under the same conditions as other tissues, the process is the same, and, as in other parts, it is limited to the area upon which the cause is acting. In the prevention of peritonitis it is necessary, therefore, to consider the causes to which it is due, with the view of excluding them, if possible.

Certain causes of inflammation, as pointed out in the chapter on the Process of Inflammation (Vol. I.) are, from their nature, limited in action. To these belong mechanical injuries, heat and cold, and the action of these chemical substances which cannot increase in quantity in the living body, such as mineral acids, saline caustics, and the like. A wound of the peritoneum, therefore, gives rise to inflammation limited to the area injured, and unless some other cause be introduced it has no tendency to spread farther. In inflammation of the peritoneum, as in all other membranes lining cavities,

the inflammatory products find their way readily to the surface. If the process be of sufficient intensity an abundant coagulable exudation takes place; the fibrin entangling white corpuscles forms a layer of "lymph" on the inflamed surface, and the serum drains away into the peritoneal cavity. The peritoneum from its intimate connexion with the lymphatic system is possessed of the power of absorption in the highest degree. The serum poured out at the seat of inflammation is therefore absorbed with great rapidity by the healthy part of the membrane, and unless the quantity be very considerable the cavity is kept dry. The experiments by which this extraordinary absorbing power of the peritoneum has been demonstrated have already been alluded to (Vol. I., p. 890). The coagulable exudation which covers the inflamed surface glues it to any contiguous layer of peritoneum, and adhesions are thus formed which subsequently become vascularized and undergo development into connective tissue by processes identical to those occurring in the formation of fibrous tissue in the union of a wound. It is by this process that adhesions form between inflamed coils of intestine, and that ligatures, sutures, and other simple foreign bodies become buried and encapsuled. It forms an essential part of the union of all wounds of the peritoneum, and is often the means of saving the patient's life by preventing perforation of the hollow viscera, or the rupture of collections of pus into the cavity of the abdomen. It is the object of the Surgeon to exclude all those sources of irritation which can convert this simple localized inflammation into a diffuse or spreading process.

The causes of spreading inflammations, as already pointed out (Vol. I., p. 176), are the chemical products of fermentative processes taking place in the normal fluids of the body, or in inflammatory exudations or other collections of fluid. For the development of septic processes in the peritoneum two conditions are necessary: first, the presence of the putrescible matter, and secondly, the contact with it of organisms capable of setting up fermentative or putrefactive changes. The putrescible matter is furnished by the liquid part of the inflammatory exudation, or by extravasated blood. The organisms may reach it either from the external wound, carried in by the Surgeon's hands, the sponges, the ligatures, or by the air; or in those cases in which the gut is injured, as in strangulated hernia, they may find their way from the interior of the intestine through the damaged coats. When infection occurs from without, the organism which appears to be most commonly met with is the *streptococcus pyogenes*, although other pyogenic organisms may be present. In cases in which the peritoneum is invaded from the bowel the organism which is almost invariably present is the **bacterium coli commune**. This rod-shaped organism which was first described by Escherich in 1885, abounds in the intestine, especially in the colon and duodenum. The organism is found in many different varieties, and appears to vary much in virulence according to the healthy or diseased condition of the bowel. It may reach the cavity of the peritoneum through a perforation of the bowel, or through a gangrenous patch, and independently of these it can pass through the wall of the bowel when the latter is damaged to an extent sufficiently to impair its normal vitality. Although it is possible that a simple chemical irritant may cause peritonitis it seems far more probable that it acts merely by sufficiently damaging the coats of the bowel to allow the escape of micro-organisms from its interior.

If the amount of the inflammatory exudation be comparatively small, it is so rapidly absorbed by the healthy part of the peritoneum that no decomposition takes place, the first essential condition being absent. If the amount of exudation be in excess of that which can be at once absorbed, an accumulation takes place, which, if the cause of putrefaction have been admitted to it, speedily decomposes.

The irritating products of decomposition become widely diffused, exciting inflammation wherever they go, and thus the whole peritoneum becomes affected. At the same time there is intense poisoning from the absorption of the chemical products of the process. In fact, in a large proportion of cases, this is the immediate cause of death, and may prove fatal before the local signs of peritonitis become very marked. The symptoms are those of acute septic poisoning, already described (Vol. I., p. 971).

It does not always happen that diffuse peritonitis occurs when the opening in the membrane communicates with a foul wound. Thus congested omentum in the operation for strangulated hernia was formerly ligatured with a piece of whipcord, the mass being cut off and the stump and ligature left lying in an open wound to which a poultice was applied. Under these circumstances septic suppuration necessarily occurred, but diffuse peritonitis by no means always followed. In those cases there was a free exit for the discharge from the wound and the opening into the peritoneal cavity became sealed by firm inflammatory exudation in the first few hours before decomposition commenced in the discharges, and thus the danger was averted. This is, however, an uncertain barrier, and these exceptional cases do not justify us in neglecting any precaution by which the contact of septic pus with the peritoneum can be avoided.

The prevention of septic peritonitis and its consequences is carried out on two principles : first, by the use of antiseptics in such a way as to exclude any living organisms from the cavity ; and secondly, by draining the cavity in all those cases in which an amount of exudation is expected beyond that which will immediately be re-absorbed. Considerable difference of opinion exists as to the relative value of these methods, some Surgeons maintaining that if antiseptics are properly used drainage is scarcely ever required ; and others that, if the peritoneal cavity be thoroughly cleansed before closing the wound, and drainage be efficiently employed if necessary, antiseptic applications are scarcely required. This is not the place to discuss this disputed point. It must, however, be insisted upon that the thorough removal of blood and other putrescible matter by sponging and irrigation is of primary importance. The great value of antiseptics in abdominal operations cannot be doubted, but the introduction of powerful chemical irritants into the peritoneal cavity must be avoided. The irritation produced by them necessarily causes an increased amount of exudation, and brings about just the condition which it is the object of the Surgeon to avoid. Antiseptics are of the greatest value in preventing the introduction of septic matter during the operation, but all fluids introduced into the abdomen for purposes of irrigation, should be as little irritating as possible. Drainage, which, to say the least, is an inconvenience, can safely be dispensed with in the majority of cases. The introduction of a drainage tube is, however, a wise precaution in any case where further effusion of blood or inflammatory exudation is likely to occur after the operation.

**Parotitis** is a somewhat frequent sequence of operations on the abdominal or pelvic viscera, a fact for which it is difficult to suggest any reasonable explanation (see p. 606).

**Shock** is a common cause of death in operations upon the abdominal viscera. It probably arises chiefly from the injury done to the large sympathetic plexuses in connexion with these parts, whilst the exposure of the viscera to cold and the loss of blood doubtless aggravate it in many cases.

It cannot be doubted, however, that in some cases death is ascribed to shock when in reality it results from septic poisoning, for it has already been pointed out the *post-mortem* evidences of peritonitis are often little marked, and may be thought insufficient to have been the cause of death.

**Hæmorrhage** is necessarily a source of danger in many cases, but it presents nothing requiring special consideration.

The following are the general rules applicable to all abdominal operations :—

1. The room in which the operation is to be performed must not be too cold, especially if the abdominal cavity is to be widely opened and the viscera exposed. The most favourable temperature is 65° F.

2. In those cases in which it is possible to do so, the bowels should be thoroughly emptied by the use of purgatives for several days before, and an enema on the day of the operation.

3. In all operations on the lower half of the abdomen the bladder should be emptied by a catheter, and the pubes shaved.

4. The patient when placed upon the table should be warmly wrapped up, lest the shock be increased by chilling the body. The limbs and chest should be completely covered with sheets of cotton wool, loosely applied with bandages. The area of the operation should be surrounded by warm carbolized towels.

5. The instruments and sponges, &c., and the hands of the Surgeon and his assistants must be cleaned and disinfected with carbolic acid, as already described (Vol. I. p. 324). During the operation all sponges must be squeezed as dry as possible, lest a dangerous amount of the antiseptic be introduced into the peritoneal cavity. They should be washed in warm carbolic lotion to avoid chilling the parts.

6. The sponges and forceps should be counted by the Surgeon before and after any operation in which they are used inside the abdominal cavity. The nurse should be directed not to tear up any of the sponges during the operation.

7. All hæmorrhage from the abdominal wall must be arrested before the peritoneum is opened.

8. If during the operation the intestines are exposed, they should be held on one side, and retained in the abdominal cavity by a large flat sponge. Should they be exposed externally, as in operations for hernia, intussusception, &c., or escape from the abdomen, they must be covered with a sheet of gauze several layers thick, wrung out of a warm 1 in 40 solution of carbolic acid.

9. When the operation is completed, if the abdominal cavity have been opened sufficiently to admit the hand, it may be cleaned with sponges squeezed as dry as possible and passed into the most dependent parts of the cavity, one after another, until they return quite clean. If there is blood or pus in the cavity, or if fæces or urine have been extravasated, irrigation through a soft india-rubber tube is often necessary. A warm solution of boric acid (1 in 50)

may be used, but simple water or 0·6 per cent. salt solution sterilized by boiling and then cooled to about 100° F. is probably preferable. Cleaning the peritoneum is a most important part of the operation, and success in many cases depends to a great extent upon the thoroughness with which it is done.

10. In closing the wound, the deep stitches, which should be of carbolized silk, must include the peritoneum, so that the serous surfaces shall be brought closely in contact. The importance of this in securing primary union was first demonstrated experimentally by Spencer Wells. Deep stitches may be passed through the whole thickness of the abdominal wall about three-quarters of an inch from the edge of the wound; both ends of the deep stitches being passed from within the abdomen to avoid any risk of puncturing the intestine. All the deep stitches must be passed before any are tightened, and care must be taken while this is being done not accidentally to include a knuckle of intestine between the edges of the wound or under a stitch. After the wound has been brought together, finer stitches may be put in to bring the edge of the skin accurately in contact. Some Surgeons prefer to suture separately the peritoneum, the muscles, and the skin. Treves sutures the peritoneum with a continuous stitch of fine silk and then brings together the other layers with interrupted sutures of silkworm gut.

11. If it be thought necessary to drain the abdomen, this is done by a tube of india-rubber or glass passed into the most dependent part of the cavity and brought out at the lowest angle of the wound. The tube must be of such size that all fluid shall escape readily from it. Inefficient drainage is worse than none at all.

12. The dressing should be composed of some efficient antiseptic material. If the wound is completely closed, a thin layer of dressing is sufficient. If it be drained, a thicker mass must be applied to absorb the discharge. In operations involving the anterior wall of the abdomen, the dressing is most conveniently kept in place by a broad band of strapping, which at the same time supports the abdomen.

13. After most abdominal operations the patient should be kept without food for from twenty-four to forty-eight hours, or in some cases even longer. A small quantity of iced soda-water or barley-water may be given to allay thirst. If the condition of the patient makes it necessary to give food, chicken-broth or iced milk and soda-water is the best, given in small quantities at intervals of about two hours. Small nutritive enemata are often useful. In operations involving the intestine, opium is often necessary to prevent peristaltic movement, but it should be avoided as far as possible. If the abdomen become distended with flatus small doses of cajuput and peppermint may be given; and much relief can often be afforded by passing a rectal tube, and thus allowing the gas to escape.

In all abdominal operations success will greatly depend on minute attention to details. The operation must be carefully considered and planned beforehand, and everything that can possibly be required must be at hand. At the end of a severe operation in this region, the patient is often suffering greatly from shock, perhaps hovering between life and death, and a little needless delay from not having everything ready the moment it is wanted, an unnecessary exposure of the intestines for want of a proper flat sponge to retain them, or a failure in some other minor detail, may just turn the scale against him.

## HERNIA.

By **Hernia**, in its widest sense, is meant the displacement of an organ from the cavity in which it is naturally contained, by being protruded through an abnormal or accidental opening in its walls; when, however, it escapes through one of the natural outlets of the part, it is not considered hernial. Thus, the protrusion of the brain through an aperture in the cranium, or of the lung through one in the thoracic walls, or of a portion of intestine through the abdominal parietes, is termed a hernia of the organ; but the descent of the bowel through the anus does not come under this designation. Here, however, we have to consider only the hernial protrusions that occur from the abdomen.

A hernia may occur at almost any part of the abdominal wall; though it is far more liable to do so in some situations than in others, being commonly met with at those points where the muscular and tendinous structures are weakened to allow the passage of the spermatic cord in the male, and of the round ligament in the female; or for the transmission of the large vessels to the lower extremity. Hence the inguinal and crural canals are the common situations of this disease. It may, however, occur elsewhere, as at the umbilicus, the thyroid foramen, the sciatic notch, in the vagina, the perinæum, through the muscular portions of the abdominal wall, the diaphragm, &c.

**STRUCTURE OF A HERNIA.**—In whatever situation it occurs, a hernia is composed of a **Sac** and its **Contents**.

The **Sac** is the prolongation of that portion of the peritoneum which corresponds to the aperture through which the hernia protrudes. It is in all cases composed of a *neck* and a *body*.

The **Neck** is usually narrowed, though in some old herniæ it becomes wide and expanded; it is commonly short, consisting indeed of a sudden constriction of the sac in this situation, as happens in many forms of femoral hernia; but in other cases it is elongated and narrowed. The neck of the hernial sac usually becomes greatly thickened and of an opaque colour, by the growth of fibroid tissue in or upon it from the irritation to which it has been subjected by the pressure of the hernial tumour or the truss, by the incorporation of the subserous areolar tissue lying externally to it, or by the puckering together of its folds, which have been compressed in the aperture.

The **Body** of the sac is usually globular or pyriform, sometimes elongated and cylindrical; it may vary from the size of a cherry to a tumour as large as the head. When recent, it is usually thin and transparent, though in some cases it becomes greatly thickened and almost laminated in structure; this is especially the case in old femoral herniæ. In other instances, however, it becomes thinned and atrophied as the tumour expands, so that the contents become visible through it. This is especially the case in old umbilical herniæ, in which I have seen it as thin as the finest gold-beater's skin.

The sac, though usually forming a perfect covering to the hernial contents, occasionally constitutes but a partial investment to them, more particularly in such organs as the bladder, which are partially uncovered by peritoneum. In other instances it may be ruptured, or altogether wanting. The sac is absent when the hernia occurs as the result of a wound, injury, or abscess of the abdominal wall. In some instances the sac may be absent in cæcal and in umbilical herniæ. More rarely a double hernial sac is met with, one being protruded into or placed behind the other. There are instances of three sacs

occurring together ; and Astley Cooper relates a case in which six were met with in the same person.

The abdominal parietes outside the sac undergo important changes. The aperture through which the hernia protrudes usually becomes circular ; after a time, indurated and rounded at the edge, and considerably enlarged ; when situated in the movable portions of the abdominal wall, as in the inguinal region, it becomes displaced in old herniæ, being dragged down by the weight of the protrusion, usually towards the mesial line. The subserous areolar tissue always becomes greatly thickened, often indurated, so as to constitute one of the densest investments of the sac, and, in some cases of old hernia, closely to resemble omentum. The more superficial structures, such as the integument and fascia, are much elongated and stretched ; often tense, but not unfrequently hanging in folds ; they are usually thinned, but, if a truss have been long worn, they become thickened and condensed by the pressure of the pad.

**Contents.**—The contents of the sac vary greatly ; every viscus except the pancreas having been found in a hernial tumour. Most frequently a portion of the *Small Intestine*, more particularly of the ileum, is protruded, constituting the form of hernia called **Enterocoele**. The quantity of intestine within the sac may vary from a small section of the calibre of the gut, the whole diameter not being included, to a coil several feet in length with its attached mesentery. After a portion of gut has once descended, the protrusion tends to increase, until, as in some large and old herniæ, the greater portion of the intestine has been known to lie in the sac. The *Large Intestine* is less often found in a hernia, though the cæcum is not uncommonly met with. When intestine has been long protruded, it usually becomes thickened, narrowed, greyish on the surface, and more or less deranged in its functions. The corresponding mesentery becomes thickened, hypertrophied, and vascular.

*Omentum* is often found in hernial sacs, together with intestine ; but is not unfrequently met with alone, constituting **Epiplocele**. After having been protruded for some time it becomes thickened, brawny, and laminated, losing its ordinary texture, and becoming indurated. Its veins usually assume a somewhat varicose condition ; and the mass of omentum becomes pyramidal in form, the apex being upwards at the abdominal aperture, and the base below, broad and expanded. In some cases it can be unfolded ; in others, it is matted together into a solid mass. Occasionally apertures form in it, through which a coil of intestine may protrude, thus becoming strangulated within the sac. In other instances, cysts are met with in it containing fluid. When both intestine and omentum are present, the hernia is termed an **Entero-epiplocele** ; and in these circumstances the omentum descends in front of and occasionally envelops the intestine. Besides these, the ordinary contents of herniæ, the stomach, liver, spleen, cæcum, sigmoid flexure of the colon, bladder, uterus, and ovaries, have all been found in them. In a case described by Scanzoni, the gravid uterus and ovaries were enclosed in the sac of an inguinal hernia.

*Adhesions* commonly form within the sac in old-standing cases. These may take place between the contained viscera merely, as between two coils of intestine, or between these and the omentum ; or they may form between the wall of the sac and its contents, either by broad bands, or else by bridging across from one side to the other, and enclosing a portion of the viscera. In recent cases these adhesions are soft, and may readily be broken down ; but when of longer duration, they are often very dense, and are especially firm about the neck of the sac.

Besides the viscera, the hernial sac always contains a certain quantity of fluid. In most cases, this is in but small quantity; but in some instances, when the sac is inflamed, or the hernia strangulated, a very considerable amount is met with: I have seen as much as a pint escape from a large hernia in an old man. In strangulated or inflamed hernia, it is generally of a reddish colour, though clear and transparent.

**Hydrocele of the Hernial Sac.**—In some instances the fluid becomes collected in a kind of cyst within the sac, formed by the omentum contracting adhesions to its upper part and leaving space below for the fluid to collect: this condition, represented in the annexed drawing (Fig. 794), has been called *Hydrocele of the Hernial Sac*, and is somewhat rare. The fluid is often in considerable quantity: in a case which I once tapped, nearly three pints of dark-brown liquid had accumulated.

If we limit the term *hydrocele of the hernial sac* to those cases in which there is a slow and gradual accumulation of fluid at the bottom of an old hernial sac, which has been cut off from all communication with the peritoneum by the adhesion of intestine or omentum to the upper part and neck, it must be considered a rare disease; and but few cases are recorded by surgical writers. Curling, in his work on the *Testis*, states that he had seen only one case; and the only others with which I am acquainted, besides one that occurred in my own practice, are two related by Pott, two by Pelletan, one by Boyer, and one by Lawrence. This disease must not be confounded with the accumulation of fluid, in whatever quantity, in strangulated herniæ, or in hernial sacs that communicate with the peritoneal cavity. Its distinguishing feature is the accumulation of fluid in a part of the sac that has been cut off from all communication with the cavity of the peritoneum.

**An Accumulation of Ascitic Fluid in a Hernial Sac** may occur when hernia is complicated with ascites. In one case of this kind which occurred

in my practice, the hernia, which was femoral, in a woman, was very tightly strangulated, as large as a shaddock, very tense, with distinct fluctuation; the skin covering it being much stretched, this was peculiarly evident. On opening the sac, fluid flowed in a jet, as if a hydrocele had been punctured, and about four inches of strangulated gut were found lying at the bottom of the sac. After division of the stricture, serous fluid in large quantity continued to drain from the peritoneal cavity for several hours after the operation.

**A rapid Accumulation of Fluid in a Hernial Sac which has been obliterated at its neck** is occasionally met with, chiefly in the femoral region, though occasionally also in the inguinal. A case of this kind occurred not long ago in University College Hospital. The patient, a middle-aged woman, was suddenly seized with pain in the abdomen, and bilious vomiting. On examining the groin a tense rounded tumour was found in the region of a femoral hernia. It was free from tenderness and fluctuated indistinctly. On cutting down upon it, it was found to be an old hernial sac distended with clear serous fluid, but without solid contents. While examining the ring the adhesions at the neck of the sac gave way, and the finger slipped into the

Fig. 794.—Diagram of Hydrocele of Hernial Sac.

abdominal cavity. The vomiting and pain proved to have been nothing more than an ordinary "bilious attack," and the patient speedily recovered.

**Loose Foreign Bodies** have occasionally been met with inside hernial sacs. They are usually rounded, smooth, and firm, varying in size from a pea to a chestnut; and are mostly single. On section, they are found to consist of a fatty central nucleus with a laminated fibrous envelope, usually of considerable thickness. They are apparently composed of one of the appendices epiploicæ, which has become detached, fallen loose into the peritoneal cavity, and become enveloped in fibrinous layers.

**Signs of Hernia.**—The signs of hernia, though varying considerably according to the contents of the sac and the condition in which it is placed, present in all cases many points in common. There is an elongated or rounded tumour at one of the usual abdominal apertures, broader below than above, where it is often narrowed into a kind of neck. The swelling usually increases in size when the patient stands, holds his breath, coughs, or makes any forcible muscular exertion. It can be pushed back into the abdomen on pressure, slipping away suddenly from under the hand. As this takes place, if intestine is present, a characteristic gurgle is heard and felt. It usually goes back readily if the patient lie down, but reappears when he stands up. On coughing, a strong and distinct impulse may be felt in it.

When the hernia is altogether **Intestinal**, it is usually smooth, gurgling when pressed upon, sometimes tympanitic and rumbling, and resonant on percussion. It may be returned into the cavity of the abdomen with a distinct slip and gurgle; it has a well-marked impulse on coughing, and is usually accompanied by various dyspeptic symptoms, often with much dragging uneasiness. **Omental Hernia** is usually soft and doughy, returning slowly on pressure into the abdomen, feeling irregular on the surface, and having an ill-defined outline. It occurs most frequently on the left side, and is rare in infants, in whom the omentum is short. In **Entero-epiplocele** there is a combination of the two conditions and their signs; but these are usually so uncertain, that few Surgeons care to predict before opening the sac what the probable nature of the contents may be.

**Cæcal Hernia** usually occurs on the right side, but the cæcum has been known to be present in a femoral or inguinal hernia of the left side. Treves has conclusively shown that the view which was at one time held that hernia of the cæcum is usually devoid of a sac is not true. A complete sac is in fact usually present, and this was so in all but two of fifteen cases collected by Treves. In the remaining two cases no sac was present, and a case of cæcal hernia without a peritoneal covering has lately been recorded by W. H. Bennett. In such cases the peritoneum is supposed to be stripped from the bowel as the latter descends into the hernia. When the sac is partially or completely absent the hernia is irreducible. When the hernia is large, and only partially invested by serous membrane, a sac usually exists at its upper aspect, into which a portion of small intestine may fall, and which may in some cases constitute a second hernia lying above or before the cæcal one, which will be found situated at the posterior wall when this hernial pouch is opened. Strangulated hernia of the cæcum has several times been met with in infants.

**Hernia of the Bladder** or **Cystocele** is very rare, and is usually partially or completely devoid of a peritoneal investment. South states that there is a preparation at St. Thomas's Hospital, in which the fundus of the bladder,

with its peritoneal covering, has passed into a distinct sac. In some instances the cystocele is accompanied by an enterocele. This hernia is always irreducible, is attended with a good deal of difficulty in urinating, with varying tension, according to the quantity of fluid contained; by squeezing it, urine may be forced out through the urethra, and fluctuation has been felt in it. Urinary calculi have been formed in the tumour, and have been removed by incision through the scrotum, or have ulcerated out.

**CAUSES.**—The causes of hernia are usually sufficiently well marked. In some instances the disease is *congenital*, arising from preternatural patency of the abdominal apertures; in other cases, it occurs at a later period of life, in consequence of some *forcible effort*, as lifting a heavy weight, jumping, coughing, straining at stool, or passing urine through a tight stricture. Such causes as these act especially in tall and delicate people, particularly in those who have a natural disposition to weakness or bulging of the groins. The displacement of the abdominal viscera by a *gravid uterus* will also occasionally give rise to the disease. Hernia frequently results from a combination of causes: thus, if an aged person of feeble build, or whose abdominal apertures are patent in consequence of rather sudden emaciation, make a violent effort, a hernial protrusion is very apt to occur.

The view that elongation of the mesentery is an important cause of hernia has been supported by many writers, but has been more or less generally abandoned. It must, however, be mentioned that a modification of this theory has lately been suggested by Lockwood, who finds that in some cases the attachment of the mesentery is lower than natural, although no elongation of the mesentery itself exists. Lockwood is of opinion that this "prolapse of the mesentery" gives rise to a flattening of the abdomen above the umbilicus and a bulging below it.

Amongst the most frequent **Predisposing Causes** of hernia, are sex, age, and occupation.

**Sex.**—Men are more liable to this disease than women, in the proportion of about 4 or 5 to 1. Thus, according to Malgaigne, in France, one man in thirteen and one woman in fifty-two are the subjects of hernia. But, though men are more generally liable to hernia than women, they are less so to certain forms of the disease, especially to the femoral and umbilical. It is to the inguinal that they are particularly subject. According to Lawrence, out of 83,584 patients who applied to the City of London Truss Society, 67,798 were males and 15,786 females. Of 43,214 applicants at the same institution during the eight years 1860-1867, 36,161 were males and 7,053 females. Of these, 34,788 males, and 3,085 females had inguinal hernia; 1,373 males, and 3,968 females had femoral hernia.

**Age** exercises a very material influence upon the frequency of hernia. Malgaigne, who carefully investigated this subject, found that in infancy the disease is sufficiently common, owing to the prevalence of congenital inguinal and umbilical herniæ at this period of life; and that, in the first year after birth, hernia occurs in the proportion of 1 in every 21 children. It then goes on decreasing in frequency, there being 1 in 29 at the second year; 1 in 37 at the third year; until, at the thirteenth year, it has fallen to 1 in 77. Shortly after this, its frequency begins to rise again, and then goes on progressively increasing until the close of life: thus, at the 21st year, there is 1 case in 32; at the 28th year, 1 in 21; at the 35th, 1 in 17; at the 40th, 1

in 9 ; at 50, 1 in 6 ; from 60 to 70, 1 in 4 ; and from 70 to 75, 1 in 3. In women, according to Malgaigne, hernia most frequently occurs from the 20th to the 50th years. Malgaigne's figures give the ages of the patients when they came under his observation. Kingdon has investigated the question of the ages at which the hernia commenced. He states that out of 9,296 cases, 5,659, or 60·8 per cent., had commenced before 35, and 3,637, or 39·2 per cent., after that age. The tendency to hernia is often *hereditary*, and congenital hernia is common in the children of hernial parents. Some races of men are less subject to hernia than others. Thus, except the ventral form, it is less frequent in the negro than in the white man.

**Occupation.**—Those occupations in which the individual is exposed to violent muscular efforts, more particularly of an intermitting character, predispose to the occurrence of hernia ; and in these employments the tendency to the disease is often increased by the injurious habit of wearing tight girths or belts round the waist, which, by constricting the abdomen, throw the whole pressure of the abdominal contents upon the inguinal regions. Hernia is also common in men such as railway drivers, cavalry soldiers, and artillery-men, exposed to much jolting in the upright or nearly upright position.

**Other Causes.**—It is probable also that hernia is predisposed to by the height of the seats of water-closets in common use. In the natural position assumed by man in defæcation the femoral and inguinal rings and the lower part of the abdomen are supported by the flexed thighs, whereas on the ordinary water-closet seat the thighs are not flexed much beyond a right angle, and the support is consequently much less perfect. The frequency with which hernia appears for the first time or becomes strangulated during defæcation would lend some support to this view. Habitual constipation is a predisposing cause in many cases. Rapid emaciation from any cause is not unfrequently followed by a hernial protrusion.

**CONDITIONS PRESENTED BY HERNIA.**—The conditions in which a hernia may be found are very various, and entail corresponding differences in the result and treatment of the affection. When first formed, most herniæ may be said to be *Incomplete*, being for a time retained within the orifice of the canal through which they eventually protrude. When they have passed altogether beyond the abdominal walls, they are said to be *Complete* ; and this is the condition in which they are usually presented to the Surgeon. A hernia may also be *Reducible*, *Irreducible*, or *Strangulated*.

#### REDUCIBLE HERNIA.

A hernia is commonly at first **Reducible** ; that is to say, it may readily be pushed back into the cavity of the abdomen, protruding again when the patient stands up, holds his breath, or makes any exertion, and having a distinct and forcible impulse on coughing. Though the contents, in these cases, are reducible, the sac is not ; it almost immediately contracts adhesions to the areolar tissue, by which it is firmly fixed in its new situation ; though in some cases, as will be seen hereafter, it may be pushed back.

The question as to whether a hernia is of recent origin or of old standing sometimes presents itself in medico-legal practice. In determining this the following points deserve attention :—1. A recent hernia resulting from injury is attended with pain—usually severe—from laceration of the structures of the

abdominal wall. 2. When direct inguinal or femoral, it may be small, but when oblique inguinal or ventral, it is often large and rounded, the aperture through which it protrudes being irregular and wide. 3. The margins of the aperture in an old hernia are more rounded than in one of recent formation. 4. Recent herniæ are more often intestinal, not omental. 5. They are readily reducible; whilst old herniæ are frequently irreducible in whole or in part, and omental. 6. After reduction the sac of a recent hernia when rolled between the fingers will feel thinner and softer than that of an old one. 7. Strangulation may occur at the moment of protrusion of a hernia. Hence, although more frequent in old than in recent herniæ, its existence does not prove the hernia to be old. 8. In old herniæ, if the patient has worn a truss, there will usually be signs of pressure, or of chafing of the skin.

**Application of Truss.**—In the Treatment of a reducible hernia, the object is to retain the protrusion within the cavity of the abdomen. In order to do this, the patient must be provided with a truss, adapted to the particular nature of the hernia. In umbilical and ventral ruptures, an elastic belt and pad may most conveniently be used. In selecting the truss, care should be taken that the spring be of proper strength, adapted to the size and power of the individual; and that it be properly shaped, so that it does not touch any part of the abdominal wall, but merely bears upon the points of pressure and counter-pressure. The pad should be convex, firmly stuffed, and of sufficient size to press, not only upon the external aperture, but upon the whole length of the canal. Before applying the truss, the hernia must be reduced, by placing the patient in the recumbent position, relaxing the muscles by bending the thigh upon the abdomen, and pressing the tumour back in the proper direction; the truss should then be put on, and worn during the whole of the day; indeed, the patient should never be allowed to stand without wearing it. At night, it may either be left off altogether, or a lighter one applied. The patient should be provided with a "bathing" truss, that is, a truss covered with india-rubber, so as to resist the action of the water. It is well that the ordinary truss be covered with linen, so that the leather may be kept clean, and unstained by perspiration and the spring free from rust. In some cases, the skin becomes irritated by the pressure of the pad; in these circumstances, an elastic air-cushion may be used, or the parts subjected to pressure may be well washed with spirit lotion and a dusting powder used. The truss may be known to fit by testing it in the following way: The patient should be made to sit down on the edge of a chair, and then, extending his legs, opening them widely, and bending the body forwards, cough several times. If the hernia do not now slip down behind the pad, we may be sure that the truss is efficient, and will keep the rupture up in all ordinary circumstances.

It is the Surgeon's duty to tell the instrument-maker what form of truss is required, and to see that the instrument fulfils its object. It is always better for the instrument-maker to see the patient and measure him for the truss, but in country practice this is often impossible, and the Surgeon must then measure the patient himself and order the required instrument. The most important measurement is the circumference of the pelvis taken midway between the crest of the ilium and the trochanter major. Most instrument-makers say that this is all they require; but to ensure accuracy, it is better to send also the exact measurement in the line in which the truss will lie, commencing at the centre of the ring, and passing round the pelvis midway

between the crest of the ilium and the trochanter, and terminating at the ring again. The Surgeon must also inform the instrument-maker of the nature of the hernia, the side on which it is situated, the size of the ring, the age, sex, and physical power of the patient. It must also be stated if his occupation is such as to necessitate a spring of more than ordinary strength.

**RADICAL CURE OF HERNIA.**—Various means have been devised in order to effect the radical cure of a reducible hernia. The only plan that is perfectly free from danger is the compression of a well-made truss. In this way, not unfrequently, the herniæ of infants become radically cured; the same result, however, seldom occurs at a more advanced period of life. In order that compression in this way may succeed, it is necessary that it should be applied not only to the external aperture through which the rupture escapes, but to the whole of the canal. It must also be continued for a very considerable time, at least a year or two; and care should be taken that during the treatment the rupture is not allowed to descend. Every time it comes down, any good that may have been derived is necessarily done away with, and the treatment has to begin, as it were, anew. Radical cure of a hernia by truss-pressure can be effected only in those cases in which the abdominal aperture has been left congenitally weak or open. Hence it can be hoped for only in children and very young adults, and only in those two congenital forms of hernia—the umbilical and the inguinal. The continued pressure of the truss in these cases seems to determine the adhesive processes necessary for the closure of the aperture. After the cure is supposed to have been effected in this way, the truss must be worn for a very considerable length of time, lest by any violent movement the rupture be forced down again.

Of the various **Operations** which have been devised for the radical cure of hernia, the only one which is practised at the present day is the *open method*. This consists in exposing the sac by an incision, ligaturing the neck, and in many cases removing the body, of the sac, and finally closing the aperture through which the hernia has escaped with sutures. This method is very ancient, and was frequently applied to inguinal herniæ in the middle ages either by surgeons or by travelling quacks. It fell into disrepute, however, owing to the mortality that attended it until the introduction of the antiseptic method of treating wounds robbed it of the greater part of its dangers. In 1871 Lister reported two cases in which he had cut down upon a hernial sac and closed the opening with cat-gut sutures, but this method of operating was found to be uncertain in its results. Since then Annandale, Banks, Czerny, Macewen, Ball, and many others have introduced modifications and improvements which have rendered the operation both safe and effectual.

Of the methods which have been entirely abandoned may be mentioned:—1. That which aims at obliterating the neck of the sac by the introduction of caustics, by scarification, by puncture, or by injection of iodine; 2. Plugging the hernial aperture by the invagination of the sac and the subcutaneous tissue into it; and 3. The subcutaneous introduction of wire, silk, or other ligatures to invaginate the sac and subcutaneous areolar tissue and to close the ring. The ineffectual and dangerous character of the first of these methods is obvious, whilst the only advantage which the others at one time possessed was that they did not involve the dangers of an open wound.

Failure must occasionally occur after operations undertaken for the radical cure of hernia, as to accomplish this it would be necessary in some cases to

effect changes in the shape and connexions of the abdominal contents, to alter the size of the cavity and to modify in various ways many conditions independent of those immediately connected with the hernial protrusion.

In young children the operation is comparatively rarely required, for during the first few years of life herniæ show a great tendency to undergo spontaneous cure. In aged persons also the operation is rarely justifiable for reducible hernia.

In healthy adults the operation may be undertaken when the hernia prevents admission to one of the public services, when it cannot be kept back by a truss, and when the patient's occupation renders the use of a truss especially inconvenient. In any favourable case the Surgeon is justified in undertaking the operation at the patient's request, after explaining that it necessarily involves a small amount of risk.

Radical cure is no longer confined to inguinal herniæ, and consequently the details of the operation will most conveniently be considered with the special herniæ.

#### IRREDUCIBLE HERNIA.

IRREDUCIBLE HERNIÆ are usually of old date, and often of large size. They generally contain a considerable quantity of thickened omentum, as well as intestine and mesentery. In many instances, a rupture of this kind is partly reducible, the greater portion remaining unreduced. It is usually the gut which slips up, and the omentum that cannot be returned.

**Causes of Irreducibility.**—The irreducibility of a rupture may be dependent either on its *shape*, on the existence of *adhesions*, or on its very *nature*. If the sac become the seat of an hour-glass contraction, or its neck become elongated and narrowed, the hernial contents may continue permanently protruding. So also, the expanded condition of the lower part of the omentum, and the narrowing of its neck, may prevent a return of the rupture. The existence of adhesions, either between the sac and its contents, or between protruded intestine and omentum, will commonly render a hernia irreducible; and most frequently these are associated with changes in the shape of the sac or of the omentum. When a hernia is devoid of a perfect sac it is necessarily, in part at least, irreducible, for the portion of the protruded viscus which is exposed contracts adhesions with the surrounding tissues. In this way hernia of the bladder, and rarely hernia of the cæcum, is irreducible. In some cases of hernia of the large intestine, such as the sigmoid flexure, the mesocolon is continuous with the peritoneum forming the sac and may thus prevent complete reduction of the gut.

**Symptoms.**—An irreducible hernia is usually a source of great inconvenience; it has a tendency to increase if left to itself, until at last it may contain, as in some extreme cases it has been found to do, the greater portion of the abdominal viscera, forming an enormous tumour, inconvenient by its size and weight, in which the penis and scrotum are buried. Even when the irreducible hernia is of small size, it gives rise to a sensation of weakness in the part, with dragging pains, and is very frequently accompanied by colicky sensations and dyspeptic derangements. Moreover the patient, in these circumstances, is in a state of considerable danger lest the rupture become strangulated by violent efforts, or injured by blows.

**Treatment.**—For the above reasons it is necessary not only to protect a rupture of this kind from external violence, but to endeavour to prevent its increase in size. This may best be done by letting the patient wear a truss with a large concave pad, which supports and protects the hernia; provided it be not of too great a size for the application of such an instrument. If its magnitude be very considerable, it must be supported by means of a suspensory bandage. Bransby Cooper recommended that an attempt should be made to convert the irreducible into a reducible hernia, by keeping the patient in bed for several weeks, on low diet, with the continued application of ice to the tumour. If it contains much omentum, and the patient be fat, the diet may be regulated accordingly. All food containing starch or sugar, except a small quantity of bread, and all alcoholic drinks must be forbidden. The patient must be fed on a small quantity of lean meat and green vegetables. At the same time a dose of blue pill and a saline purgative must be given occasionally. The scrotum, if the hernia be inguinal, must be raised on a pillow, and the foot of the bed may also be elevated. Taxis may be attempted daily. By this plan I have seen very large irreducible herniæ returned in a few weeks. If the patient be young and otherwise healthy, the question of performing the operation for radical cure by opening the hernia, dissecting through the adhesions, removing the sac and sewing up the ring, may be considered. Such an operation, however, should not be rashly undertaken if the hernia be large and the patient fat.

**Inflamed Irreducible Hernia.**—The occurrence of inflammation in an irreducible hernia is a serious complication, and one that simulates strangulation very closely. When this complication occurs, the part becomes swollen, hot, tender, and painful; there is not much tension in the tumour, which is seldom increased beyond its usual magnitude; there is a good deal of pyrexia, and symptoms of peritonitis spreading from the vicinity of the inflamed rupture set in. In some cases there is vomiting; but it is not constant, and never feculent, occurring generally early in the disease, and consisting principally of the contents of the stomach; being apparently an effort of nature to get rid of an indigestible meal. If there be constipation, as usually happens in all cases of peritonitis, it is not complete, flatus occasionally passing *per anum*, together with a small quantity of fluid fæces. It is of importance in these cases to observe that the inflammation commences in the body of the sac, and extends into those parts of the abdomen that are contiguous to its neck; the gastric and intestinal derangements being secondary.

The *Treatment* of an inflamed irreducible hernia must be directed to the peritonitis which attends it. The application of leeches over the sac and its neck, and the administration of opium or hypodermic injections of morphia if the vomiting continues, followed by hot fomentation, with strict spoon diet and rest, will usually speedily subdue all signs of inflammation.

**Incarcerated or Obstructed Hernia.**—An irreducible hernia occasionally becomes blocked, thus constituting the condition termed *incarcerated or obstructed hernia*. This occurs principally in old people, from the accumulation of flatus, or of undigested matters, such as cherry-stones or the remains of a large meal of cabbage or spinach, in a coil of the gut. The solid nature of the contents of the large intestine renders this part of the bowel especially liable to become obstructed, and for this reason incarceration chiefly affects large umbilical hernia which commonly contain part of the colon. In these

cases there is constipation, with eructation, and perhaps occasional vomiting. There may be some degree of pain, or uneasiness about the tumour ; but there is no tension in it or in its neck, and the symptoms altogether are of a chronic or subacute character.

The *Treatment* of such a case as this should consist in the administration of a good purgative injection ; the compound colocynth enema is the best, thrown up as high as possible by means of a long tube. Ice may then be applied to the tumour for about half an hour ; and the taxis, as will afterwards be described, may be used under chloroform. The ice may be omitted in those cases in which, on handling the tumour, gurgling can readily be felt ; but the taxis should always be used, as by it the incarcerated gut may be partially emptied of its contents ; or if any additional protrusion should have slipped down, this may be returned. After these means have been employed, an active purgative, such as a full dose of castor oil or a calomel and colocynth pill may be administered. Should there be any signs of inflammation, purgatives must be avoided, and the case treated as already described.

#### STRANGULATED HERNIA.

A hernia is said to be **Strangulated** when a portion of gut or omentum that is protruded is so tightly constricted that it cannot be returned into the abdomen ; having its functions arrested, and, if not relieved, speedily running into gangrene. This condition may occur at all periods of life, being met with in infants a few days old, and in centenarians. It commonly arises from a sudden violent effort, by which a fresh portion of intestine is forcibly protruded into a previously existing hernia, which it distends to such a degree as to produce strangulation. But, though old herniæ are more subject to this condition than recent ones, it may occur at the very first formation of a hernial swelling, the gut becoming strangled as it is protruded. There are therefore two distinct kinds of strangulation. One may be said to be *passive*, occurring chiefly in elderly people, the subjects of old and perhaps irreducible herniæ ; which, in consequence of some accidental circumstance, become distended by the descent of a larger portion of intestine than usual, and this, undergoing constriction at the neck of the sac, gradually becomes strangulated. The other kind is more frequent in younger individuals ; in it the symptoms are active, the bowel becoming protruded in consequence of violent exertion, and undergoing rapid strangulation, the tension of the parts not having been lessened by the previous long existence of an irreducible hernia.

**Mechanism of Strangulation.**—Strangulation has been attributed either to a spasmodic action of the walls of the aperture through which the hernia protrudes, or to changes taking place in the protruded parts, occasioned by their constriction by the tissues external to them. Strangulation cannot, I think, ever be regarded as of spasmodic character ; for the aperture in the abdominal wall, through which the hernia escapes, is tendinous or fibrous, and certainly not in any way contractile, though the action of the abdominal muscles may undoubtedly increase the tension of its sides. The continued and permanent character of the strangulation also, when once it has taken place, would discountenance this opinion ; those forms of hernia, indeed, as the ventral, which occur in purely muscular structures, are very rarely strangulated, and, when they are, the constriction is generally occasioned by

times the quantity increases greatly and rapidly, but more commonly the chief alteration that takes place is in its character. It becomes reddish or brown in colour from transuded blood. Sometimes even pure blood is found in the sac, and I have seen the protruded intestine invested with a layer of coagulum. If gangrene of the gut takes place, the fluid becomes turbid, dark, and offensive. Suppuration in the sac is very rare. I have only once met with it in a woman, 32 years of age, three months pregnant, who was suffering from an acutely strangulated femoral hernia of sixty hours' duration. In that case, taxis had been freely used. Fluctuation could be felt deeply, there was diffused doughy infiltration of the groin, and on opening the sac it was found filled with dark thick pus—about half an ounce; at the bottom of which lay a small deeply congested but not gangrenous knuckle of intestine, which was replaced after the division of a very slight stricture. The patient recovered.

The interesting fact has been established by the researches of Nepveu, Clado and others that the fluid in the sac may contain micro-organisms, among which is the bacterium coli commune (p. 817), even when the gut is neither gangrenous nor perforated. This fact may help to explain some cases in which peritonitis follows the reduction of the hernia by taxis or operation.

**Inflammation of the Gut after relief of Strangulation** occurs in a large proportion of cases. It has already been pointed out in the chapter on Inflammation (Vol. I., p. 175) that the arrest of circulation through a part of the living body produces different effects according to the length of time that it is kept up. If the arrest is complete and of sufficient duration, gangrene sets in, such blood as the vessels contain coagulates, and on relief of the strangulation the blood is unable to enter the dead tissues. If the arrest of the circulation has been maintained for a length of time sufficient to lower the vitality of the part considerably but not to kill it, on the relief of strangulation all the phenomena of inflammation manifest themselves. The vessels become engorged with blood, abundant exudation takes place causing great swelling by which the feeble circulation may be again arrested and gangrene may set in. In other cases the inflammation may fall short of this, but may, in the case of the intestine, be sufficient to suspend the functions of the affected part so that although the strangulation is relieved, the obstruction to the passage of faeces remains for some days, or even till death results. If the arrest of circulation has been less complete or of shorter duration, the relief of strangulation is followed by temporary hyperæmia, which soon subsides. It is not uncommon in fatal cases to find the coil of intestine free from gangrene, but swollen, covered with a thick layer of inflammatory exudation fixing it to the neighbouring coils, and evidently incapable of performing its functions. This inflammation after reduction is a fact of great importance, as it shows the necessity of giving the gut rest as far as possible after the strangulation has been relieved by the avoidance of purgatives or irritating food.

It was formerly assumed that in all cases of prolonged strangulation general peritonitis sets in. This assumption is not borne out by the results of the *post-mortem* examination of cases dying of unrelieved strangulation. In such cases, as a rule, local peritonitis is found at the neck of the sac, but the membrane generally is free from any signs of inflammation. Should inflammation occur it is always slight, and seems to be secondary to acute inflammation of the mucous membrane of the intestine above the stricture,

which in too many cases is the result of the injudicious administration of purgatives.

**SYMPTOMS.**—The signs and symptoms of strangulation are of two kinds :

1. Local ; and 2. General.

1. **Local Signs.**—The tumour, if the hernia be an old one, will be found to be increased in size ; or it may have appeared for the first time. At the moment of strangulation it will generally be found to be hard, tense, and rounded, more particularly if it be an enterocele. When, however, the hernia is in a great measure omental, it is not unfrequently soft and doughy, though strangulated. After strangulation has occurred no fresh protrusion can take place below the stricture ; but the tumour may be greatly augmented in bulk after the strangulation has existed for some hours, by the effusion of serum into the sac. If the hernia have previously been reducible, it can no longer be put back ; there is no impulse in it nor increase in its size on coughing, the stricture preventing the transmission of the shock to the contents of the tumour ; and in this way, as pointed out by Luke, the situation of the constriction may sometimes be ascertained by observing at what point the impulse ceases. In most cases there is considerable local tenderness.

2. **Constitutional Symptoms.**—As soon as the strangulation has occurred, intestinal obstruction takes place, and the patient becomes uneasy and restless. If the constriction be of an active character, he will be seized with acute pain in the part, which speedily extends to the contiguous portion of the abdomen. The first thing that happens when intestine is strangulated, whether a large coil be constricted, or a small portion only of the diameter of the gut be nipped, is an arrest of the peristaltic movement of the part implicated ; and the occurrence of obstruction to the onward course of the intestinal contents is followed by constipation, vomiting, and colicky pains. The obstruction is always complete, neither feces nor flatus passing : the bowels may sometimes act once after the strangulation has occurred from that portion which lies below the seat of constriction, but they cannot, of course, empty themselves thoroughly, nor from above the strangulated part.

Vomiting usually sets in early, and is often very severe and continuous, with much retching and straining ; at first the contents of the stomach are ejected, with some bilious matters, but afterwards the vomiting becomes feculent or stercoraceous. The cause of feculent vomiting has usually been supposed to be an inverted peristaltic action of the intestines. Brinton, however, opposed this time-honoured view, maintaining that the peristaltic action continues direct and causes a peripheral downward current as far as the obstruction, from which point a central upward current returns the contents of the intestine towards the stomach, but the evidence supporting this theory is far from conclusive. The quantity brought up is often very large in amount, and consists not only of the normal contents of the intestine, but of an abundant secretion from the congested and irritated mucous membrane above the obstruction. It is greatly increased in quantity should the patient have taken a purgative. In cases of prolonged obstruction it is sometimes mixed with black shreds of altered blood, indicating intense inflammatory congestion of the mucous membrane. The vomiting is attended with colicky and dragging pains about the navel. These symptoms are more severe in their character when the strangulation is acute than when it is passive. They occur equally in the incomplete and the complete forms of hernia ; indeed, it not unfrequently

happens that the tumour may be so small as to have escaped observation, the occurrence of the above-mentioned symptoms being the first indication of the probable nature of the mischief. Hence, it is a rule of practice always to examine for hernia when called to a patient suddenly seized with constipation, vomiting, and colicky pains, even if told that no tumour exists.

At first the abdomen appears normal, but after the strangulation has existed for some time it becomes distended and tympanitic, with much pain and distress. The pulse becomes small and rapid, and perhaps intermittent; the tongue is dry and speedily becomes brown; the countenance is pale, anxious and dragged. The extremities become cold, congested and clammy, and the temperature falls below normal. When gangrene of the rupture takes place, hiccup usually comes on, with sudden cessation of pain in the tumour, and intermittent pulse, cold sweats, pallor, anxiety, rapid sinking of the vital powers, usually with slight delirium; and death speedily occurs.

**Modifications of Symptoms.**—The symptoms just described are those which are usually met with in strangulated hernia. They may, however, be modified in some important respects.

1. There may be little or no tension in a strangulated hernia, the tumour continuing soft and lax; this is especially the case when the hernia contains omentum, and in congenital herniæ when strangulated. It may occur also in the case of double herniæ on the same side, in consequence of the outer sac being empty, or merely filled with fluid, and the posterior one being protruded against this and strangulated, but its tension being masked by the lax state of the outer one.

2. Vomiting sometimes does not take place from first to last, there being at most a little retching; at other times the patient vomits once or twice, and then there is no recurrence of this symptom so long as he remains quiet, and keeps the stomach empty; but, on moving or taking nourishment of any kind, even if fluid, it comes on again, and thus the Surgeon may *elicit* this symptom, should it be necessary from a diagnostic point of view. If opium has been freely administered there may be no vomiting or pain.

3. Extensive peritonitis, with copious effusion of a puriform liquid, may occur without any pain, and with but little tenderness and no elevation of temperature; the anxiety of countenance and sharpness of pulse being the only symptoms that lead to a suspicion of its existence.

4. Death may result from exhaustion consequent on vomiting, without any sign of gangrene in the constricted portion of intestine.

**Partial Enterocoele.**—In the year 1700 Littre, a celebrated anatomist and surgeon of Montpellier, described a new form of hernia first observed by himself, in which the strangulated portion was a pouch-like projection from the side of the intestine; the lumen of gut not being completely obstructed. In two of the three cases described by him the strangulated portion was evidently a congenital diverticulum from the ileum. According to F. Treves, who has collected over fifty cases of partial enterocoele, including four under his own care, the first accurate description of strangulation of a portion of the circumference of the gut was given by Richter in 1778. He therefore suggests as a distinction that the strangulation of a diverticulum should be termed Littre's hernia and that of a portion of the circumference of the gut, Richter's. The terms "partial enterocoele" and "strangulation of a diverticulum" would, however, be less likely to lead to confusion. From an analysis of 53 cases

Treves states that partial enterocele is most common in femoral herniæ and consequently in women. It has been most frequently met with in old irreducible herniæ of small size. The tumour is always small, and in nearly half of the recorded cases was not recognised during life. In 7 out of 38 cases of femoral hernia an enlarged gland lay over the sac, obscuring the diagnosis. The bowel engaged is almost always the ileum, but in three it was the jejunum and in one the colon. The proportion of the gut included varied from four-fifths to one-sixth; it was below a half in the majority of the cases. When more than two-thirds of the gut is strangulated the passage of fluids is arrested by the bending of the bowel; when less is implicated the lumen may remain partly free. It has been supposed that a partial enterocele arises primarily from adhesion of a portion of the intestine over the mouth of a small sac, and the gradual formation of a pouch-like projection, but there is little evidence to support this theory. In the 53 cases collected by Treves the symptoms were those of ordinary strangulated hernia in about one-third, and in some of these after death there was found not to be complete mechanical obstruction of the lumen of the bowel. In the remaining cases the symptoms were characterised by less intensity. In three there was persistent diarrhœa throughout the case; in several the bowels responded to aperients; in others flatus and fæces were passed from one to three days after strangulation had occurred. The vomiting was usually less frequent and severe, and in only six of the 53 cases was it distinctly fæculent. In almost all cases there was no distension of the abdomen. The gut was reduced by taxis in two cases only and both of these died rapidly from peritonitis. In four cases (three femoral and one inguinal) reduction *en masse* occurred. The mortality in this form of hernia is very high, amounting to 62·2 per cent., owing to the difficulty and delay in diagnosis, and the tightness of the strangulation. There is nothing special in the treatment of this condition.

**Strangulated Omental Hernia** has been described by some writers as giving rise to symptoms identical in character with those of strangulation of the gut, but of less intensity. When signs of intestinal obstruction are present and on operating only omentum is found in the sac, it may be assumed that a small knuckle of gut has been reduced without being noticed or that the omentum is in some way dragging on the gut so as to occlude its lumen. A pure epiplocele is very rarely strangulated. When irreducible, omentum may become inflamed, possibly as the result of injury, and an abscess has been known to form in it, and in these cases the swelling of the protruded portion may lead to its partial or complete strangulation. In this condition there are signs of peritonitis; the vomiting is never stercoraceous; there is constipation with pain in the hernia and in the abdomen. The skin covering the sac becomes red and swollen. If such a condition could be diagnosed the best treatment would be to cut down on and open the sac and then to remove the congested and inflamed omentum.

**DIAGNOSIS.**—The diagnosis of strangulated hernia requires to be made from the following conditions:—

1. **Obstructed Irreducible Hernia.**—In this there are no acute symptoms, and the rupture will generally be found to be a large one of old standing. It may become somewhat tense and swollen, but is not tender to the touch, and always presents a certain degree of impulse on coughing. There may be constipation; but there is no vomiting, or, if there be any, it is simply mucous

and bilious, consisting of the contents of the stomach. The speedy restoration of the intestinal action, by the treatment already indicated as proper in these cases, will remove any doubt as to the nature of the affection.

2. **Inflamed Irreducible Hernia.**—This is accompanied by great tenderness and pain in the tumour, with pyrexia, and some general peritonitis, and there is no vomiting; or, if the patient have vomited once or twice, he does not continue to do so with the same degree of violence, or in the same quantity, as he would if it were the result of strangulation. Again, the obstruction is not complete, but flatus and liquid fæces will usually pass.

3. **General Peritonitis conjoined with Hernia.**—Here the diagnosis is often extremely difficult, especially if the hernia be an irreducible one. In these cases, however, it may be observed that the peritonitis is most intense at a distance from the sac; that there is little or no vomiting, or, if there be, that it is not stercoraceous; and that the constipation is not complete, flatus or even fæces occasionally passing.

4. In **Double Hernia**, one tumour may be strangulated and the other not, though irreducible. In these circumstances, it may at first be a little difficult to determine which one is the seat of constriction. This, however, may be ascertained by observing greater tension and tenderness about the neck of the strangulated than of the unconstricted hernia.

5. The co-existence of **Early Pregnancy**, or a **threatened Miscarriage**, may obscure the diagnosis, the Surgeon possibly being in doubt whether the vomiting is dependent on the state of the uterus or on the strangulation of the hernia. Here, however, the character of the vomiting, the absence of complete obstruction, and the general condition of the patient will serve to exclude strangulation.

Besides these various conditions of hernia, which may be confounded with strangulation, there are other tumours which may be mistaken for this disease; but these we shall have to consider when speaking of the special forms of hernia.

In connexion with the diagnosis it may be pointed out that the absence of the general symptoms above described, does not prove that the contents of a hernial sac are not strangulated. It has already been stated that the symptoms may be obscure in cases of partial enterocele and of strangulated omental hernia, and the same is true when the hernial sac contains only such structures as the vermiform appendix, the ovary, or the Fallopian tube.

**TREATMENT.**—The treatment of strangulated hernia is one of the most important subjects in surgery. The object to be accomplished is the removal of the constriction from the strangulated hernial tumour. This is effected either by the Reduction of its Contents by Taxis; or by the Division of the Stricture or Herniotomy.

**Taxis.**—By taxis is meant the various manual procedures employed in order to reduce the hernia. When properly employed in suitable cases it is seldom attended with any serious consequences. I have never myself seen it followed by death; and out of 293 cases of hernia reported by Luke, as having been reduced by taxis in the London Hospital, none died. It must not, however, be concluded that taxis is to be regarded as a mode of treatment to be lightly undertaken, and its routine adoption in all cases cannot be followed by other than disastrous results. In the Reports of University College Hospital one fatal case is recorded in which death from ulceration and

perforation of the gut at the seat of constriction followed reduction by taxis, and another in which death occurred from enteritis with profuse diarrhoea, followed by collapse. Taxis is not unfrequently followed by a rather sharp attack of peritonitis, which might probably, in some instances, prove fatal ; in one instance I have seen it followed by very abundant hæmorrhage from the bowel, probably owing to the rupture of some of the congested vessels of the strangulated portion of the gut. Actual rupture of the bowel has in rare instances been caused, and reference will subsequently be made to various conditions in which, although the hernia appears to be reduced, the real obstruction is not relieved.

It is obvious that no just comparison of taxis and herniotomy can be made from the relative mortality of the two methods, for whereas taxis is attempted only in the more favourable cases, herniotomy is often performed in desperate, if not absolutely hopeless, cases. At the present day, when the mere exposure of the hernia and division of the stricture involve very little additional risk, taxis is employed much less extensively than formerly, and in many cases the Surgeon will be wise to resort at once to operation, rather than run any danger of increasing the already damaged state of the gut by his own efforts at reduction. It is extremely difficult to lay down any definite rules for the guidance of the Surgeon in selecting cases suitable for taxis, because not only is the patient's history often misleading, but the character of the symptoms may be a very imperfect indication of the condition of the gut. When the parts over the hernia are inflamed, or if there is reason to fear, from the duration of the strangulation or from the symptoms, that gangrene has occurred, it need hardly be said that the use of taxis is unjustifiable. In ordinary cases in which the strangulation is believed to be of only a few hours' duration taxis may fairly be tried, but in some instances in which a small hernia has been at once formed and strangulated by a single straining effort and is accompanied by very acute symptoms, it is wiser to proceed at once to operation. When symptoms of strangulation occur in a hernia which has long been irreducible, the failure to reduce it completely by taxis will often leave such doubt as to whether or not the strangulation is relieved that herniotomy will prove a much more certain method of treatment. Vigorous taxis is certainly contra-indicated when any doubt exists as to the true nature of a supposed hernia.

In using taxis great care should be employed, and no undue force should be had recourse to. It must be borne in mind that there are two obstacles to overcome—the resistance of the parts around the ring, and the bulk of the tumour. The first may be somewhat diminished by relaxing the abdominal muscles, and consequently diminishing the tension of the tendinous apertures and fasciæ of the groin. In order to effect this, the patient should be placed in a proper position, the body being bent forwards, and the thigh adducted, and semi-flexed upon the abdomen ; the Surgeon may then, by employing steady pressure on the tumour, endeavour to squeeze out some of the flatus from the intestine, and thus to effect its reduction. In doing this, the neck of the sac should be steadied with the fingers of the left hand : whilst, with the right hand spread over the tumour, the Surgeon endeavours to push it backwards, using a kind of kneading motion, and sometimes in the first instance drawing it slightly downwards, so as to disentangle it from the neck of the sac. The direction of the pressure is important ; it should always be

in the line of the descent of the tumour. These means may be employed as soon as the patient is seen by the Surgeon, when, by steadily carrying on the taxis for a few minutes, he will perhaps hear and feel a gurgling in the tumour, which will be followed by its immediate reduction. If the patient be thin, and the outline of the aperture through which the hernia escapes tolerably defined, the protrusion may be reduced, after failure of the taxis in the ordinary way, by passing the tip of the finger or the nail under the edge of the ring, and pulling this firmly and forcibly on one side, so as to steady and at the same time dilate it, pressure being kept up on the tumour with the other hand. This manœuvre can be practised with more facility and success in femoral hernia, where the upper edge of the saphenous opening is sharply defined, but may also successfully be had recourse to in inguinal and umbilical protrusions.

No good can ever be effected by violence; the inflamed and softened gut can easily be bruised or even torn by being pushed forcibly against the hard resisting ring. A few minutes will generally suffice to show whether further taxis is likely to prove successful, and much harm may follow prolonged efforts. If taxis has been fairly used by another Surgeon it is better not to repeat it.

*Auxiliary Measures.*—If a careful trial of taxis has been thought justifiable but has failed to reduce the hernia, the patient's consent to an operation should be obtained and an anæsthetic administered. The choice of the anæsthetic in such cases has been considered in Vol. I., p. 35. Where complete muscular relaxation is produced, it occasionally happens that the hernia slips back with very slight manipulation, but if this does not happen the Surgeon should proceed at once to herniotomy. All other methods of treatment which occupy valuable time and delay the operation must, as a general rule, be condemned. If taxis has failed in the case of a hernia which is seen almost immediately after the occurrence of strangulation, and if there is unavoidable delay in obtaining an anæsthetic, an ice-bag may be applied over the hernia. This sometimes succeeds in effecting reduction, and is assisted by placing the patient flat on his back and slightly raising the foot of the bed. The application of ice to a hernia containing damaged intestine is likely to deprive the gut of such vitality as it still possesses. The use of a hot-bath may be reserved for the very rare cases in which consent to an operation is refused.

All Surgeons will acknowledge the truth of the remark of the late Hey of Leeds—that he had often regretted performing this operation too late, but never having done it too early. It is true that cases have been recorded, in which after four or five days of treatment the hernia has gone up, but it is very rare to meet with such cases in practice; and, in all probability, in delaying the operation in the hope of finding one such case, the lives of dozens of patients would be sacrificed. Luke showed, as the result of the experience at the London Hospital, that the ratio of mortality increases in proportion to the length of time during which the strangulation is allowed to continue. Of 69 cases of strangulated hernia operated upon within the first 48 hours of strangulation, 12 died, or 1 in 5·7; whilst of 38 cases operated on after more than 48 hours had elapsed, 15 died, or 1 in 2·5. The same point is well illustrated by 129 cases of strangulated inguinal and femoral hernia abstracted by Macready from the tables of Reichel and Habs: 12·5 per cent. died after one day's strangulation or less, 26·1 per cent. after 2 days, 36·3 per cent. after

3 days, and 44 per cent. after 4 and 5 days. Indeed, one chief reason of the greater mortality from operations for hernia in hospital than in private practice, probably arises from the fact that much valuable time is frequently lost before assistance is sought, or in fruitless efforts to reduce the swelling before the patient's admission. Not only is time lost in this way, but the bowel is often bruised, so that inflammation is more likely to follow reduction. The mortality in operations for strangulated hernia performed within twenty-four hours of the descent of the gut, with antiseptic precautions, or even with common attention to cleanliness, is so small, that it may be said to be almost inconsiderable.

In certain cases of large umbilical or inguinal hernia occurring in feeble or elderly people, the strangulation is of a very gradual and passive character, and it may be difficult to decide if strangulation really exists or whether the symptoms are not due to simple incarceration. In such herniæ, which usually contain extensively adherent bowel and omentum, herniotomy may be a very formidable proceeding. In addition to taxis certain other measures may sometimes be tried in these cases.

It is a useful practice to commence the treatment by the administration of a large enema; which, by emptying the lower bowel, will alter the relations of the abdominal contents, and may materially facilitate the reduction of the tumour. The best enema is one of gruel and castor-oil, with some spirits of turpentine added to it; it should be injected through a full-sized tube, passed high up into the gut, and with a moderate degree of force. In administering it, care must be taken that no injury be done to the bowel. It would scarcely be necessary to give such a caution as this, were it not that I was once summoned by two very excellent practitioners, to see a woman with strangulated hernia, to whom an enema of about two quarts of tepid water had been administered; and as this had not returned, and did not appear to have gone up the bowel, they suspected that it must have passed out of the rectum into the surrounding areolar tissue. As the patient, however, did not seem to be suffering from this cause, and as the symptoms of strangulation were urgent, I operated on the hernia. Death suddenly occurred, apparently from exhaustion, in about eight hours; and it was found that the rectum had been perforated, and the fluid injected into the meso-rectum, separating the gut from the sacrum, whence it had extended into the general subperitoneal areolar tissue; some of the water appeared to have entered the peritoneal cavity also.

The ice-bag may safely be tried in some cases of this nature, and in very large herniæ reduction has been effected by the uniform pressure of an elastic bandage passed several times round the tumour.

**Persistence of Symptoms after Reduction.**—After the reduction of the hernia by taxis, the symptoms of strangulation may continue unabated. This may arise from the following conditions: 1. The hernia may have been reduced in mass. 2. An internal strangulation has existed within the sac, the taxis having overcome the external stricture, but failing to influence that within. 3. The gut may have been so severely nipped or strangulated for so long a time, that as soon as the constriction of the vessels is relieved, the phenomena of acute inflammation manifest themselves, with complete arrest of peristaltic movement. This condition, as before stated, may end in gangrene. 4. The sac may be of an hour-glass shape, lying partly within the abdomen and partly outside, and in the apparent reduction the gut may have been merely squeezed

from the outer part of the sac into that lying within the cavity of the abdomen. 5. A second hernia may exist in a state of strangulation, which has escaped detection. 6. Rushton Parker has recorded a case in which apparent reduction was effected by merely forcing the contents back from a small knuckle of gut uniformly adherent by recent adhesions to the sac. 7. The gut is reduced, but being adherent to the neck of the sac, it is bent upon itself so as to occlude its lumen.

The accident known as "**reduction en masse**" needs special consideration. It was first described by the French surgeons of the last century, but received little notice in this country until attention was drawn to it by Lake. In the ordinary form the sac, with its contents still in a state of strangulation, is forced back into the abdominal cavity into the subserous areolar tissue behind and beneath the parietal peritoneum, between it and the abdominal muscles. A second form of reduction in mass was first described by Birkett. In this variety the sac is not torn from its connexions, but it is ruptured, usually at its posterior part near the neck, and the contents of the sac, still strangulated by the neck, are forced through the rent into the subperitoneal tissue. The reduction in mass has been far more frequently observed in cases of inguinal than in those of any of the other varieties of hernia. It has only very rarely been met with in femoral herniæ, and, so far as I know, not in any other form of the disease. The comparative frequency of its occurrence in inguinal herniæ is doubtless due to their large size, and loose areolar connexions. The accident has more often occurred from the patient's own efforts at reducing a strangulated hernia, than from those of the Surgeon. It is a remarkable fact that, in most of the instances in which it has occurred, only a very slight degree of force appears to have been employed; and the accident would seem to have resulted from the adhesions between the sac and the neighbouring parts being much weaker than natural, so that a moderate degree of force caused the whole to slip through the canal. It may, however, occur from the Surgeon's efforts, if these be too forcible or long-continued.

The **Diagnosis** of these several conditions may possibly be made by attention to the following points. In the *reduction in mass* the tumour has slipped up without any gurgle; there is a complete absence of that fulness of the part which is occasioned by the presence of the empty sac; the abdominal ring is peculiarly open, much larger than usual, and somewhat rounded; on pushing the finger into the canal, this will be found quite empty; but in some cases, on deep pressure with the finger, especially when the patient stands up or coughs, a rounded tumour may be indistinctly felt behind the ordinary seat of the hernia. In the case of *internal adhesions* there will have been no gurgling, but the canal is still filled by the sac; the abdominal apertures are not preternaturally patent and distinct. In the case of *extreme nipping* and consequent inflammation and paralysis of a portion of the gut, gurgling will have been felt and heard in effecting the taxis, which does not happen in either of the other conditions, and the symptoms of intestinal obstruction will not be quite complete. The vomiting will lose its stercoraceous character, and probably some flatus will pass. An *hour-glass sac* is met with only in old inguinal herniæ, and appears to arise from a partial reduction in mass. Four cases of this kind have occurred in University College Hospital. In each apparent reduction was easily effected, with slight gurgling. The protrusion readily re-appeared, and was easily put back again. The nature of the case

was recognized only after operation performed for persistence of symptoms in three cases, and after death in the fourth. In the case of the *co-existence of a second hernia* in a state of strangulation, the cause of the continuance of the symptoms may be ascertained by careful examination of the abdominal walls. It is especially the co-existence of a small femoral with a large umbilical or inguinal hernia that is apt to be overlooked. This I have seen happen in a very fat person. A man was admitted into the hospital with strangulated inguinal hernia. It was reduced by the house-surgeon, but the symptoms persisted, and the patient died unrelieved, there being no indication for operation. After death a very small piece, half a knuckle, of intestine, was found strangulated in the crural canal of the same side. The patient being extremely fat, this strangulation was not detected, and could not be recognized during life. The folds of the groin should be very carefully examined in all these cases.

The **Treatment** of these different conditions is full of anxiety and difficulty to the Surgeon. The difficulty depends chiefly upon the uncertainty of the diagnosis. The Surgeon has to decide whether the case requires immediate operation, and if so, whether this shall consist of an incision in the region from which the hernia has been reduced or of an exploratory laparotomy. The only condition in which no operation is required, is that in which the gut after reduction remains for a while more or less paralysed, on account of the extreme degree of strangulation to which it has been exposed. In the slighter forms of this condition, although the vomiting may continue after the operation it ceases to be stercoraceous, supposing it to have been so before, and the passage of flatus shows that the complete obstruction is relieved. The length of time during which the congested condition of the bowel will continue after reduction, is very considerable. In a case of strangulated femoral hernia under my care, reduction was effected, but, strangulation recurring at the end of twelve days, an operation became necessary, and the patient died on the eighth day after it, or the twenty-first from the first strangulation. On examination, the small intestine was found congested in two portions, each of which was about eight inches in length; several feet of healthy gut intervening between them. One of these lay opposite the wound, and was evidently the intestine that was last strangulated. The other was altogether away from the seat of operation, but was equally darkly congested, being almost of a black colour, and was clearly that portion which had been constricted some time previously, and which, although twenty days had elapsed, had not as yet recovered itself. In more severe degrees of this condition, the paralysed segment of bowel acts as a complete block, and the symptoms continue with such urgency that only an exploratory operation can show whether or not a mechanical obstruction still exists unrelieved.

The rule of practice which is usually adopted in such cases consists in exploring the region from which the hernia has been reduced. In the case of an *inguinal hernia* the first incision should be made so as to expose the external abdominal ring which, if reduction in mass have occurred, will be found peculiarly wide and open. The inguinal canal must next be laid open, and the parts contained within it carefully examined. If no appearance of a hernial sac be found, but the cord be distinctly and clearly seen, still further presumptive evidence will be afforded of the reduction having been effected in

mass; for, if the hernia have been put back in the usual way, the sac will necessarily be left in the canal, and will preserve its usual relations to the cord. This supposition will be strengthened almost to a certainty if it be found that the "condensed cellular capsule immediately investing the sac," as it is termed by Luke—in other words, the condensed and laminated subserous areolar tissue—has been left in the canal. An opening made into this will, as that Surgeon observes, allow the finger to be brought into contact with the hernial tumour itself. Should, however, this condensed areolar tissue not be found, it must not be concluded that no hernia is present, inasmuch as this investment may have been accidentally absent. The finger should then be passed into the internal ring, which will probably be found open, and should be carried from side to side; the tumour, if present, will be detected lying externally to the peritoneum behind the abdominal wall. When found, it must be brought down into the canal by enlarging the ring; it must then be opened, its contents examined, and the stricture in its neck divided. The intestine that has been so strangled must be dealt with in accordance with the rules to be subsequently laid down. If the tumour cannot be readily brought down so as to allow of an examination of it and its contents, firm pressure may be made upon the abdomen, so as to cause it to protrude. If it still do not come down, it must be opened, and the stricture cautiously divided within the abdomen with a sheathed bistoury.

Should the hernia not have been reduced in mass, the sac should be opened, and possibly a small knuckle of gut may be found gripped at the inner ring, which, if not gangrenous, may be reduced. If the sac be empty the wound may be sufficiently enlarged upwards to allow an examination of the parts about the neck of the sac, where possibly a band or adhesion may be found by the division of which the obstruction may be relieved. If nothing be found the coil of intestine near the neck of the sac may be drawn out and examined. If this be gangrenous it must be treated by the formation of an artificial anus or by resection (see p. 853). Should the gut be only congested and swollen it may be returned into the abdomen in the hope that it will gradually recover. In two cases at University College Hospital in which this treatment was adopted, nothing but a coil of congested paralysed intestine was found, and complete recovery followed; in each case the operation might have been avoided if it had been possible to recognize from the symptoms the actual condition which existed. If the condition of the gut be so bad that the possibility of recovery seems doubtful the lower end of the wound may be left open, and the chance thus given to the patient of the formation of an artificial anus if sloughing of the intestine occur; a result that I have more than once witnessed about the fourth or fifth day, the patient ultimately recovering.

In the case of a *femoral hernia* the first part of the treatment is the same, but if nothing be found in the crural canal to account for the symptoms the wound cannot be conveniently extended upwards so as to open the abdominal cavity. If, therefore, it be determined to explore the inner aspect of the ring, this may be done by an incision at the outer border of the rectus or in the middle line.

An alternative treatment in the cases under consideration consists in proceeding at once to a median laparotomy below the umbilicus. From such an incision it is possible to examine both inguinal and femoral, and even the obturator openings without difficulty; and in cases where the diagnosis is

altogether uncertain the median incision undoubtedly presents considerable advantages. Thorburn has recorded two cases, and Barker a third, in which *reduction en masse* was successfully treated by median laparotomy. In Thorburn's first case the intestine was liberated by gentle traction, and in the second case by notching the neck of the sac. In Barker's case the constricting neck of the sac was divided with scissors, and after releasing the bowel the sac was turned inside out, ligatured with silk and removed.

When a second strangulated hernia exists, it, of course, must either be reduced by the taxis, or the operation practised on it.

#### OPERATION FOR STRANGULATED HERNIA. HERNIOTOMY.

All operations for hernia should be performed with efficient antiseptic precautions. The Surgeon and his assistants must first carefully clean their hands (Vol. I., p. 324), and the sponges and instruments must be disinfected as already described (Vol. I. p. 40). The skin for some distance around the seat of the incision must be shaved, cleaned and disinfected. The wound should be occasionally irrigated with carbolic lotion (1 in 40) or perchloride of mercury (1 in 2000), or other antiseptic solution, care being taken that the fluid does not pass into the peritoneal cavity; a basin of carbolic acid lotion should be at hand, into which the Surgeon should dip his hands before introducing the finger into the abdominal cavity. Should a coil of intestine be unavoidably exposed for any length of time, it may be covered with a piece of gauze soaked in a warm 1 in 40 solution of carbolic acid. In all cases the patient's extremities must be covered with warm blankets, and no more of the body exposed than is necessary.

The only operation which will be described is that in which the sac is opened before the stricture is divided, so that the condition of the contents may be accurately determined. Before the introduction of antiseptics this was a serious procedure, and, as in many cases, the stricture is seated outside the neck of the sac, it is not always necessary for the reduction of the hernia. The operation without opening the sac was performed by Petit as long ago as 1718, and was subsequently advocated by Aston Key and Luke. At the present day, however, the additional risk is so small that the sac is almost invariably opened in order that the Surgeon may avoid the possibility of reducing gangrenous gut or gut which is still in a state of strangulation by bands of adhesion or by inclusion in an omental aperture.

It may, however, happen occasionally that the Surgeon may be called upon to operate in an emergency without the proper means of ensuring asepsis, and under such circumstances I am decidedly of opinion that opening the sac should if possible be avoided whenever the hernia has not been long strangulated and presents no signs of gangrene, and more especially when it is femoral or umbilical.

When an old irreducible hernia of large size becomes strangulated it is usually better to avoid opening the sac if possible, as the contents cannot be completely reduced, and owing to the difficulty in dressing such cases septic inflammation may follow, terminating in fatal general peritonitis. In these cases, as Luke has pointed out, it rarely happens that the old adherent parts are seriously strangulated, but the whole mischief seems to be occasioned by the new protrusion, which is tightly nipped; and if this can be liberated and

reduced, the Surgeon has done all that need be accomplished. The evidence of the reduction of the recent protrusion, although the old adherent and irreducible hernia be left, is usually sufficiently clear; the portion of gut returning with a slip and a gurgle, with considerable diminution in the general tension of the tumour.

**OPERATION.—Exposure of the Sac.**—The patient must be placed on a table of convenient height and brought to the edge of it. The dissection of the hernial coverings in layers anatomically arranged is never done at an operation. The Surgeon proceeds as follows: An incision of sufficient length is made over the neck of the sac; this may be best done by pinching up a fold of skin, pushing the scalpel through its base with the back of the instrument turned towards the hernia, and then cutting upwards (Fig. 796). A linear incision is thus made, which may be extended at either end if necessary; the dissection is then carried through the superficial fascia and fat with the scalpel and forceps. If any small artery spout, it should be tied at once, or seized in forcipressure forceps,

Fig. 796.—Operation for Hernia: Division of the Skin.

Fig. 797.—Operation for Hernia: Incision of Subserous Areolar Tissue.

lest the bleeding obstruct the view of the part in the subsequent steps of the operation. As the Surgeon approaches the sac, greater caution is required, particularly if the subserous areolar tissue be dense, opaque, and laminated. The Surgeon must pinch this up with the forceps, make a small incision into it, introduce a director, and lay it open upon this, or on the finger (Fig. 797). If it be thin and not opaque, so as to admit a view of the subjacent parts, he may dissect it through with the unsupported hand. In this way he proceeds until the sac is reached, which is usually known by its rounded and tense appearance, its filamentous character, and its bluish colour. In some cases the Surgeon thinks that he has reached the sac, when in reality he has only come upon a deep layer of condensed areolar tissue in close contact with it: here the dull and opaque character of the tissue and its more solid feel, together with the absence of the peculiar tension that is characteristic of the sac, will enable him to recognize the real state of things. In other cases, the sac is so thin, and the superficial structures are so little condensed, that the Surgeon may lay it open in the earlier incisions before he thinks he has reached it. In these circumstances a portion of the intestine protruding

might be mistaken for the sac. This dangerous error may be avoided by observing the highly polished appearance presented by the dark and congested gut, and the non-existence of any adhesions between its deeper portions and the tissues upon which it lies. If the sac be prematurely opened, the escape of fluid will indicate this; and if omentum protrude, its granular appearance and peculiar feel will at once cause its recognition.

**Opening the Sac.**—The sac, having been exposed, must be carefully opened; this should be done towards its anterior aspect; and, if it be a small one, at its lower part. It may best be done, if the sac be not very tense, by seizing a portion of it between the finger and thumb, and thus feeling that no intestine is included; a small portion of it is then pinched up with the forceps, and an opening is made into it by cutting upon their points with the edge of the scalpel laid horizontally. This may be rather difficult if the sac is tensely distended with fluid. In these cases, the fluid sometimes squirts out in a full jet, and occasionally in a very considerable quantity. I have seen at least a pint of slightly bloody serum escape on opening the sac of an old inguinal hernia which had become strangulated. Most frequently, however, there is not more than from half an ounce to an ounce; and sometimes the quantity is considerably less than this. If the fluid be clear and transparent, of a yellow tint like serum, it is a good sign, as probably no great amount of con-

Fig. 798.—Broad and narrow Director on which the Scar may be divided.

gestion has taken place. If reddened by extravasation of blood, it is an evidence of increased congestion; and the deeper the discoloration, the browner, the more muddy the fluid, the greater probably has been the congestion or inflammation of the strangulated parts. In some instances scarcely any fluid exists; and then it becomes necessary to proceed with extreme caution in opening the sac, as the gut or omentum is applied closely to its inner wall. In such cases as these the sac is not unfrequently sufficiently translucent to enable the Surgeon to see its contents through it; and he should then open it over the omentum, or any small mass of fat which he may observe shining through it. The opening, when once made into the sac, may be extended by the introduction of a broad director (Fig. 798), upon which it is to be slit up to a sufficient extent to allow the examination of its contents.

**Division of the Stricture.**—The next point in the operation is the division of the stricture; and this requires considerable care, lest injury be done to the neighbouring parts of importance, or the gut be wounded. Vessels and structures in the vicinity of the stricture are avoided by dividing it in a proper direction, in accordance with ordinary anatomical considerations, which will be described when we come to speak of the special forms of rupture. All injury to the intestine is prevented by introducing the index finger of the left hand up to the seat of stricture, insinuating the finger-nail underneath it, and dividing the constriction by means of a hernia-knife having a very limited cutting edge (Fig. 799). If a director be used to guide the knife, the intestine will be in considerable danger, as the instrument may be slid under that portion of it

which lies beneath the stricture ; or the tense gut, curling over the side of the groove, may come into contact with the edge of the knife. These accidents are prevented by using the finger as a director, and slipping the hernia-knife (which should not have quite so long a probe-point as those usually made)

Fig. 799.—Hernia-knife.

along the palmar surface of the finger, upon its flat side (as represented in Fig. 800) : the finger serves to keep the bowel out of the way, and detects any part that may be interposed between the edge of the knife and the stricture.

During the division of the stricture, the protruding portions of intestine must be protected from the knife. The operator may spread his left hand

Fig. 800.—Mode of using the Hernia-knife.

over them in such a way that they cannot be touched by the edge of the instrument : or they may be protected by an assistant.

In some cases the stricture is so tight that it is at first almost impossible to get the edge of the nail underneath it. The Surgeon will, however, generally succeed in doing so, by directing his assistant to draw down the coil of

intestine, so as to loosen it, as it were, from underneath the stricture ; he will then usually succeed in passing his finger up in the middle of the coil, where the mesentery lies. As soon as the blunt end of the hernia-knife has been passed under the stricture, its sharp edge must be turned up, and the constriction divided in a proper direction, to a very limited extent, from one-eighth to a quarter of an inch.

**Reduction.**—The intestine and omentum, having been examined, must be dealt with according to the condition in which they are found ; as will subsequently be described. If these structures be sufficiently healthy to admit of reduction, the intestine should first of all be replaced. This must be done by pushing it back with as much gentleness as possible, and chiefly by using the index fingers. When it has slipped up into the abdomen, the omentum must be returned in the same way. Care should be taken that the margins of the sac are firmly held down by means of a pair of forceps ; lest it, together with its contents, be returned *en masse*, the stricture being undivided. After reduction, the Surgeon should pass his finger through the neck of the sac, and feel that all is clear.

**Treatment of the Sac.**—As a general rule, the operation should be completed by closing the neck of the sac, and, if possible, the ring, as in the radical cure of a reducible hernia. The details of this part of the operation vary with the variety of the rupture, and will be described with the special herniæ. There are, however, many exceptions to the rule. It may happen that the

Surgeon is obliged to operate without the means of carrying out efficient antiseptic treatment; it is wiser then not to attempt a radical cure. If the patient be much exhausted, or be very old and feeble, or suffering from bronchitis, the operation should be concluded as quickly as possible, as the prolonged administration of the anæsthetic and exposure necessitated by attempting a radical cure might turn the scale against him. Lastly, if there is the slightest doubt as to the vitality of the gut, the ring should not be closed, as should gangrene or ulceration occur after reduction, the patient's only chance of life lies in adhesion of the damaged gut to the ring, and in the formation of an artificial anus at the wound. The experience of recent years has clearly shown that in properly selected cases the patient's danger is not increased by concluding the operation with a radical cure. If no means be taken to close the neck the opening in the sac heals readily under the pressure of the dressing, but obliteration by adhesion of its sides rarely occurs, and consequently the hernia returns when the wound is healed.

**Treatment of the Wound.**—After the operation is completed, whether the sac be removed or not, the wound must be brought together with sutures, and unless it is perfectly dry it is better to introduce a small tube at the lower angle. Any efficient antiseptic dressing may be used, and care must be taken that it surrounds the wound for some distance. Uniform elastic pressure is best obtained by a large wool-dressing firmly secured with a bandage, and a single turn of an elastic bandage may conveniently be passed over the abdominal opening to act as a truss. In the absence of other dressings, simple dry lint or cotton-wool may be used. Primary union occurs in most cases, and unless a drainage-tube has been used the dressing can usually be left undisturbed for eight or ten days. Should suppuration occur the stitches must be removed and a light antiseptic dressing applied, lest the pus, not finding a ready outlet, may either be diffused between the muscular planes of the abdominal wall, or return into the peritoneal cavity, exciting inflammation of it,—a result which I have more than once seen occur.

**After-Treatment.**—The patient should be kept quiet in bed, with the leg on the affected side bent over a pillow. From 30 to 40m. of laudanum may then be given, or  $\frac{1}{4}$  to  $\frac{1}{2}$  gr. of morphia hypodermically. If the strangulation has been of very short duration—under 24 hours—and the gut but little congested, the patient may be left without further medical treatment until the bowels act by themselves, unless this be delayed for five or six days, when a castor-oil and gruel enema may be given. In all cases in which the strangulation has been of longer duration and more severe, the bowels must be kept confined by small doses of opium till the fourth day at least. The opium may then be discontinued if there is no abdominal tenderness or other bad symptom, and the bowels allowed to act naturally. If they do not act before the end of a week and the patient is well in other respects, an enema may be given. It is of very great importance not to administer any purgatives. If the mechanical obstruction has been removed the bowels will be sure to recover their proper functions; though, in consequence of the gut having been severely constricted by the pressure of the stricture, it may require to be left quiet for a few days before it can recover its peristaltic action. The administration of purgatives, by still further irritating it, will increase the risk of inflammation, and will probably do much harm. The patient, of course, must be kept upon the simplest and most unirritating

diet—indeed, he should be allowed only barley-water and ice for the first day, and afterwards some beef-tea or chicken-broth; milk should be avoided, as it coagulates in the stomach and is not easily digested. No solid food must be given till the bowels have acted, and all risk of peritonitis has passed.

The *mortality* after the operation for strangulated hernia is influenced chiefly by the length of time which has elapsed before it is undertaken (see p. 840). Of 132 consecutive cases operated upon in University College Hospital during the ten years 1881 to 1890, 37 died, giving a general mortality of 28 per cent. The result is also greatly influenced by the age of the patient; being very much more favourable in the earlier than in the later periods of life. Of 1,063 cases collected by Macready from the Reports of St. Bartholomew's, St. George's, St. Thomas's, and University College Hospitals, 33 were under ten, and of these 25 recovered and 8 died; between ten and twenty, 19 recovered and 5 died; between twenty and thirty, 83 recovered and 17 died; between thirty and forty, 106 recovered and 28 died; between forty and fifty, 165 recovered and 72 died; between fifty and sixty, 127 recovered and 94 died; between sixty and seventy, 102 recovered and 96 died; and above seventy, 44 recovered and 72 died.

Bronchitis with emphysema is a very serious and not uncommon complication, the strangulation being often due to the cough. It is frequently aggravated to a fatal degree by the anæsthetic and the exposure during the operation. In these cases chloroform should be used in preference to ether. Obesity, also, has a very unfavourable effect. The depth of the wound in fat people adds to the difficulty of drainage, and the discharges, if allowed to decompose, readily soak into the subperitoneal cellular tissue, and give rise to diffuse cellulitis with sloughing.

ACCIDENTS AND MODIFICATIONS OF THE OPERATION.—The operation having thus been described, we have next to consider in detail certain accidents attending it, or modifications which may be required; such as Peritonitis, Acute Enteritis, the Management of the Intestine according to its conditions, the Management of Adhesions and of the Omentum, Wounds of the Intestine and of Arteries, Sloughing of the Sac, Artificial Anus, and Faecal Fistula.

**Diffuse Peritonitis** is a most serious complication after operations for strangulated hernia. It very rarely exists at the time of the operation. In a certain number of cases it arises from the introduction of septic matter into the cavity of the abdomen from the wound either at the time of the operation or at a later period should suppuration take place. In other cases it is dependent upon the condition of the gut at the time it is reduced. Even if it be actually gangrenous it may rapidly become surrounded by firm inflammatory exudation, and diffuse inflammation may thus be prevented. More commonly this fails, the inflammation extends more widely, and the quantity of the exudation becomes so great that the healthy part of the peritoneum cannot absorb it (see Vol. I., p. 890); septic changes then take place in the accumulated fluid; the irritating products are diffused widely, and general peritonitis results. When the gut is gangrenous, and probably if it be very acutely inflamed as the result of long strangulation, the surrounding inflammation of the peritoneum may assume a septic form, the infection taking place from within the gut. The first cause can be obviated by the use of antiseptics during the operation, but

it is evident that these can have no influence when the source of infection comes from within the gut.

The *Symptoms* vary much in different cases. Sometimes all the ordinary signs of acute inflammation of the peritoneum are present. There is tenderness of a diffused character, with lancinating pains. The patient lies on his back, with his knees drawn up, has an anxious countenance, a quick, hard pulse, a dry tongue, and high fever; the respiration is principally thoracic, and tympanites soon comes on. The bowels are usually constipated, though sometimes irritated. Vomiting usually forms a marked symptom.

In other cases, especially in elderly or debilitated subjects, the local symptoms above mentioned are little marked, and the patient dies rapidly of acute septic poisoning. Two or three days after the operation, the patient becomes depressed, with a quick and weak pulse, an anxious countenance, a tumid and tympanitic abdomen, and rapid sinking of strength. In the majority of cases, however, some of the ordinary local signs of peritonitis are present. After death, the abdominal cavity will be found to contain a quantity of turbid serous fluid mixed with flakes of lymph; in many instances in such quantity as to give it a puriform appearance, and not unfrequently matting together the coils of intestine.

The *Treatment* of this complication is best conducted by the administration of opium. A pill containing gr. j of opium may be given every fourth or sixth hour, and hot fomentations should be applied to the abdomen. The patient must be confined to barley-water, milk, and ice. If the inflammation subsides, the constipation which is occasioned by it will be relieved without purgatives. The tympanites may be removed in some cases by the passage of a long tube up the rectum. If there be any reason to suppose that the peritonitis is due to perforation of the gut or the supervention of gangrene, and if the patient's general condition allow of it, laparotomy may perhaps hold out slight hope in an otherwise hopeless case.

**Localized Peritonitis** is of common occurrence. It is not characterized by any very evident symptoms beyond pain and tenderness at some point of the abdomen near the seat of the hernia. It is most commonly due to the condition of the gut when reduced, and is often conservative in character. Thus in a case in University College Hospital, in which the patient died six days after the operation from bronchitis and emphysema, the part of the intestine which had been nipped was found to be firmly adherent to the surrounding coils by recent inflammatory exudation. Opposite the seat of stricture was a small slough, about half an inch in diameter, affecting the whole thickness of the coats. It was already partly separated, and had the patient not died from other causes, would probably have been thrown off into the intestine, without fecal extravasation, owing to the firmness of the surrounding adhesions. The presence of the signs of local peritonitis are of importance only as indicating the necessity of avoiding purgatives or even enemata, until they have passed off. The patient must be kept slightly under the influence of opium to maintain rest of the inflamed bowel till all tenderness has disappeared.

**Acute Catarrhal Inflammation of the Mucous Membrane** of the intestine or **Acute Enteritis** occasionally follows reduction of a strangulated hernia whether by taxis or by operation, and may prove fatal. In this condition the vomiting continues, but becomes altered in character, being no longer

stercoraceous but often very abundant and watery, with much mucus and shreds of blackened blood floating in it. At the same time there may be profuse diarrhoea unaccompanied by any marked pain, the stools being dark and very offensive. Unless this condition be relieved by treatment collapse speedily sets in, the extremities become cold and congested, the pulse fails, and death soon follows. Acute enteritis may possibly occur as the result of prolonged obstruction, but it is far more commonly due to the administration of powerful purgatives before the nature of the case was ascertained. The best treatment is the administration of a mixture containing a sixth of a grain of morphia and ten grains of nitrate or carbonate of bismuth every four hours. At the same time no solid food must be allowed. Milk and soda-water, barley water, arrowroot, or carefully prepared chicken-broth may be given. Beef-tea is apt to increase the diarrhoea. Brandy is frequently very useful, both as a stimulant and in arresting the diarrhoea.

**Management of Congested Intestine.**—The condition in which the contents of the sac are found in a case of hernia determines greatly the course which the Surgeon should pursue after division of the stricture. Most frequently the intestine is deeply congested, being of a reddish purple, a claret, or chocolate colour. This congested state must not be confounded with gangrene—a mistake which might happen if the Surgeon were to judge of the condition of the bowel by its colour only. However dark this may be, the gut cannot be said to be gangrenous so long as it is polished and firm, free from putrescent odour, and without a greenish tinge. In cases in which there is much doubt as to whether its vitality continues or not, it has been proposed to scarify its surface lightly with the point of a lancet. If blood flow from the punctures, this may be taken as a proof of the continuance of the vitality of the part. Such a procedure as this, however, is certainly attended with some degree of danger, and can seldom be required.

When the intestine is merely congested, however deeply, the rule is, that it should be returned into the cavity of the abdomen in the hope of its ultimately recovering. This it will generally do if it have not been too much handled after the sac has been opened; but in some cases it will slough a few days after it has been reduced, and, the faeces being discharged through the wound, a faecal fistula will be formed; this may happen as late as the eighth or tenth day after the operation. In doubtful cases the wound should be left partly open and lightly dressed with some antiseptic material, no effort being made to close the neck of the sac with the idea of obtaining a radical cure.

**Management of Tightly Constricted Intestine.**—When the intestine has been very tightly nipped by a sharp-edged stricture, so that a deep sulcus or depression is left upon it, it seldom recovers, whether the whole of the coil of gut have been thus affected, or only a small portion of its diameter. It is remarkable how very quickly changes which are incompatible with life may ensue in a portion of gut that has been very tightly strangulated. I have known a coil of intestine, that had been but eight hours strangulated, so tightly constricted as not to regain its vitality after reduction (Fig. 801). In such cases the patient usually dies of peritonitis in the course of a few days without the bowels having acted, all peristaltic motion having necessarily been annihilated at the injured point. On examination after death, the constricted intestine will be found to present all the appearances of *gangrene*, being of a black or ashy-grey colour, without having any flocculi of lymph

deposited upon its surface, though these may be in abundance in the neighbouring parts. From the very unfavourable result of those cases in which there has been very tight nipping of the protruded bowel, a very cautious prognosis should be given; and, in reducing the gut after division of the stricture, care should be taken not to push it far back into the abdomen, but to leave it near the inner ring; so that, in the event of its ultimately giving way, there may be less risk of feculent extravasation into the peritoneal cavity. In those cases in which the nipping has been very severe, the sulcus being distinctly marked, and the intestine excessively dark and congested, though not certainly gangrenous, it would, I think, be better to treat it as if it were so and, after dividing the stricture, to leave it outside the ring instead of returning it; the reduction of intestine in this state being almost invariably followed by fatal peritonitis.

It is important to observe that it is not always possible to tell certainly whether the gut is past recovery or not. Intestine which has been so severely nipped as to be unable to recover its vitality, and which will fall into a state of gangrene after being reduced, may not, at the time of its exposure, present the characters of putrescence: there is no fœtor, no green or pulpy appearance, no loss of polish, nor separation of peritoneum; it is simply of a dark purple or maroon colour, and that it has been tightly nipped is evident from the sulcus upon it. There are no signs of gangrene, simply because sufficient time has not elapsed for putrefaction to set in. As, when a pile or nævus has been tied, though vitality be extinct in the part, some time must elapse before signs of putrescence manifest themselves, so it may be with a strictured gut.

Fig. 301.—Gangrene of Intestine from Strangulation.

**Management of Gangrenous or Ulcerated Intestine.**—When the intestine is actually gangrenous, the integuments covering the tumour will be infiltrated, brawny, and dusky congested, and the structures immediately overlying the sac matted together; the sac will contain fetid dark-coloured serum or pus; and the softened, lacerable, or pulpy look of the protruded part, its loss of lustre, and peculiar greenish-black or dark-grey colour, will cause the nature of the mischief to be readily recognized. In the majority of cases there will be much constitutional depression, with clammy skin, tympanitic abdomen, and brown or black tongue; but in some instances I have known all these symptoms to be absent, and the condition of the patient to present no very unfavourable features. Much difference of opinion has always existed among Surgeons as to the proper line of practice in such cases, and the question is far from settled at the present day. The treatment of those cases in which only a small ulceration exists in the bowel will need separate consideration, but when the gut is actually gangrenous in a part or the whole of its circumference, the two courses which are open to the Surgeon are: 1. To make an artificial anus, which, should the patient recover, may

possibly be closed by one of the methods subsequently to be considered.

2. To resect the gangrenous portion of the gut and restore the continuity of the gut by suture. After these methods have been described, their advantages will be discussed.

1. If it be decided to make an artificial anus, the stricture should be made in the usual way, great care being taken to disturb as little as possible adhesions which may have formed about the neck of the sac. Traill, Lawrence thought that the division of the stricture was unnecessary. Dupuytren, Astley Cooper, and Key (with whom I concur), advised that it should be done.

A free incision should next be made into the protruded portion of the gut which must be left unreduced, so as to allow the escape of fæces; the wound left open and covered by an absorbent dressing. The gut in the vicinity of the stricture is retained *in situ* by masses of plastic exudate which prevent the peritoneal cavity from being opened. If the exudate should already have given way before the operation is performed, the stricture must be divided, and the part then left unreduced, care being taken not to interfere as little as possible with any adhesions lying inside the neck of the sac.

When only a small portion of the bowel is gangrenous, the better plan is to return it just beyond the mouth of the sac, without laying it open; it should not be pushed any distance into the cavity of the abdomen. The pressure of the surrounding parts will prevent extravasation. When the slough separates, it will probably be discharged into the cavity of the abdomen, and the aperture resulting will be closed by the adhesions that extend to the margin and the abdominal wall.

A modification of the method of treatment above described consists in drawing down the bowel, excising the gangrenous portion, and uniting the ends of the gut to the skin incision.

2. During recent years, the operation of removing the gangrenous portion of the gut and uniting the intestine by suture as originally performed with success by Ramdohr in 1727, has been revived and repeatedly performed by Billroth, Czerny, Kocher, Hagedorn, and Mikulicz, and in this country by R. Parker, Lockwood, Kendal Franks, Arbuthnot Lane, and others. In adopting this method, the wound must be sufficiently enlarged to allow the intestine to be exposed well beyond the gangrenous area. The details of the operation will be the same as in enterectomy performed for ruptured intestine or for tumour (see Vol. I. p. 886, and Vol. II. p. 934). In approximating the ends, the contents of the loaded upper part of the gut should be allowed to escape, but the greatest care must be taken not to allow fæcal matter to enter the peritoneum. The incisions in the bowel should be made well beyond the damaged area, as it is far better to remove a few inches of healthy gut than to put sutures in a part which is already swollen, inflamed, and congested. No mesentery should be removed unless its vessels have suffered from strangulation.

In endeavouring to draw a comparison between these two methods of treating gangrenous intestine, it must be observed that the mortality following the formation of an artificial anus is very high. In the cases collected by Lockwood from the Reports of St. Bartholomew's Hospital, the death rate was 90 per cent.; and of 202 cases tabulated by Kendal

or 80·7 per cent., died. The two most common causes of death are peritonitis and gradual starvation, due to the escape of the contents of the intestines. Lockwood has also shown that in some cases the loaded sac fails to relieve itself on account of its paralysed condition. Even the results above mentioned do not fully indicate the mortality of this method of treatment, for a certain number of the few patients who survive die subsequently as the result of operations undertaken for the cure of the artificial

turning now to the mortality following immediate resection of the gangrenous bowel and intestinal suture, we find that of 222 cases collected by Marshall Franks, 104, or 47 per cent., died. If, therefore, we are to judge by results alone, the balance of evidence is certainly in favour of this treatment. It must, however, be concluded that not a few of these cases were selected as especially favourable, and further, it is open to question whether in all cases the gut was past hope of recovery. Allowing, however, for all the fallacies of statistics, the results certainly justify a further trial of the method. The objection, that it necessitates a prolonged operation in a patient unable to bear it, may, it is hoped, be partly removed by improved methods of intestinal suture.

It can hardly be anticipated that any treatment in these desperate cases is to be unattended with a high rate of mortality, for in the majority, the condition of the patient as well as the state of the intestine are unfavourable to any operative procedure.

In perforations of the intestine resulting from ulceration opposite the constricting band have been successfully treated by excising the perforation and closing the wound with Lembert's sutures.

**Management of Adhesions.**—This varies according to the condition of the sac, and the nature and situation of the bands. As has just been stated, if gangrene be present, especial care must be taken not to disturb adhesions that have been formed about the neck of the sac, and which constitute the most effectual barrier against feculent extravasation. When adhesions are recent, they may readily be broken down with the finger or the blade of the scalpel, and the parts then returned. When of old standing, however, they must be dealt with according to circumstances. When of the constricted form, and more particularly when seated in the neck of the sac, or stretching like bridles across its interior, they may readily be divided by a probe-pointed bistoury, or the hernia-knife. If they consist of firm attachments, they may be dissected away, by a little careful manipulation of the parts in the inside of the sac; though, if the adhesions be very extensive and of old standing, it may sometimes be more prudent to dissect away that portion of the sac which is in connexion with them than to endeavour to separate them. They may, however, attach themselves in such situations that it becomes necessary to divide them: thus I have, in a case of congenital hernia, found it necessary to dissect away some very extensive adhesions that were formed between the omentum and the testicle, and indeed had almost completely enveloped that organ.

**Adhesions** between the omentum and intestine or mesentery usually exist, consisting usually of rather firm bands stretching across the part to the other, sometimes connected with the inner wall of the intestine but in other cases confined to its contents. As these bands may

possibly be closed by one of the methods subsequently to be considered ; and

2. To resect the gangrenous portion of the gut and restore the continuity of the gut by suture. After these methods have been described, their relative advantages will be discussed.

1. If it be decided to make an artificial anus, the stricture should be divided in the usual way, great care being taken to disturb as little as possible any adhesions which may have formed about the neck of the sac. Travers and Lawrence thought that the division of the stricture was unnecessary ; while Dupuytren, Astley Cooper, and Key (with whom I concur), advised that it should be done.

A free incision should next be made into the protruded portion of bowel, which must be left unreduced, so as to allow the escape of fæces ; and the wound left open and covered by an absorbent dressing. The gut in the vicinity of the stricture is retained *in situ* by masses of plastic exudation, which prevent the peritoneal cavity from being opened. If the intestine should already have given way before the operation is performed, the stricture must be divided, and the part then left unreduced, care being taken to interfere as little as possible with any adhesions lying inside the neck of the sac.

When only a small portion of the bowel is gangrenous, the better plan is to return it just beyond the mouth of the sac, without laying it open ; but it should not be pushed any distance into the cavity of the abdomen ; the pressure of the surrounding parts will prevent extravasation. When the slough separates, it will probably be discharged into the cavity of the intestine ; and the aperture resulting will be closed by the adhesions that extend between its margin and the abdominal wall.

A modification of the method of treatment above described consists in freely drawing down the bowel, excising the gangrenous portion, and suturing the ends of the gut to the skin incision.

2. During recent years, the operation of removing the gangrenous portion of the gut and uniting the intestine by suture as originally performed with success by Ramdohr in 1727, has been revived and repeatedly performed by Billroth, Czerny, Kocher, Hagedorn, and Mikulicz, and in this country by R. Parker, Lockwood, Kendal Franks, Arbuthnot Lane, and others. In adopting this method, the wound must be sufficiently enlarged to allow the intestine to be exposed well beyond the gangrenous area. The details of the operation will be the same as in enterectomy performed for rupture of the intestine or for tumour (see Vol. I. p. 886, and Vol. II. p. 934). Before approximating the ends, the contents of the loaded upper part of the bowel should be allowed to escape, but the greatest care must be taken not to allow faecal matter to enter the peritoneum. The incisions in the bowel must be made well beyond the damaged area, as it is far better to remove a few inches of healthy gut than to put sutures in a part which is already swollen, softened, and congested. No mesentery should be removed unless its vitality has suffered from strangulation.

In endeavouring to draw a comparison between these two methods of treating gangrenous intestine, it must in the first place be observed that the mortality following the formation of an artificial anus is very high. In 40 cases collected by Lockwood from the Reports of St. Bartholomew's Hospital, the death rate was 90 per cent. ; and of 202 cases tabulated by Kendal Franks,

163, or 80·7 per cent., died. The two most common causes of death are peritonitis and gradual starvation, due to the escape of the contents of the small intestines. Lockwood has also shown that in some cases the loaded bowel fails to relieve itself on account of its paralysed condition. Even the figures above mentioned do not fully indicate the mortality of this method of treatment, for a certain number of the few patients who survive die subsequently as the result of operations undertaken for the cure of the artificial anus.

Turning now to the mortality following immediate resection of the gangrenous bowel and intestinal suture, we find that of 222 cases collected by Kendal Franks, 104, or 47 per cent., died. If, therefore, we are to judge by figures alone, the balance of evidence is certainly in favour of this treatment. It must, however, be concluded that not a few of these cases were selected as being especially favourable, and further, it is open to question whether in all the cases the gut was past hope of recovery. Allowing, however, for all the possible fallacies of statistics, the results certainly justify a further trial of the method. The objection, that it necessitates a prolonged operation in a patient little able to bear it, may, it is hoped, be partly removed by improved methods of intestinal suture.

It can hardly be anticipated that any treatment in these desperate cases will be unattended with a high rate of mortality, for in the majority, the general condition of the patient as well as the state of the intestine are most unfavourable to any operative procedure.

Small perforations of the intestine resulting from ulceration opposite the constricting band have been successfully treated by excising the perforation and closing the wound with Lembert's sutures.

**Management of Adhesions.**—This varies according to the condition of the bowel, and the nature and situation of the bands. As has just been remarked, if gangrene be present, especial care must be taken not to disturb any connexions that have been formed about the neck of the sac, and which constitute the most effectual barrier against faeculent extravasation. When the adhesions are recent, they may readily be broken down with the finger or the handle of the scalpel, and the parts then returned. When of old standing, and dense, they must be dealt with according to circumstances. When of a narrow and constricted form, and more particularly when seated in the neck of the sac, or stretching like bridles across its interior, they may readily be divided by a probe-pointed bistoury, or the hernia-knife. If they consist of broad attachments, they may be dissected away, by a little careful manipulation, from the parts in the inside of the sac; though, if the adhesions be very extensive and of old standing, it may sometimes be more prudent to dissect away that portion of the sac which is in connexion with them than to endeavour to separate them. They may, however, attach themselves in such situations that it becomes necessary to divide them: thus I have, in a case of congenital hernia, found it necessary to dissect away some very extensive adhesions that had formed between the omentum and the testicle, and indeed had almost completely enveloped that organ.

*Internal Adhesions* between the omentum and intestine or mesentery occasionally exist, consisting usually of rather firm bands stretching across from one part to the other, sometimes connected with the inner wall of the sac, but in other cases confined to its contents. As these bands may

constitute the real stricture, continuing to strangulate the gut after the division of the structures outside and in the neck of the sac, they must necessarily be divided. This operation requires great care, lest the neighbouring intestine be wounded. It is best done by passing a director underneath, and cutting the bands through with a probe-pointed bistoury; or if this cannot be done on account of their connexions, they must be seized with forceps, and carefully dissected off the gut. In a case of large inguinal hernia, containing both gut and omentum, on which I once operated, I found, after dividing the stricture, and taking hold of the omentum in order to push back the intestine, that this could not be done. On drawing the mass well down, I found high up, in the part corresponding to the neck of the sac, a band like a piece of whipcord, stretching across from the omentum to the mesentery and firmly tying down the gut. On dissecting this through, the constricted portion of intestine subjacent to it sprang up to its full diameter, and was then very readily reduced.

**Management of Omentum.**—According to the condition of the omentum it may be returned into the abdomen or excised, but under no circumstances should it be left in the sac. A small piece of healthy omentum, even though it be congested, may safely be reduced. If it is gangrenous it must of course never be returned into the abdomen, nor is reduction advisable when the omentum is indurated, congested or otherwise altered in structure. In such cases inflammation of it—*Epiplöitis*—is likely to occur, and may prove fatal from peritonitis. So also if the omentum is acutely inflamed, the inflammation is very liable to run on into a sloughy condition of the whole mass. If it is adherent to the sac, it should be excised and then either separated from the sac or removed with it.

In excising omentum it should be drawn down until a healthy unaltered part is reached, and then tied in several pieces with fine silk. None of the ligatures should be cut short until all are tied, and the omentum cut away. The stump must then be reduced just within the ring, as the constriction of this may be arresting the bleeding from an imperfectly secured vessel. If no blood flows out, the stump is drawn out again, and the ligatures cut short and allowed to retract with the stump of the omentum into the abdomen.

**Sacs or Apertures in the Omentum** are occasionally met with, in which a knuckle of intestine may become enveloped, or by the margins of which it may be strangulated. These envelopes of omentum around the gut, which were especially described by Prescott Hewett, may occur in all kinds of hernia, at least in the inguinal, the femoral, and the umbilical, and sometimes attain a large size, completely shutting in the gut. They appear to be formed in some cases at least by the adhesion of the opposite edges of floating layers of omentum around a piece of intestine, which thus becomes included. It is of importance to bear in mind the possibility of their existence, and in all cases to unravel the omentum before removing it, lest it contain a knuckle of intestine, which might be wounded in the operation.

**Cysts**, usually containing pellucid serous fluid, straw-coloured or reddened, but sometimes filled with blood, are occasionally met with in the omentum. They appear to be formed in the same way as the sacs containing intestine just described, except that they are enclosed on all sides, their serous contents being merely exudations from the peritoneal lining of the cyst. They are globular, elastic, and closely resemble in form a knuckle of intestine, occasioning

not a little embarrassment to the Surgeon ; by a careful unravelling, however, of the omentum, their true nature will be made out ; their fluid contents may then be discharged, and the omentum dealt with according to the rules already given.

**Wounds of the Intestine** may accidentally occur at two periods of the operation ; either from the Surgeon cutting too freely down upon the sac, and opening this before he is aware of what he is about ; or else, at the time of the division of the stricture, from a portion of the gut which lies beneath it getting in the way of the edge of the knife, and being nicked by it. The first kind of accident can happen only from a certain degree of carelessness ; but it is not always so easy to avoid wounding the gut, when the stricture is so tight that the finger-nail cannot be slipped under it as a guide to the hernia-knife. In cases of this kind, a very narrow director must be used ; and this is a most dangerous instrument, as, in passing it deeply out of sight under the tight stricture, a small portion of the gut may curl up over its side into the groove, and thus become notched by the knife as this is slid along it. This accident has happened to the most careful Surgeons. Lawrence relates two cases that occurred to him ; and Astley Cooper, Cloquet, Jobert, and Liston all met with it. It may be known to have occurred by the bubbling up of a small quantity of flatus and liquid feces from the bottom of the incision.

The *Treatment* of a wound in comparatively healthy gut should consist in closing it by Lembert's sutures (Vol. I., p. 885). The gut must be very carefully cleaned with some antiseptic solution before being returned. If the wound occur in gut which is softened and inflamed, the case should be treated as one of perforation from ulceration. In the case of minute punctures in the gut, Astley Cooper recommended that the margins of the wound should be seized with a pair of forceps, and a fine silk ligature tied tightly round them. This plan has been successfully adopted, and in a case in which I once used it, and in which the patient died on the fourth day from gangrene of the gut, the silk ligature was found to be completely enveloped in firm plastic exudation. It is probably safer, however, to approximate the serous layer with two or more Lembert's sutures, even though the wound be a mere puncture.

**Wound of one of the Arteries** in the neighbourhood of the sac may occur during the division of the stricture, either in consequence of some anomaly in the distribution of the vessel, or from the Surgeon dividing the parts in a wrong direction. This accident usually happens to the epigastric or to the obturator artery ; and Lawrence collected fourteen cases in which it occurred. The result in these has been very various : in some the patients have died ; in others, after much loss of blood, and consequent faintness, the bleeding ceased spontaneously. The proper *Treatment* would certainly consist in cutting down upon and securing the bleeding vessel. In the event of the Surgeon operating on a case of hernia, without having been able previously to satisfy himself as to its precise character, or if from any cause, in dividing the stricture, he have reason to dread the proximity of an artery, he may readily divide the constriction with a knife that would not easily cut an artery ; and he will find, that if he blunt the edge of his hernia knife by drawing it over the back of a scalpel, it will still be keen enough to relieve the strangulation, whilst it will push before it any artery that may happen to be in the way.

**Sloughing of the Sac** is of rare occurrence, and, when it happens, is com-

monly attended with fatal results ; it is not, however, necessarily so. It has twice happened in my practice ; and in both cases the patient recovered. In an old woman on whom I operated for femoral hernia of very large size, the sac sloughed away, exposing nearly the whole of Scarpa's triangle with almost as much distinctness as if it had been dissected ; but, although in much danger for a time from an acute attack of peritonitis, she ultimately recovered.

**Artificial Anus and Fæcal Fistula.**—When an aperture exists in the bowel by which the whole of the intestinal contents escape externally, the condition is denominated an *artificial anus*. When but a small portion so escapes, the greater part finding its way through the natural anus, a *fæcal fistula* is said to exist. The quantity of fæculent discharge necessarily depends upon the extent of destruction of the intestinal coats ; and its character on the part of the gut that is injured. The escape takes place involuntarily, and is usually continuous.

This condition may occur in several ways. Thus the gut may be accidentally wounded during the operation, and the fæces may afterwards continue to be discharged through the aperture so made ; or it may have been gangrenous, and have given way into the sac before the operation ; or the Surgeon may have intentionally laid open a gangrenous portion of intestine, so as to facilitate the escape of the fæces. In some cases in which the bowel has been severely nipped, and is dark and congested, though it have not actually fallen into a state of gangrene, it may not be able to recover itself after its return into the abdominal cavity, but will give way in the course of three, four, six, or even ten days after the operation. In these cases, a small quantity of fæculent matter is first observed in the dressings ; and gradually a greater discharge appears, until at last the fistulous opening is completely established. In such cases, it is of importance to observe that, although the bowel gives way within the peritoneum, the fæces do not become extravasated into the cavity, but escape externally. This is owing to the portion of the bowel that is nipped losing its peristaltic action, and consequently remaining where it is put back ; whilst the parts in the neighbourhood inflame, throw out a coagulable exudation, and become consolidated to each other and to the parietal peritoneum, so as to include the gangrenous portion of the gut, and completely to circumscribe it. It is consequently of great importance, in cases of this kind, not in any way to disturb the adhesions that have formed between the sides of the aperture in the gut and the neck of the sac.

The *Pathology of Artificial Anus* is commonly as follows. The edges of the aperture in the gut become firmly adherent to the abdominal wall ; and whether the whole or only a portion of the calibre of the intestine be destroyed, the apertures of the upper and lower end, though at first lying almost in a continuous line, soon unite at a more or less acute angle. These are at first similar in size, and present no material differences in shape or appearance ; as the disease becomes more chronic, they gradually alter in their characters ; the lower aperture, being no longer used for the transmission of fæces, gradually becomes narrower, until at last it may be almost completely obliterated ; whilst the upper portion of intestine becomes dilated in consequence of there usually being some slight obstruction to the outward passage of the fæces. The mesentery opposite the aperture becomes drawn out into a kind of prolongation or spur, the full importance of which was first pointed out by Dupuytren. This spur-like process projects between the two apertures, and

being deflected by the passage of the fæces, has at last a tendency to act as a kind of valve, and thus occlude the orifice into the lower portion of the gut. The integuments in the neighbourhood of such an aperture as this usually become irritated and excoriated from the constant passage of the fæces over them. In some cases, the mucous membrane lining the edges becomes everted and pouting; and, in others, a true prolapse of the gut takes place, large portions protruding. An artificial anus fully formed in this way never undergoes spontaneous cure. Besides this, which is the ordinary form of artificial anus, we must, I think, recognize at least two other varieties, both of which I have met with in practice. In one of these, the angle formed by the gut is adherent to the upper extremity of the sac which has been returned, and thus lies at some distance from the surface, so that the fæcal matter traverses a long channel before it reaches the external aperture. In the other variety the angle of the gut is fixed at a higher point within the abdomen, and the fæces find their way out through a channel bounded by agglutinated coils of intestine and layers of lymph. In both of these forms there is a considerable distance between the external opening and the aperture in the gut. Thus, then, there are three forms of artificial anus, differing from one another according to the situation of the angle of the gut in relation to the external opening and to its connexions.

When a *Fæcal Fistula* has formed, the condition of the parts is somewhat different. The aperture in the intestine consists of merely a small perforation in its coats, through which a quantity of thin fæculent matter exudes, giving rise to a good deal of irritation of neighbouring structures. In some cases, there are several apertures communicating with the gut, and extending through the skin. Fistulous openings of this kind not unfrequently undergo spontaneous cure after a few weeks or months.

**Treatment.**—If the aperture be merely a small one, with a narrow fistula leading into the gut, the chief inconvenience suffered by the patient often arises from the irritation of the skin around the opening by the continued moisture of the fæculent matter. In such cases the skin should be protected by means of zinc or boric acid ointment or eucalyptus oil and vaseline spread on lint; and the patient should wear a pad to restrain the discharge. By the pressure of this pad the aperture may sometimes be made to close. In other cases, the occasional application of the galvanic caustery or of a red-hot wire will induce contraction of its edges; and in other instances, again, a plastic operation of some kind may be required. But I confess I have not usually seen much advantage result from such operations. As the existence of an artificial anus, by interfering with nutrition, commonly gives rise to considerable emaciation, it becomes necessary to support the patient's strength by a sufficient quantity of good and nourishing food; this is of greater consequence the higher the fistula is, as the interference with the earlier stages of the digestive process, and the loss of nutritive material by the discharge of the chyme, is proportionally great. Spontaneous cure will occasionally take place, even though a perfect artificial anus exist. In a case under my care at the Hospital, a whole knuckle of intestine was gangrenous, and sloughed away, leaving an artificial anus, which discharged the greater part of the intestinal contents, but gradually contracted and closed without any local application or treatment beyond attention to cleanliness.

If the aperture become a permanent artificial anus, surgical means must be

adopted in order, if possible, to effect a cure. Many plans have been suggested for effecting this object. Mitchell Banks succeeded in curing one case by introducing a piece of thick india-rubber tubing, pushing one end up the ascending and the other down the descending tube. A piece of silk was attached to it and hung out at the artificial anus. The tube was kept in for a week at a time and inserted "twice or thrice." It was calculated that the continuous pressure of the tube would press back the spur-like process. The patient was completely cured in about two months, the opening closing without further operative interference. If this simple treatment fails, the two most important modes of cure are Dupuytren's operation and suture of the gut, with or without removal of a portion.

In Dupuytren's operation two important indications have to be fulfilled: the first is to diminish or destroy the projecting valvular or spur-like process, and thus to re-establish the continuity of the canal; and, after this has been done, the external wound may be closed, by paring its edges, and bringing them together with sutures.

The first object is accomplished by the *enterotome* (Fig. 802); this consists

Fig. 802. — Dupuytren's Enterotome.

Fig. 803. — Enterotome applied.

of an instrument something like a pair of scissors, with blunt but serrated blades, which may be brought together by acting upon a screw that traverses its handle. One blade of the instrument (*a*) is passed into the upper, the other (*b*) into the lower portion of the intestine; they are then approximated slowly, and fixed by means of the screw in such a way as to compress on each side the spur-like process (Fig. 803). Very gradually, day by day, this screw is tightened so as to induce sloughing of this projection, and cohesion of its serous surfaces. As this process goes on, the irritation caused by the instrument will occasion inflammatory exudation in the angle formed by the intestine, so that the peritoneum and mesentery become consolidated, and all opening into the peritoneal cavity is avoided. Should the spur-like process be accidentally cut through before the lymph is thrown out in sufficient quantity, the peritoneum would be opened, and death would probably ensue; hence the necessity for caution in this procedure. As soon as the blades of the instrument have come into contact, and the spur-like process has consequently sloughed away, the great obstacle to the closure of the artificial anus will

be removed; and the continuity of the canal being thus re-established, the lips of the external opening may be pared and brought together by sutures. In some cases, from the length of time that has elapsed—many years, possibly—the fistula continues permanently patent, and no treatment is available for its closure. Its existence is not incompatible with good general health. I have had two cases under my observation, in one of which, that of a woman about fifty years of age, the whole of the intestinal contents were discharged for four years through an aperture at the umbilicus, in consequence of the sloughing away of a large coil of intestine in an umbilical hernia; the other being that of a lady over eighty, who for upwards of thirty years had a faecal fistula in the right groin, consequent on an operation for femoral hernia.

In the second method of operating adopted by Dittel, Billroth, Czerny, and many other Continental Surgeons, the gut is freely exposed and dissected away from its adhesions to the abdominal wall. This must be done with antiseptic precautions. The bowels must have been thoroughly emptied before the operation is commenced. The external opening must be carefully cleaned with some efficient antiseptic, and unhealthy granulation tissue must be scraped away with a sharp spoon. The orifice of the gut must also be cleansed, and a small piece of sponge, which has been properly disinfected by carbolic lotion, may be pushed into the upper orifice to prevent the escape of any faecal matter. The opening through which the gut protrudes must then be enlarged by an incision carried in the most convenient direction, and the gut dissected away and drawn out. If the opening is on one side only and very small, it may be closed by sutures; if large, the whole affected portion of the gut is cut away. The details of this operation are described later on, as they are identical with those practised in the removal of portions of intestine for other causes. The death-rate among the published cases in which this operation has been performed is high; so it must not be lightly undertaken. If the patient suffers merely from a faecal fistula, which can easily be controlled by a pad, it would evidently be unjustifiable to submit him to the risk of such an operation. If, however, the patient is otherwise in good health, but suffering great inconvenience from the artificial anus, and other means have failed, the operation holds out a fair prospect of relief and may be undertaken.

In comparing these two methods of treating an artificial anus it will be found that resection and suture is more certain than the use of the enterotome in its results, but is also attended with a higher mortality. Thus of 111 cases collected by Körte in which the enterotome was used 11 died, and in 30 the operation failed; whereas of 39 cases collected by Makins, which were treated by resection, 15 died, and in 3 others the artificial anus was not cured. In both instances the mortality is much lower than that which has hitherto followed the treatment of gangrenous gut by immediate resection and suture; but it must be remembered, as Lockwood and Kendal Franks have very rightly insisted, that these secondary operations are performed only on those patients who escape the many dangers resulting from the formation of an artificial anus—probably only 10 to 20 per cent of the whole number (see p. 854).

**Treatment of Strangulated Hernia by Aspiration.**—Dieulafoy, in 1873, suggested that the reduction of a strangulated hernia might be effected

by removing the fluid and gaseous contents of the included portion of the gut by means of the aspirator, through a needle not exceeding  $\frac{1}{16}$ th inch in diameter, and immediately employing taxis. He recorded 27 cases, in 20 of which the treatment was successful; in the remaining 7 it was harmless. Others, however, have not succeeded in obtaining such results, and Depres sums up the experience of the Parisian surgeons by saying that one of two things happens: if a small needle be used, it becomes choked and withdraws nothing; if a large needle be inserted, fæcal extravasation frequently occurs from the puncture. In very large passively strangulated herniæ, tensely distended with gas, the introduction of a fine needle might possibly aid in reduction, and experience has shown that if it be below  $\frac{1}{16}$ th inch in diameter the risk of fæcal extravasation is scarcely appreciable. In one case in University College Hospital in which aspiration was tried, and the patient died a few minutes afterwards from other causes, neither gas nor fluid could be squeezed from the punctures at the *post-mortem* examination. In ordinary cases aspiration should never be practised in preference to the ordinary operation for hernia.

## CHAPTER LXI.

### SPECIAL HERNIÆ.

#### INGUINAL HERNIA.

By **Inguinal Hernia** is meant that protrusion which occupies the whole or a portion of the inguinal canal, and when fully formed, passes out of the external abdominal ring into the scrotum. An inguinal hernia is said to be *Incomplete*, or a *Bubonocoele*, so long as it is contained within the canal; *Complete*, when it passes out of the external ring; *Scrotal*, when it distends the scrotum; *Oblique*, when it occupies the whole course of the canal; *Direct*, when it passes forwards through a limited extent of it; *Congenital*, when it descends through an unobliterated processus vaginalis and lies in the sac of the tunica vaginalis; and *Encysted*, or *Infantile*, when it lies behind this. Inguinal herniæ constitute the commonest species of rupture, and would be much more frequent than they are, were it not for the obliquity of the canal, and the manner in which its sides are applied to one another, and closely overlap the spermatic cord. They occur with greatest readiness in those cases in which the canal is short and the apertures wide. Although these herniæ are commonly incomplete in their early stages, it is seldom that they come under observation of the Surgeon until the protrusion has passed beyond the external abdominal ring.

**Oblique Inguinal Hernia**, often called *External*, on account of its relation to the epigastric artery, passes through the whole length of the canal, from one ring to the other.

**Coverings of Oblique Hernia.**—As the hernia passes along the canal, it necessarily receives the same investments as the spermatic cord, although these are often greatly modified by being elongated, hypertrophied, and otherwise altered in appearance. If we regard the inguinal canal as consisting of a series of protrusions of the different layers of the abdominal parietes, the outermost being the skin, and the innermost the fascia transversalis with the peritoneum applied to this, it is easy to understand how the hernia in its descent has these prolongations drawn over it, thus becoming successively invested with the same coverings as the spermatic cord. Thus it first pushes before it that portion of the peritoneum which lies in the fossa just external to the epigastric vessels; it next receives an investment from the subperitoneal fat, which, uniting with the fascia transversalis, constitutes the *fascia propria* of the sac; as it passes under the internal oblique, it receives some of the fibres of this muscle, in the shape of the cremasteric fascia; and, lastly, when it reaches the external abdominal ring, which it greatly distends and renders round and open, it becomes covered by the intercolumar fascia, receiving also a partial investment around its neck from some of the expanded and thickened fibrous bands that lie near the ring, and which are always most marked upon its outer side.

**Relations of Oblique Hernia.**—The relations of the spermatic cord and testis, and of the epigastric artery, to an inguinal hernia, are of great importance. The *spermatic cord* will almost invariably be found to be situated behind or rather underneath the oblique inguinal hernia; and the *testis* will be found to lie at its lower and back part, where it may always be distinctly felt. In rare cases the elements of the spermatic cord become separated, the *vas deferens* lying on one side, and the spermatic vessels on the other. In other still rarer cases, a specimen of which is in the University College Museum, the hernia lies behind the cord and has the testis in front. In other cases, again, it may happen that the elements of the cord are all separately spread out on the back of the hernial tumour. The *epigastric artery* has the same relations to the oblique inguinal hernia that it has to the spermatic cord, lying to the inner side of and behind its neck. The pressure of large and old inguinal herniæ has, however, a tendency to modify somewhat the relations of this vessel. By distending the rings, and dragging the posterior wall downwards and inwards, they shorten the canal, and cause a great deflection of the artery from its natural course, which is changed from an oblique direction to one curved downwards and inwards, towards the outer edge of the rectus muscle.

The sac of an inguinal hernia may be formed by the unobliterated funicular portion of the processus vaginalis (p. 868), which retains its communication with the peritoneum but is shut off from the tunica vaginalis below. To such a hernia the name "*funicular*" is applied. Clinically it does not differ from an ordinary acquired inguinal hernia, and it is probable that in children it is the most common form of hernia. The sac is usually very thin, and intimately connected with the structures of the spermatic cord.

**Direct Inguinal Hernia.**—This does not pass out like the oblique through the internal abdominal ring, but pushes forwards through a triangular space, which is bounded by the epigastric artery on the outer side, the edge of the rectus on the inner, and the crural arch at its base; through this the hernial tumour protrudes, pushing before it or rupturing the posterior wall of the inguinal canal.

**Coverings of Direct Hernia.**—These vary according to the length of the canal that the hernia traverses, and the portion of the posterior wall through which it protrudes. In fact, there are at least two distinct forms of direct inguinal hernia, which differ in their relation to the obliterated hypogastric artery. One, the more common variety, is situated internal to the cord-like remains of this vessel, between it and the outer edge of the rectus. The other is situated outside this vessel, between it and the epigastric artery.

In the form of direct inguinal hernia which lies *internal to the hypogastric artery*, the protrusion takes place through that part of the posterior wall of the inguinal canal which is situated almost behind and opposite to the external ring. In this situation, the investments successively received by the hernia are, first, the peritoneum, the subperitoneal fat, and the fascia transversalis; it then comes into contact with the conjoined tendons of the internal oblique and transversalis muscles, which it may either rupture or push before it, thinned out and expanded. Most frequently these are ruptured, constituting a partial investment to the protrusion, which is most evident on the innermost part of the sac, that which is nearest the mesial line. As the hernia passes through the external ring, it receives from it the intercolumnar fascia, and lastly, it is invested by the common fascia and integuments.

In the rare form of direct inguinal hernia which lies *external to the hypogastric artery*, the protrusion may pass under the lower edge of the internal oblique muscle, and then receives a partial investment of cremasteric fascia, especially on its iliac side, as it comes into relation with the internal oblique. This form of direct inguinal hernia, therefore, receives very nearly the same coverings that the oblique does, though its investment by the cremaster is not so perfect. It does not come into relation with the conjoint tendon.

**Relations of Direct Hernia.**—In the direct inguinal hernia, the *spermatic cord* lies to the outer side of the sac; and its elements are never separated from one another, as occasionally happens in the oblique. The *epigastric artery* also is on the outer side, but usually arches very distinctly over the neck of the sac, sometimes indeed completely encircling the upper as well as the outer margin (Fig. 804).

**Incomplete Hernia, or Bubonocoele,** is usually of the oblique kind; but

Fig. 804.—Double Direct Inguinal Hernia: Neck Sac crossed by Epigastric Artery.

Fig. 805.—Double Inguinal Hernia on the same side: Oblique above, Direct below; separated by Epigastric Vessels.

Lawrence pointed out that it may be direct. It often escapes notice, but may not unfrequently be observed on the opposite side to an ordinary inguinal hernia.

**Double Inguinal Herniæ**, on opposite sides, are of very common occurrence, and they may be of the same, or of different forms. In some instances, the two forms may be observed on the same side (Fig. 805).

**Signs of Inguinal Hernia.**—The signs of inguinal hernia vary somewhat according to its character, whether incomplete, complete or scrotal, oblique or direct. In the *incomplete hernia*, a degree of fulness will be perceived in the canal when the patient stands or coughs; and, on pressing the finger on the internal ring, or passing it up through the external ring, and directing the patient to cough, a distinct impulse, together with a swelling, may be felt. In the ordinary *oblique inguinal hernia*, a tumour of an oblong or oval shape, oblique in its direction, taking the course of the canal downwards and forwards, will be felt protruding through the external abdominal ring, and

presenting all the usual signs of a hernia. So long as it is confined to the neighbourhood of the pubes, it is of moderate size; but when once it enters the scrotum, where it meets with less resistance, it may gradually enlarge until it attains an enormous bulk. The testicle, however, may always be felt with tolerable distinctness at its posterior inferior part. When of large size, these ruptures usually contain both intestine and omentum, most frequently a portion of the ileum, though the various other viscera, such as the cæcum, sigmoid flexure, bladder, &c., have been found in them. In the *direct inguinal hernia*, the symptoms closely resemble those of the oblique, except that the tumour is more rounded, and usually not so large; the neck is wider, and situated near the root of the penis, with the cord on its outer side. The oblique inguinal hernia is most common in young males, whilst the direct form is almost confined to elderly men. This appears to be owing to the imperfect closure of the funicular process of the peritoneum being the common cause of the first, and absorption of fat of the second, form.

The different forms of inguinal hernia are not unfrequently complicated with various other affections: either with other kinds of rupture, or with diseases of the cord or testis, such as hydrocele and varicocele. These complications make the diagnosis more obscure, but with care and practice it may generally easily be made out.

The **Diagnosis** of inguinal hernia is usually readily effected, the characters and position of the tumour enabling the Surgeon to determine its true nature. In most cases it is useless to endeavour to ascertain whether the hernia is oblique or direct; all old oblique herniæ having a tendency to drag the inner ring downwards and inwards, so as to bring it nearly opposite to the outer one, shortening or destroying the obliquity of the canal. Hence the direction of the neck and of the axis of the tumour in these cases so nearly resembles what is met with in the direct hernia, that the Surgeon should not be guided in an operation, more particularly in the division of the stricture, by any imaginary diagnosis. *Femoral hernia* may occasionally be confounded with inguinal; the distinguishing points between the two will be considered in the section on femoral hernia.

The diagnosis of inguinal hernia from other diseases in this vicinity has to be considered under the two conditions in which the rupture is found,—1, *in the canal*, and 2, *in the scrotum*.

1. Whilst still lying *in the canal*, inguinal hernia requires to be diagnosed from the following conditions:—*a. Abscess*, descending from the interior of the abdomen or pelvis through the canal, and passing out through the abdominal ring. The diagnosis may here be effected by recognizing the soft fluctuating feel of the abscess, which, though reducible on pressure, and descending on coughing with a distinct impulse, does not present the more solid characters and the gurgling sensation of a hernia. *b. Encysted and Diffused Hydrocele of the Cord*. In the *encysted hydrocele* there is a smooth oval swelling situated on the cord, which can be apparently reduced, being pushed up into the canal, and descends again on coughing or straining; but it may be distinguished from hernia by being always of the same size, by not being reducible into the cavity of the abdomen, by the absence of all gurgle, and by its very defined outline. If the testicle be drawn downwards the encysted hydrocele becomes fixed and is no longer reducible even into the canal. In the *diffused hydrocele* of the cord, which is an extremely rare affection, the absence of distinct impulse on

coughing, and the impossibility of returning the swelling completely within the abdominal cavity, will distinguish it from hernia. *c. Hæmatocele of the Cord* is distinguished by the soft and fluctuating nature of the swelling, the ecchymosis, the impossibility of complete reduction, and the absence of gurgling. *d. Fatty or other Tumours* occasionally form on the cord; but the circumscribed character and limited size of these swellings, the absence of impulse on coughing, and of reducibility into the cavity of the abdomen, and their fixation when the testicle is drawn down so as to put the cord on the stretch, will prove that they are not herniæ. *e. Retention of the Testis in the Inguinal Canal* will give rise to a swelling, which closely resembles incomplete inguinal hernia; and if it should happen to become inflamed in this situation, the difficulty of the diagnosis from strangulated hernia may be very considerable. In the ordinary undescended testis, the absence of that organ in the scrotum on the affected side, the peculiar sickening pain occasioned by the pressure of the tumour, the absence of gurgling, and of all possibility of reduction, will enable the diagnosis to be effected. *f. Inflamed Undescended Testis.* From this it is not always at once easy to make the diagnosis of incomplete inguinal hernia in a state of strangulation, with which indeed it may be complicated. This point in diagnosis will be more fully treated of in speaking of congenital hernia. In the meanwhile, it may be stated that the absence of *persistent* and *continuous* vomiting and constipation, the feel of the tumour, hard below, elastic above, and the peculiar testicular pain when it is compressed, will enable the Surgeon to recognize its true nature.

2. When the hernia has descended *into the scrotum*, it may be confounded with : *a. Hydrocele of the Tunica Vaginalis.* In this disease there is an oval or pyriform tumour, usually translucent, dull on percussion, unchangeable in size or shape by pressure, and having the cord clear and distinct above it, with an absence of impulse on coughing, or of gurgling in attempts at reduction. The resemblance is greater in cases in which the sac of the hydrocele is prolonged upwards into the inguinal canal. The patient will usually have noticed in hydrocele that the swelling first appeared at the bottom of the scrotum, while in hernia it descended from above. In cases of congenital hydrocele in children, in which there is still an opening communicating with the peritoneal cavity, the tumour may be diminished in size by steady pressure, but gradually returns, fluctuates, and is translucent. In these cases its translucency, and the gradual manner in which the sac is emptied and is refilled, very different from the sudden slipping up and protrusion of a hernia, enable the Surgeon to establish the diagnosis. In infants, however, it must be remembered that a hernia is often translucent, as it seldom contains omentum, and the contents of the gut may be chiefly gas. It not unfrequently happens that *hernia is complicated with hydrocele of the tunica vaginalis.* In these cases the two separate tumours can usually be distinguished, there being some degree of constriction, or of consolidation, between them. The hydrocele will present its ordinary characters of translucency, irreducibility, and circumscribed outline, and is placed chiefly below the hernia, which lies towards the upper and anterior part of the scrotum, and may be distinguished by its reducibility and impulse on coughing. It sometimes happens, as in a case which once fell under my observation, that a *hydrocele of the cord is associated with one of the tunica vaginalis and a hernia*; in such circumstances, the diagnosis requires a little care, but may be effected readily enough by separately deter-

mining the characters of the different swellings. *b. Varicocele.* Here the diagnosis may be effected in the way pointed out by Astley Cooper. The patient should be placed in the recumbent position, and the swelling reduced; the Surgeon then presses upon the external ring with his fingers, taking care to cover the whole of it, and desires the patient to stand up. If it be a hernia, the tumour cannot descend; but if it be a varicocele, it will reappear *whilst the pressure is being kept up*, the blood being conveyed into it through the spermatic arteries. *c. Tumours of the Testis.* These may be distinguished from hernia by their solid feel, rounded shape, by the absence of all impulse on coughing, and, especially, by the cord being felt free and clear above them, and the inguinal canal unoccupied. *d. Hamatocoele of the Tunica Vaginalis.* Here the cause of the swelling, its oval shape, opacity, solid feel, the absence of impulse on coughing, and the defined characters of the cord, will enable the Surgeon to make the diagnosis.

**Hernia into the Tunica Vaginalis. Congenital Inguinal Hernia.**

—After the descent of the testis into the scrotum the communication of the processus vaginalis testis with the peritoneum usually becomes obliterated; the *funicular* portion which lies in front of the cord remains only as a delicate thread of fibrous tissue, while the unobliterated *testicular* portion forms the tunica vaginalis testis. It occasionally happens that the funicular portion remains open, and along the unobliterated processus vaginalis the gut and omentum may descend into the tunica vaginalis, and thus constitute the condition known as congenital inguinal hernia (Fig. 806). It therefore differs from ordinary inguinal hernia in the fact that the sac is not a new formation. The hernia is necessarily oblique, following the course of the cord. When the testicle has imperfectly descended into the scrotum, the hernia may remain in the groin, but most commonly it reaches the scrotum.

Fig. 806.—Hernia into the Tunica Vaginalis.

The term "congenital hernia" is apt to be misleading; the anatomical condition which predisposes to the hernia is congenital, but the hernia itself is not. It not unfrequently happens, it is true, that these hernia show themselves early in life, in infants a few weeks or months old; though even at these ages the funicular prolongation of the peritoneum may be so completely occluded that the hernia which occurs is of an ordinary character. Not unfrequently, however, the hernia does not take place until a considerably later period of life than this, and may suddenly happen in the adult: thus Velpeau relates instances in which it occurred for the first time between the ages of eighteen and twenty-five. I have operated on a man about fifty years of age, in whom, on the most careful inquiry, it would appear that the protrusion had not shown itself until he was about thirty.

**Signs and Diagnosis.**—The signs of hernia in the tunica vaginalis closely resemble those of the ordinary oblique; most commonly, however, if scrotal, the tumour is much rounded, and the neck feels narrow and constricted. The testis, also, cannot be felt separate from the tumour, but is surrounded by, and, as it were, buried in, the substance of the hernia, through which it may sometimes be felt at the lower and back part of the scrotum. In an ordinary

inguinal hernia, the tenser the sac the more clearly is the testicle seen and felt outside it ; in a congenital hernia, if the sac is tense the testicle cannot be felt at all. On inquiry, also, it will sometimes be found either that the hernia has existed in childhood, or that the testis is still in the canal, or has descended later than usual. A hernia in the tunica vaginalis may be associated with a congenital hydrocele. In these cases, after the fluid has been returned into the peritoneal cavity by directing the patient to lie on his back and raising the scrotum, the portion of protruded gut may be felt and recognised by its gurgle and upward slip when reduced. This hernia may be associated with the testis, either undescending or lying at the external abdominal ring. In the first case, the hernia is, of course, incomplete ; in the second, it is scrotal. When incomplete, the diagnosis may be made by feeling a soft swelling with the ordinary hernial signs above the testis.

When symptoms of strangulated hernia occur in a person in whom the *testes have not descended* into the scrotum, the diagnosis may be very difficult. An oblong or rounded tumour, tense and painful, will be found to occupy the inguinal canal, not passing beyond the external ring, with some abdominal tenderness, and possibly nausea and constipation. The question here arises as to the nature of this tumour : Is it simply an inflamed undescended testis ? Or is it an undescended testis, inflamed or not, as the case may be, having a knuckle of strangulated intestine lying behind it ?

When the tumour consists chiefly of an inflamed undescended testis, the pain will be of that peculiar character which is indicative of orchitis, and the constitutional symptoms of strangulation, however simulated for a time, will not be persistently present. The following case is a good illustration of this condition. A man, aged about forty, said to be labouring under strangulated hernia, was sent up from the country for operation. On being called to him, I found the house-surgeon attempting the reduction of the tumour in the hot bath. The history showed that the patient had for the previous two days suffered from occasional vomiting, and had been constipated ; that the tumour in the groin had not appeared suddenly, though it had enlarged with great rapidity ; that it was excessively painful ; and that he had always worn a truss for a supposed rupture on that side, until the last few weeks, when, in consequence of the instrument breaking, he had discontinued it. On examination, a tumour about as large as the fist was found in the right inguinal canal : it was tender to the touch, hard, and irregular at the upper and outer part, but somewhat soft and fluctuating below ; when the finger was passed into the external ring, the outline of the tumour could be very distinctly felt in the canal. There was no impulse in it on coughing, but there was some abdominal tenderness on that side. The right testis was not in the scrotum. I ordered the man to be bled, the tumour to be leeches, and salines administered ; under this treatment the case did well. When a knuckle of strangulated intestine lies behind and above the testis, still retained above the external ring, the symptoms of strangulation will be violent and persistent ; and this, even though the tumour present but little the ordinary character of a hernia. In fact, in such a case, the Surgeon is guided by the character of the general symptoms, and not by those of the local condition. In a case of this kind to which I was called, there could be felt behind and above an inflamed and swollen testicle which lay at the external abdominal ring, a small, hard, round tumour in the upper portion of the canal. As symptoms of strangulation

were urgent, this was cut down upon, the anterior wall of the canal was incised, and the tunica vaginalis, much distended with fluid, was laid open, when a small knuckle of intestine was found lying at its upper part, very tightly constricted by the inner ring. But in some cases the diagnosis is not so easy; the whole tumour lying in the canal feels smooth, elastic, and uniform, so that no examination can enable the Surgeon to say with certainty whether the tumour is an inflamed testis surrounded by a hydrocele, or whether there is a loop of intestine lying above an undescended testis. In such cases as these, however, the Surgeon is guided in the course he should adopt by the symptoms. If these indicate strangulation of intestine, he should, without further delay, cut down on the tumour and examine its nature.

**Encysted Hernia of the Tunica Vaginalis, or Infantile Hernia.**—

In this variety the hernia does not enter the tunica vaginalis, but forms a separate sac, which passes down behind the processus vaginalis; the latter, although its communication with the peritoneum is obliterated, remains open along the greater part of its length (Fig. 807). Should an operation be under-

Fig. 807.—Infantile Hernia.

taken in such a case, the tunica vaginalis will be opened first, and altogether behind this will be found the hernial sac, three separate layers of peritoneum requiring division before the contents of the hernia are exposed (Fig. 807). In some instances the hernial sac bulges so prominently into the tunica vaginalis that it appears as if descending into it from above—a condition from which the name “encysted” has been derived. According to another view of the nature of encysted hernia, the funicular portion of the tunica vaginalis is partly obstructed by a septum, or by being converted into filamentous tissue, but in such a way as to leave a pouch above, which is protruded down into the tunica vaginalis by the hernia entering it. According to Lockwood there is no

evidence to support such a view. In many cases it is possible to trace a distinct band which connects the lower end of the sac of an infantile hernia to the upper end of the testicle. Lockwood has shown that this band contains plain muscular tissue, which probably represents a remnant of the gubernaculum testis, and plays an important part in drawing down the hernial sac. The distinction between an infantile and an acquired hernia can hardly be made except during an operation undertaken for its cure or for the relief of strangulation.

**Interstitial Hernia.**—In some cases of inguinal hernia there is, in addition to the sac which occupies the inguinal canal, a more or less extensive pouch lying between the layers of the abdominal wall. To such a hernia the term “interstitial” has been applied. In very rare instances the diverticulum of the sac has been situated immediately external to the parietal peritoneum. This variety has been called “properitoneal” by Krönlein, and the pouch of the hernial sac has been found in the iliac fossa, or in front of the bladder. Its existence may be quite unsuspected, and death has resulted from the strangulation of intestine in the deeply placed diverticulum of the sac. In the more common forms of interstitial hernia the sac extends either between the internal and external oblique muscles, or lies superficial to the latter. The hernia then causes a swelling of the abdominal wall above the inguinal canal,

in addition to that caused by the projection of the hernia into the canal itself. In a case of this kind, in which an operation for radical cure was performed by Marcus Beck, the hernial sac extended along the inguinal canal into the scrotum, and from its upper part a large diverticulum passed upwards in the abdominal wall between the internal and external oblique muscles. Interstitial hernia is frequently associated with an abnormal position of the testis. Of 129 cases seen at the Truss Society between 1866 and 1890, Macready finds that in 73.4 per cent. there was some abnormality of the testis, in 67.1 per cent. the organ being completely retained or having only partially descended.

**Inguinal Hernia in the Female** is much rarer than the corresponding hernia in the male. It accompanies the round ligament of the uterus, and may either be arrested at the external abdominal ring, or may pass into the labium, where it occasionally forms a tumour of considerable size. The process of peritoneum (canal of Nuck) which accompanies the round ligament is usually closed at birth, and it is believed that a failure in the obliteration of the process predisposes to the occurrence of inguinal hernia in females, especially during childhood. Such a hernia would be analogous to the "congenital" variety in the male, although there are no anatomical differences by which it can be distinguished from an acquired hernia.

Besides the contents commonly found in hernial sacs, an inguinal hernia in the female may contain the ovary, Fallopian tube, or uterus. (See Chap. LXXIV.) It occasionally happens that an unobliterated portion of the canal of Nuck becomes distended with fluid, and may be mistaken for an inguinal hernia, especially if a communication still exists with the peritoneal cavity, so that the fluid is reducible. Among the conditions which have been mistaken for a labial hernia may be mentioned lipoma, cysts, and varicose veins of the labium.

**TREATMENT.**—When an inguinal hernia is reducible, the rupture must be kept up by a well-made truss, the pad of which, of an oval shape, should press not only upon the external ring, but upon the whole length of the canal. In this way a reducible hernia may occasionally be cured, and in young children in whom this result is frequently obtained, the truss should be worn constantly. When a truss is used in the treatment of an irreducible hernia it should be provided with a hollow cup-shaped pad or a suspensory bag, according to the size of the rupture. The chief points relating to the choice of cases suitable for attempting a radical cure by operation have been considered at page 829. For reducible inguinal hernia operation may be undertaken in children and adults if a properly made truss fails to keep up the rupture, and in cases where the use of a truss proves a serious inconvenience to the patient. Irreducible herniæ, unless of very large size, are usually suitable for operation; but in all cases the patient's health must be satisfactory, and the age not too advanced.

**Radical Cure of Inguinal Hernia.**—It is unnecessary to enter into the history of the operations undertaken for the cure of inguinal hernia. Among the methods which have almost universally been abandoned may be mentioned the injection of irritants into or around the sac with the object of setting up adhesive inflammation in it, and the closure of the inguinal canal by the invagination of a plug of the scrotal tissues into it, as in the operation practised by Wutzer, of Bonn. Mention must also be made of the subcutaneous method, which was devised by Wood and extensively practised by him with

very considerable success. The principle of this operation consisted in the invagination of the sac of the hernia, and the approximation of the structures forming the boundaries of the inguinal canal, by the application of a subcutaneous suture of tendon or wire through a small opening in the skin. An ingenious modification of Wood's operation was devised by Dunnett Spanton, who, instead of approximating the walls of the canal by a subcutaneous suture, used an instrument like a cork-screw, the point of which was introduced through the skin at the upper end of the canal, and was made to pass downwards through its opposite walls so as to draw them together. The instrument was left in for about a week, till some inflammatory swelling was perceptible around it. Since the introduction of the antiseptic treatment of wounds these complicated subcutaneous methods have lost all the advantages which they once possessed, and at the present day the only operation which can be recommended is that known as the *open method*—a revival of the old operation of ligaturing the neck of the sac and cutting it away. In 1871 Lister reported two cases in which he cut down upon a hernial sac and closed the abdominal opening with catgut sutures. Experience, however, showed that suture of the ring alone was not enough to effect a cure. Since then Banks, Annandale, Czerny, Ball, Macewen, and many others have devised various proceedings having the common object of obliterating the neck of the sac and narrowing the dilated ring.

**Operation.**—The operation as performed by Mitchell Banks may be taken as a type, and the various modifications of other operators may be subsequently noticed. The operation is thus performed: The whole area having been cleaned with soap and water, followed by turpentine to remove grease, and spirit to remove the turpentine, is covered with a towel soaked in carbolic lotion (1 in 20) for an hour before the operation. A free incision is then made, reaching from about one inch above the external abdominal ring to near the bottom of the sac. The dissection is then carefully carried down to the sac, all bleeding vessels being secured as they are cut, and great care being taken that the sac itself is exposed in the whole length of the wound, and that one of the coverings be not mistaken for it. The sac is then very carefully dissected out with as little damage to the scrotal tissues as possible. It will usually be found to be slightly adherent to the tunica vaginalis, requiring some careful dissection to separate it. The cord must be early sought for and separated from the sac. The vas deferens can easily be recognized by its cord-like feel, and must be kept in view during the whole operation. The sac being completely separated, is emptied of its contents if they are reducible, and opened to make sure that it is really empty. If omentum is present in the sac and is irreducible, either from its size or from the presence of adhesions, it must be cut away in the manner already described (p. 856), and the pedicle reduced into the abdominal cavity. The sac is then drawn well down and ligatured as high up as possible, so that the inner aspect of the peritoneum may be smooth and not present a pouch, which might favour the formation of a fresh hernia. The ligature may be of chromic catgut or of fine carbolised silk. The sac below the ligature is then cut away. The next step in the operation is to close the pillars of the ring by sutures. These must be introduced by means of a curved needle guided by the finger passed into the canal. The sutures should get a firm hold on each side of the ring, and three or four may be required, according to the size of the aperture. While passing

the sutures care must be taken not to injure the cord, which must be kept out of the way with the finger, and the situation of the epigastric artery should be felt for lest it be punctured by the needle. The sutures may be of carbolised silk, kangaroo tendon, or catgut. Banks uses silver wire, which he ties in a single knot and cuts very close, so as to leave no projecting ends, and allows to heal into the wound.

In congenital hernia the sac may be cut across, leaving the lower part to form a tunica vaginalis. This may be closed by catgut sutures. The upper part is then separated from the cord and treated as above described.

After the operation an absorbent antiseptic dressing should be applied and covered with a piece of jaconette or other thin waterproof material, with a hole through which the penis is drawn, so that the dressing shall not be soiled during micturition.

The chief modifications of the operation above described are first in the treatment of the sac, and secondly in the closure of the ring. In the first place many Surgeons content themselves with ligaturing the neck of the sac and dividing it below the ligature, leaving the fundus undisturbed in the scrotum. This certainly greatly simplifies the operation, and the part of the sac left behind seems to give no trouble in the after-treatment. It has the further advantage that the incision need not be prolonged into the scrotum, and thus firm pressure can be brought to bear upon its whole length, and the risk of extravasation of blood into the loose tissues of the scrotum is avoided. Barker, after ligaturing the neck of the sac with fine silk and dividing it below, passes the two ends of the ligature through the borders of the ring as high up as possible, and thus fixes the stump of the sac, and at the same time the ligature serves as the highest stitch in closing the ring. Macewen, after dissecting out the sac and emptying it, inserts the index finger outside the sac till it reaches the internal ring and separates the peritoneum from the abdominal wall for about half an inch. He then inserts a long catgut suture into the distal extremity of the sac; the free end of this is then passed in a proximal direction several times through the sac, so that when pulled upon the sac is folded upon itself like a curtain; it is then passed by means of a needle through the inguinal canal and made to penetrate the abdominal muscles about an inch above the level of the internal ring. By pulling on this thread the sac is folded upon itself and dragged into the inguinal canal, the part that was the fundus being highest up. It is finally fixed in this position by passing the end of the thread several times through the superficial layers of the muscles. The pad thus formed helps to obliterate the inguinal canal. The ring is afterwards closed with sutures. Ball, of Dublin, has recommended twisting the stump of the sac four or five times with torsion-forceps as a means of more certainly occluding it.

In closing the ring, silk, catgut, and wire have been used. Perhaps silk is the best, as it is not too early absorbed, and can be rendered aseptic with great ease and certainty.

The method which has been most generally adopted consists in simply passing the sutures through each side of the ring without paying any special attention to the structures pierced by the needle, care being merely taken to avoid puncturing the cord, or strangulating it by too tight closure of the ring. Macewen, however, pointed out that this method of suturing failed in every way to restore the natural *valved* condition of the inguinal canal, and with

this object he recommended that the conjoined tendon should be stitched to the aponeurosis of the external oblique in the outer side of the ring.

By a slight but important modification of this method, Bassini of Padua has devised an operation which must be regarded as a nearer approach to perfection than any of those above described.

Bassini's operation is carried out as follows :—An incision is commenced at the pubic spine, and is carried upwards and outwards along the line of the inguinal canal to a point about two inches internal to the anterior superior iliac spine. The external abdominal ring and the part of the external oblique which lies in front of the inguinal canal having been freely exposed, the latter is opened in its whole length by slitting up the aponeurosis of the external oblique. By reflecting the divided aponeurosis upwards and downwards the border of the internal oblique and the conjoined tendon are defined above and the inner aspect of Poupart's ligament below. The sac of the hernia is now carefully separated, and after its contents have been reduced, the neck is ligatured high up with silk. If the sac is small it may be completely removed, but if it descends into the scrotum it should be left *in situ*. The spermatic cord is next lifted out of the canal and held by an assistant in a blunt hook. The arched border of the internal oblique and conjoined tendon is now drawn down *behind* the cord, and secured to Poupart's ligament by a series of silk sutures, of which five or six will usually be sufficient. Interrupted stitches are generally to be preferred to the continuous suture recommended by Bassini. The cord is now allowed to drop back into its place, and finally the divided edges of the external oblique and the pillars of the external ring are brought together with fine silk sutures.

By this operation the inguinal canal is more nearly restored to its natural condition than by any of the other methods, and it differs from Macewen's plan of suturing in that the conjoined tendon is drawn down *behind* the spermatic cord, and not in front of it. For the cure of inguinal hernia in adults Bassini's operation can be strongly recommended, but in children such an extensive procedure is by no means always required. In them excellent results are obtained by simply isolating the neck of the sac and applying a silk ligature to it as high up as possible. In children inguinal hernia is doubtless due in many cases to the existence of an open funicular process, and nothing more than the closure of this is required. If, however, the ring is large, this should be partly closed by one or two stitches, and if the whole inguinal canal is dilated, Bassini's operation may be performed.

The difficulty of the operation in children, especially when the hernia is congenital, is increased by the extreme thinness of the sac and its intimate connexion with the structures of the spermatic cord.

When an inguinal hernia is associated with a retained testis, a cure may sometimes be obtained by the use of a truss, the pad of which is applied above the testis. If operation is required, the testis should, if possible, be brought down into the scrotum; but should this be impossible, and the testis imperfectly developed, its removal may be advisable.

*After-Treatment.*—As a rule the use of a drainage-tube is unnecessary, and the dressing may be left unchanged for a week or ten days, when primary union will usually have occurred and the sutures may be removed. No opium need, as a rule, be given unless the gut has been freely handled in the separation of adhesions. Fluid diet should be given until the bowels have acted,

and if this has not occurred by the fourth or fifth day, an enema should be administered. The patient should be kept in bed for at least a fortnight, and should not be allowed to walk about for another week, nor to resume his ordinary habits for a month. The support of a pad, applied with a spica bandage, is advisable for about two months after the operation, when, as a general rule, all support may be dispensed with. In exceptional cases, especially when the patient's occupation involves severe straining efforts, the use of a light truss may be advisable.

The **Results** of the operation for the radical cure of non-strangulated inguinal hernia have been very satisfactory. Statistics show that, when undertaken in uncomplicated cases, the operation is attended with a very low mortality. Thus, Banks has recorded 72 cases in which the hernia was of moderate size with 2 deaths, and 11 operations on very large herniæ not capable of support by trusses, with 3 deaths. Rushton Parker performed 137 operations on 107 persons with 5 deaths, or 3·6 per cent.; Bassini, 262 operations with 1 death; and Lucas-Championnière, 376 with 2 deaths. Of 105 cases in which the operation was undertaken in University College Hospital during the years 1885 to 1890, 5 died: one of these was a marasmic child, and one a woman aged seventy-two, in whom an omental hernia was thought to be strangulated; in one case of very large hernia containing the sigmoid flexure, reduction was impossible, and the patient died of intestinal obstruction; in the remaining two cases, which were uncomplicated, death was due to peritonitis, which in one case appeared to have started in the wound, and in the other in the ligatured stump of the omentum.

The result as concerns the cure of the hernia is also very satisfactory. Of the 72 cases of moderate-sized hernia recorded by Banks, the result, after long periods, was known in 47 cases; in 37 it was completely successful, in 8 partially successful, and in 2 unsuccessful. Of the 262 operations performed by Bassini, 108 were known to be followed by a cure without the use of a truss after periods varying from one to four years. It cannot be too strongly insisted upon that the operation should not be indiscriminately recommended in all cases, and Banks's rule is undoubtedly a wise one—that it should not be undertaken when the hernia can be kept up without discomfort by a truss.

**Operation for Strangulated Inguinal Hernia.**—When the hernia is strangulated, if the taxis properly employed in the direction of the canal have failed, the operation must be performed in the following way: The pubes having been shaved, the patient should be brought to the edge of the bed; and the Surgeon, having the skin covering the external ring well pinched up, divides the fold in the usual way, by an incision two inches in length, commencing about half an inch above the external abdominal ring. Should any spouting vessel, as the external pudic, be divided in this incision, it must be secured at once. The Surgeon then proceeds to divide the various coverings of the hernia layer by layer until the sac is reached. The thickness of the coverings varies much in different cases, and is often considerable when the hernia is old and the patient has long worn a truss. In some cases the inter-columnar fibres form a thick band across the external ring, and the cremasteric fascia is usually readily recognizable. When this is divided the transversalis fascia and subserous areolar tissue, or *fascia propria*, will be laid bare, and may form a thickened vascular layer. If the hernia has not protruded beyond the external abdominal ring, it may be necessary to slit up the external oblique,

and possibly to divide the lower border of the internal oblique. After freely opening the sac the contents must be dealt with according to the rules laid down on p. 828. It may be found that the contents are now reducible, the stricture having been situated outside the sac and having already been divided. If, however, as will happen in the majority of instances in inguinal hernia, it be found that the stricture is in the neck of the sac itself, this must be divided from within, by pressing the finger-nail under it, and cautiously sliding the hernia-knife along this. It is an established rule in surgery that this division should be effected in a direction *immediately upwards*, so that it may lie parallel with the epigastric vessels, whether it be situated upon the inner or outer side of these. It is true that, if the Surgeon could be sure that he had to do with an oblique hernia, he might safely divide the stricture outwards; or, if he were certain that the protrusion was of the direct kind, he might make the section inwards; but as it commonly happens that he cannot determine with absolute certainty upon which variety of hernia he is operating, he adopts the safer plan recommended by Astley Cooper and Lawrence, of cutting upwards from the middle of the ring parallel to the epigastric vessels. After the hernia has been reduced the operation should be completed, if the patient's condition allow, by performing the steps necessary for producing a radical cure.

The *Seat of Stricture* in inguinal hernia will thus be seen to differ in different cases; and in some instances it exists in two situations. I think it most commonly occurs in the neck of the sac, owing to contraction and elongation of it, with condensation of the subserous areolar tissue lying immediately upon it. In other cases, though much more rarely, it seems to be formed by a thickening of the transversalis fascia in the inner ring, but altogether outside the sac. Occasionally it is met with in some part of the canal, at the lower edge of the internal oblique, but much more frequently at the external abdominal ring.

*Congenital Hernia* when strangulated does not commonly admit of reduction, and thus necessarily renders an operation imperative. The procedure is more commonly required for this kind of hernia in adults than in infants. The operation is the same as that for acquired hernia, but the parts concerned are usually thinner; hence more caution than usual is required in these cases. The tunica vaginalis commonly contains a large quantity of fluid, clear or dark in colour, according to the severity of the strangulation. The stricture will always be found in the neck of the sac, and appears to be formed by the imperfect contraction of that portion of the funicular prolongation of the peritoneum, which normally becomes obliterated before birth, and establishes the separation between the two serous sacs of the tunica vaginalis and of the peritoneum. As the congenital hernia is always external to the epigastric vessels, the section of the stricture may be done with perfect safety in a direction upwards and outwards, though, if the Surgeon should have any doubt as to the exact nature of the case, it will be better to divide the stricture directly upwards. The reduction of the contents of the hernia may in the adult be prevented by adhesions in the neck of the sac, or between them and the testis. I have found both the gut and the omentum closely incorporated with this organ, and requiring some nice dissection to separate them. In operating upon infants of a very tender age, much caution will necessarily be required, on account of the thinness of the coverings, their tension, and the small size

of the aperture. The testis, as well as the spermatic cord, the veins of which are excessively turgid, come into view, and will usually be found much congested, and of a black or bluish-black colour.

In *Inguinal Hernia*, containing either the *Cæcum*, the *Sigmoid Flexure of the Colon*, or the *Urinary Bladder*, the protruded viscera are sometimes only partially covered by peritoneum; hence, in operating upon such herniæ, when strangulated, care must be taken that the contents be not wounded, which is apt to occur if the Surgeon divide the parts without due caution, and mistake the viscus for a sac which does not exist. If the protruded parts are adherent, the Surgeon must content himself with leaving them unreduced after the division of the stricture; in such circumstances it has happened that the protrusion has ultimately been drawn back into the abdomen by some natural action of the parts.

Operations for strangulated inguinal hernia are required during a greater range of ages than those for any other kind of protrusion. I have operated successfully for congenital hernia in infants less than six weeks old, and for ordinary oblique inguinal hernia at seven weeks and at four months of age, and the operation has been done on centenarians. When small and recent, the protrusion usually consists of intestine only; when large, it commonly contains omentum as well. The after-management of the case must be conducted in accordance with the rules laid down at p. 849, *et seq.*

## FEMORAL HERNIA.

By **Femoral Hernia** is meant a protrusion that escapes under Poupart's ligament, and enters the sheath of the femoral vessels internally to the vein. This hernia passes down the innermost compartment of the sheath, which is occupied by fat and lymphatics, and usually contains a gland or two. It passes

Fig. 808.—1. Femoral Artery; 2. Femoral Vein; 3. Innermost Compartment of the Sheath of the Vessels, into which a small Hernia is protruding; 4. Saphena Vein.

Fig. 809.—Femoral Hernia turning upwards.

first of all through the crural ring, where it has Gimbernat's ligament to its inner side; the septum which separates the femoral vein from the inner compartment of the sheath of the vessels, to its outer aspect; Poupart's ligament and the deep crural arch in front; and the bone, covered by the pectineus and the pubic portion of the fascia lata, behind (Fig. 808). After

passing through the crural ring, the hernia enters the crural canal, which extends for about half an inch down the thigh in front of the pectineus muscle, and is covered by the iliac prolongation of the fascia lata. As it approaches the lower corner of the saphenous opening where the canal terminates, it passes under the falciform process of the fascia lata, and out upon the thigh through the saphenous aperture; here it expands, becomes rounded, and has a tendency to turn upwards over Poupart's ligament (Fig. 809), lying in this way upon the iliac region, and sometimes even ascending to some distance upon the anterior abdominal wall. In the descent of the hernia through this course, it first pushes before it the peritoneal sac, and then receives an investment of the subserous areolar tissue—the **septum crurale**, a mass of dense areolar tissue, containing fat and lymphatics, occupying the crural ring. This septum often becomes incorporated with the covering derived from the crural sheath, thus constituting the **fascia propria**

Fig. 810.—1. Femoral Hernia; 2. Femoral Vein; 3. Femoral Artery, giving off. 4. Common Trunk of Epigastric and Obturator Arteries, and 5. Epigastric Artery; 6. Spermathe Cord.

of this hernia, which is commonly thickened, laminated, and of an opaque fatty structure, like omentum. As the hernia continues to descend, it comes into relation with the cribriform fascia, which occupies the saphenous opening; and, lastly, it pushes before it the integumental structures.

As the tumour descends through this course, it necessarily comes into relation with very important parts (Fig. 810). Thus it is separated from the femoral vein solely by the septum of the sheath of the vessels. It has the epigastric artery above and to its outer side; and the spermatic cord in the male, or the round ligament in the female, almost immediately above it. The obturator artery, when arising in the normal manner from the internal iliac, does not come into relation with the neck of the sac; but when it takes its origin, as it not unfrequently does, from the external iliac, the epigastric, or the common femoral, it may have important relations to this part of the hernia. Most commonly, in these circumstances, it passes to the iliac or outer side of the neck, but occasionally it winds round its inner or pubic side, coming

into close relation with it ; and then, as will immediately be mentioned, it may be in considerable danger during the operation. The combination, however, of this particular variety of the obturator artery and femoral hernia is a very uncommon occurrence : because, in the first place, this internal distribution of the artery is rare ; and when it does occur, as it usually passes directly over that portion of the crural ring through which the sac would protrude, it necessarily strengthens this, and so diminishes the chance of rupture.

The **Contents** of a femoral hernia are usually intestinal, and most commonly consist of a portion of the ileum. Occasionally omentum is contained within the sac, but seldom in large quantity. I have, however, several times had occasion to operate in cases of old femoral hernia, in which it became necessary to remove large portions of adherent omentum : in one, ten and a half ounces, and in another about seven. In each case there was a small knuckle of intestine strangulated behind the omentum. The ovaries, Fallopian tubes, &c., have been met with in this variety of hernia.

The **Signs** of femoral hernia are usually well marked. They consist of a tolerably firm and tense tumour, of a rounded shape, situated in the groin, to the inner side of the femoral vessels, and to the outer side of the spine of the pubes, having its neck under Poupart's ligament, though, as it increases in size, its base is turned above that structure ; sometimes, though rarely, it passes downwards upon the thigh. Its size varies considerably : most commonly it is not larger than a walnut or a pigeon's egg, and then is deeply seated in the angle between the body of the pubes and the femoral vessels ; but occasionally it may attain a considerable bulk, as large as the fist or a French roll. When large, this hernia rises up above Poupart's ligament, and extends outwards parallel to it, so that it assumes an elongated shape ; it is then usually somewhat doughy and soft, even when strangulated—very different from the excessively tense feel that it has when small.

In some rare cases the femoral hernia has been found lying external to the vessels, the mouth of the sac being between them and the iliac spine. In these circumstances strangulation cannot well occur, inasmuch as the mouth will be the widest part of the sac ; but, as Hesselbach has observed, if the fascia iliaca be torn by the pressure of the tumour, the rupture may be strangled in the aperture thus formed. Should an operation ever be required in such circumstances, it must be borne in mind that the circumflex iliac artery may be in some danger.

As a femoral hernia passes out through the crural ring, it comes into very close relation to the femoral vein, being separated from the vessel merely by the septum which divides the inner from the middle compartment of the femoral sheath. Were it not for this septum, as Roser has observed, the femoral vein would be compressed by the tense hernial tumour protruded between it and Gimbernat's ligament, and the inevitable consequence would be œdema of the whole lower extremity. As the hernia pushes down in the track of the crural canal, it can make no impression on the inner or on the posterior wall of the canal—both of which are unyielding ; but, pushing the anterior wall upwards, it drags upon the septum on the outer side of the neck of the sac, renders this tense, and thus saves the femoral vein from compression.

The **Diagnosis** of femoral hernia is not always easy. When the hernia is large, and more particularly when it rises up above Poupart's ligament, it may at first be mistaken for an inguinal rupture. The diagnosis, however, may

usually be effected by ascertaining the relation that the neck of the sac has to Poupart's ligament, the inguinal hernia being situated *above*, the femoral *below* this cord. When, however, a small femoral hernia in a fat man rises upwards, so as to lie over Poupart's ligament, it resembles very closely an incomplete inguinal hernia; but its characters may be determined by the passage of the finger up the inguinal canal, which will be found to be free, and the hernia can be felt only through its posterior and inferior wall. In the female the finger cannot be passed up the canal, but the inguinal hernia will descend into the labium, and may thus be distinguished from the femoral, which lies in the upper and inner part of the thigh. In both sexes the relation of the neck of the sac to the spine of the pubes, which can always be felt in the fattest subjects, is most important. In femoral hernia the spine is to the inner, in inguinal hernia to the outer side of the protrusion; and, should a patient happen to be the subject of both inguinal and femoral hernia on the same side, the spine would be felt between the two. After reducing a femoral hernia, the finger can sometimes be pushed into the inferior aperture of the crural canal, when the situation and sharp outline of the falciform process will determine the nature of the opening through which the protrusion has occurred.

The diseases occurring in the groin, with which femoral hernia may most readily be confounded, are—1. *Enlarged Lymphatic Glands* in this situation. From these it may be distinguished by the absence of impulse in the glandular tumour, and by the simultaneous enlargement of several glands. A small strangulated hernia may, however, co-exist with these; being covered in by them. When this is the case, and the local signs of hernia are obscure, whilst the symptoms of strangulation continue, an incision should be made into the part, and the dissection carefully carried through and underneath the glands, with the view of determining whether the hernia exist or not. 2. *A small Fatty Growth* has been met with in the crural canal, closely simulating a hernia. The want of impulse on coughing, together with the doughy character of the tumour, will enable the Surgeon to distinguish it from hernia. Such a fatty mass may, however, consist of the thickened subserous tissue surrounding a small hernial sac. 3. *Psoas Abscess*, as it leaves the abdomen external to the vessels, can rarely be confounded with hernia. It may be further distinguished by its fluctuating feel, by its soft yet semi-elastic character, and by the general history of the case. The impulse on coughing, which is very distinct in the abscess, is commonly more forcible and direct than that of a hernia; and although the purulent collection may in many cases be squeezed back into the abdomen when the patient lies down, yet it returns without a gurgle, and without that distinct slip which accompanies the reduction of a hernia. 4. *Varix of the Saphena Vein* is in some danger of being confounded with hernia. It may, however, be distinguished from this by the impulse in it being less distinct than in hernia, and by the enlargement of the lower part of the vein being marked in the varix, but not existing in the rupture.

Femoral hernia most commonly occurs in women, and very seldom under the age of twenty; differing in both these respects from the inguinal rupture. Astley Cooper states that he had seen only three cases under the above age. It very seldom becomes strangulated at an early period of life. I have had under my care a girl of nineteen with femoral hernia, in whom strangulation

had already occurred on four occasions ; reduction, however, having been happily effected each time.

The **Treatment** of femoral hernia, when it is reducible, must be conducted in the ordinary way by the application of a proper truss. A cure, however, is never, I believe, effected by the pressure of a pad, as sometimes happens in inguinal hernia ; owing probably to the rigidity and incompressibility of the tendinous and aponeurotic structures through which this rupture protrudes. It is often difficult to keep this form of hernia up by means of a truss. I have sometimes found the Mocmain truss succeed when all others have failed. When the hernia is irreducible and operation is for some reason contra-indicated, it should be protected by a truss with a hollow pad ; or if large, supported in a suspensory bag-truss. Operation may be undertaken for the radical cure of a femoral hernia if it cannot be kept up with a properly-fitting truss, or if it is irreducible, provided that the patient's age and general condition are favourable. As in the case of inguinal hernia, the operation should not too readily be undertaken if the hernia is very large and of long standing.

**Radical Cure of Femoral Hernia.**—The early steps of the operation are the same as when it is undertaken for the relief of strangulation. After the sac has been opened and its contents dealt with, it is drawn down and a carbolized silk ligature applied as high up as possible. If the sac, as often happens, can be freed from the surrounding tissues with but little dissection, it may then be cut off ; or if it be more adherent, its neck may be divided below the ligature, and the fundus left *in situ*.

In many cases, the ligature of the neck of the sac is all that is necessary to effect a cure ; but if the crural canal is much enlarged, an attempt may be made to close it by sutures. With this object, Wood devised the following method : The sac having been ligatured and cut off and the stump allowed to retract through the ring, a curved needle on a handle is passed through the pubic portion of the fascia lata, just internally to the femoral vein, which is carefully protected by the finger. The point of the needle is then carried upwards and forwards, across the crural canal, and is made to penetrate Poupart's ligament, and then brought out at the upper end of the wound. It is then threaded with silk, kangaroo tendon, or catgut, and withdrawn. Having been freed from the ligature the needle is then passed again through the pubic portion of fascia lata in a direction inwards and forwards, so as to skirt the border of Gimbernat's ligament, and again penetrate Poupart's ligament and appear in the wound. The upper end of the ligature is next passed through the eye of the needle, which is then withdrawn. The two ends are then tied firmly in a reef-knot. The result is to close the ring by the approximation of the inner end of Poupart's ligament to the pubic portion of the fascia lata. If the ring be very wide, a third ligature may be placed through the same parts between the other two. It is somewhat doubtful whether these sutures will not cut out very soon after their insertion, owing to the tension of the parts, and to avoid this Salzer, of Utrecht, recommended that a small flap of the fascia over the pectineus muscle should be turned upwards and sutured to the crural arch. Watson Cheyne raises a small rounded flap composed of the whole thickness of the pectineus and the fascia covering it. This is turned forwards and attached to the abdominal wall by two sutures, one passed above Poupart's ligament and another through it. In this way it

is intended that the canal may eventually be closed by a dense plug of fibrous tissue.

The **Results** of the operation have been very satisfactory. Banks has recorded 25 cases with one death, which occurred from septicaemia after operation on a very large hernia; Rushton Parker has performed 25 operations on 20 persons with one death. In the large majority of cases the cure appears to be permanent.

**Treatment of Strangulated Femoral Hernia.**—When a femoral rupture is strangulated, reduction should be effected either by taxis or by operation as speedily as possible, gangrene ensuing more rapidly in this than in any other form of hernia. In attempting taxis, the structures in the groin should be well relaxed by flexing the thigh upon the abdomen, and abducting it, which relaxes the margin of the saphenous opening; if it do not succeed, the operation should be proceeded with at once.

The **Operation** may most conveniently be performed when the tumour is small by making an incision by transfixion along the inner side of its neck. If the hernia be of considerable size some Surgeons prefer to expose it more freely by an  $\Gamma$ -shaped incision, the vertical limb of which passes along the inner side of the sac and the horizontal limb parallel to Poupart's ligament and immediately below it; but this extensive incision is rarely if ever necessary. In whichever way the first incision be made the dissection must next be carried through the superficial fascia and the cribriform fascia, when the fascia propria (crural sheath and septum crurale fused together) will be exposed. In some cases, especially if the hernia be a large one, this is thin, but in many instances it is so dense, laminated, and changed in structure, as scarcely to be recognized for what it is. It not unfrequently happens that, after the superficial fascia has been divided, an oval, smooth, and firm body is exposed, which at first looks like the hernial sac, or a lump of omentum; this is in reality the fascia propria, thickened by the long-continued pressure of the truss, and congested perhaps by the attempts at reduction; and in the midst of it the sac will at last be found, after the dissection has been carried through several layers of this tissue. Cysts containing bloody serum may occasionally be found in it, and then the difficulty in the recognition of the structures is greatly increased. When the sac has been exposed it must be opened very carefully, there being often very little if any fluid between it and its contents; the finger-nail must then be passed under the sharp edge of the stricture, which should be divided in a direction upwards and inwards. The reason why this line of incision is universally chosen is, that it is the only direction in which the stricture can be divided without risk of inflicting serious injury upon neighbouring parts. If the section be made outwards, the femoral vein will be in danger; if upwards and outwards, the epigastric artery; if directly upwards, the spermatic cord: hence the only direction is either inwards, or upwards and inwards. If the cut be made inwards, the sharp edge of Gimbernat's ligament alone will be divided, and the crural arch not sufficiently liberated. But if the division be made upwards and inwards, the tension of the whole of the arch is lessened; the only danger that can occur from the division of the stricture in this direction is the very remote one of wounding the obturator artery, when it takes the anomalous course round the inside of the neck of the sac. Guthrie states that he has known some of the best Surgeons in London lose patients by hæmorrhage after the operation for femoral

hernia. This accident, however, is of extremely rare occurrence, and might in a great measure be guarded against by slightly blunting the edge of the hernia-knife before dividing the stricture, so that the tense fibrous bands constituting the constriction would yield, while the artery would probably escape, being pushed before the blunted edge. I have, however, more than once seen blood well up rather freely on the division of the stricture; but it has ceased spontaneously, and I have never known it to give any trouble. If the division of the stricture be limited to a line or two, there will be but little danger of wounding the vessel, even when it takes the abnormal course.

Barker, to whom this accident happened in operating on a patient in University College Hospital, successfully arrested the hæmorrhage by pressure, the patient dying from gangrene of the gut four days after. In a case recorded by A. H. Corley, of Dublin, the bleeding was very free, but was easily controlled by passing the forefinger into the wound and grasping the abdominal wall between it and the thumb. A curved needle was accordingly passed in through the ring and out immediately above Poupart's ligament, and a twisted suture applied around it. The hæmorrhage ceased, and did not recur. The patient died from other causes, and the *post-mortem* examination showed the obturator arising from the epigastric and cut opposite the neck of the sac. The two ends had retracted one inch apart, the distal having gone so far in the direction of the obturator foramen that any attempt to reach it would have been out of the question. The needle was found to have passed immediately in front of the proximal end, crossing the track of the artery, but not actually including it; yet the traction so exerted seems to have been enough to close the vessel, as it was obliterated by a clot. The distal end contained no clot. Bartley has recorded a case in which he successfully ligatured the vessel after enlarging the wound sufficiently to bring it into view. The patient recovered. Barker, who collected the records of 16 cases of this accident, states that in 6 a ligature was applied. Probably the best means would always be to enlarge the wound up to Poupart's ligament, and attempt torsion or ligature. The artery might also be exposed by an incision above Poupart's ligament, like that for ligature of the external iliac by Cooper's method, if simple enlargement of the wound did not bring it into view. If these means fail acupressure or pressure may be resorted to.

It will generally be found that the intestine contained in the sac of a femoral hernia is dark-coloured and tightly nipped; it requires to be treated in accordance with the general principles already laid down. After the stricture has been divided it is very desirable that the gut be gently drawn down so that the part which lay against the sharp edge of Gimbernat's ligament may be inspected, for this has been known to slough, although the rest of the knuckle of gut presented a healthy appearance.

The *Stricture* in strangulated femoral hernia is usually outside the sac, and in the large majority of cases is formed by the edge of Gimbernat's ligament. In some instances, however, the constriction is produced by the fibres of the deep crural arch, or by the falciform border of the saphenous opening—the so-called "femoral," or Hey's ligament. It is thus possible, in many cases, to relieve the stricture without opening the sac, but for reasons already given, this should not be attempted unless the Surgeon be obliged to operate in an emergency, without the means of carrying out the antiseptic treatment.

## UMBILICAL HERNIA.

By **Umbilical Hernia** or **Exomphalos** is meant a protrusion through the umbilical aperture. It occurs either in children or in adults.

**Umbilical Hernia in Children** is sometimes *congenital*. At an early period of foetal life, a great part of the intestinal canal lies without the abdomen, and is gradually drawn in as development advances. Congenital umbilical hernia or true exomphalos is the result of an imperfection in this process. In other cases a diverticulum from the ileum, due to an imperfect closure of the vitelline duct, may extend some distance up the cord from the navel. In either of these conditions it may happen that the protrusion is included in the ligature applied to the umbilical cord. If a large portion of intestine be strangulated in this way, a fatal result usually follows; but if it be merely a diverticulum, the stump of the cord may separate safely, the opening in the gut being obliterated. In other cases a fecal fistula may form at the umbilicus.

Umbilical hernia occurs more frequently shortly after birth in consequence of the child straining and crying, forming the condition termed by nurses "starting of the navel." In this form the umbilical cicatrix yields, the natural depression being completely replaced by the projection of the hernia. It is readily recognized by the presence of a smooth, rounded, and tense tumour, starting forwards at the umbilicus, readily reducible on pressure. The *treatment* should consist in the application of a small pad, made of a slice of cork, wrapped in a soft piece of lint and powdered with starch. This must be secured in position by a circular piece of soap-plaster spread on amadou, or of the American rubber-plaster. An elastic belt with an air-pad is sometimes recommended, and may be applied to older children, but in infants it is quite useless, as the variation in size of the abdomen, according to the amount of flatus in the intestines, is such that no bandage can be really efficient. It most commonly happens that, after pressure has in this way been kept up for some months, a radical cure results; it is very rare to see one in a child ten years of age, though in infants we meet with them by the score.

Strangulation of umbilical hernia in infants is excessively rare. In a case of this nature in University College Hospital, the child was two months old; herniotomy was successfully performed, and the sac was found to contain congested and swollen gut and about a drachm of blood-stained fluid.

**Umbilical Hernia in Adults** most frequently occurs in women, especially those who have borne many children, or who are loaded with internal fat. It is by no means unlikely that a tendency to this disease is often established in childhood, but does not become developed until the abdominal muscles have been relaxed by the pressure of the gravid uterus. The hernia in adults does not as a rule stretch the umbilical cicatrix in the skin. This is usually clearly recognizable at the lower part of the tumour, the hernia most commonly escaping through the upper part of the umbilical aperture.

Umbilical rupture generally attains a considerable bulk, and often acquires an enormous size; when large, it is commonly irregular or semilunar in shape, sometimes appearing to be composed of several distinct tumours. It is usually partly doughy and partly tympanitic to the feel, has a distinct impulse on coughing, and is readily reducible; not unfrequently, however, it happens that a portion of the rupture continues irreducible, owing to the existence of

adherent omentum. The coverings of an umbilical rupture are usually extremely thin, consisting merely of the peritoneum, a layer of condensed fascia which is often perforated at several points by circular openings through which the hernia protrudes, and the integuments which are expanded over the part, and in which the umbilical cicatrix is usually clearly perceptible. The sac generally contains both intestine and omentum, but the stomach and other viscera have been included in it; and Murray has recorded a case in which the gravid uterus, at the eighth month of pregnancy, formed the contents of an umbilical hernia.

In rare instances sloughing of the coverings of the hernia may occur, as the result of a spreading gangrenous inflammation usually beginning in the fold below the tumour, and due to accumulated secretion and dirt. I have known fatal peritonitis caused in this way, and have also seen recovery, with diminution in the size of the hernia, after the separation of extensive sloughs and exposure of the sac. Large umbilical herniæ with very thin coverings have been known to burst, with extensive escape of the bowels.

**Treatment.**—The treatment consists, if the hernia be reducible, in wearing a properly-constructed truss; if irreducible, in applying a hollow cup-shaped pad supported by a bandage over the part. It not unfrequently happens that, in consequence of an indigestible meal, an irreducible umbilical rupture in old persons becomes obstructed, the symptoms consisting of tension of the protrusion, with nausea and constipation. In these cases, much discrimination will be required to avoid confounding this condition of the hernia with acute strangulation (p. 835). By fomentations, and enemata, relief may usually be afforded. Should, however, the bowels not speedily act, and stercoraceous vomiting come on, the tumour continuing irreducible, it will be better to cut down upon it, and treat it as a strangulated hernia, dividing adhesions, and reducing the swelling; for, if it be left obstructed and unreduced, the whole tumour may run into a state of gangrenous inflammation, and then operative interference will be of little use. In such circumstances death usually results; but I have known the patient to survive the gangrene, the whole of a coil of intestine, the sac, and much mesentery and omentum sloughing away, and an incurable artificial anus resulting.

When an umbilical hernia becomes strangulated, as often happens in old irreducible tumours of this description, the symptoms are not usually very acute at first; but no time should be lost in effecting reduction, if possible, by taxis, as they speedily assume an active and urgent character. If taxis fail, a large umbilical hernia may sometimes be reduced by the application of the elastic bandage. This must be carefully applied round and over the tumour. The gentle and uniform pressure exerted by it may displace some flatus, and thus the contents of the hernia may gradually be emptied and the protrusion reduced. If this fail and the symptoms are not acute, small doses of opium may be given, and an ice-bladder applied, and kept on for a few hours. Taxis may then again be employed, when reduction of some portion of the swelling will usually follow. Should this not succeed, the operation must be proceeded with without further delay, lest gangrene set in. If the symptoms are from the first acute, the same rules apply to umbilical as to other herniæ, not to waste time with inefficient means, but to try taxis under an anæsthetic, and if that fail, to operate immediately.

**Operation.**—The nature of the operation undertaken for the relief of

strangulated umbilical hernia must depend chiefly upon the size of the hernia and the general condition of the patient. When the hernia is of old standing and of very large size, and the patient aged and feeble, any attempt to reduce the protrusion completely is out of the question. Not only are the contents inextricably bound together by firm adhesions, but when a large part of the abdominal contents occupy the sac, there may be insufficient space to allow of their reduction. The obstruction is usually due to the constriction of a comparatively small loop of gut which has recently entered the sac. In such cases the Surgeon, especially if he be single-handed, will find himself in a serious dilemma if he freely lay open a sac which contains nearly all the small intestines and a considerable part of the large. The stricture should, if possible, be divided without opening the sac. This may usually be accomplished by drawing the tumour well down, and then making an incision in it about two inches in length over the neck at its upper part in the mesial line. If the tumour overlap here, it may be more convenient to make the incision by the side of the umbilical cicatrix; but, as a general rule, the upper part is the best. After the division of the integumental structures, and often of a deep layer of fat, the end of the nail may be slipped under the edge of the sharp circular aperture through which the protrusion has occurred, and the stricture divided away from the sac, and if possible in the mesial line. Should the strangulation not be thus relieved, the sac must be opened, and any stricture divided from within. As a rule this will not allow the complete reduction of the hernia, but relief of the symptoms may be expected if the size of the tumour is appreciably diminished, for, as already stated, the strangulated coil of gut is often not adherent.

When the hernia is of more moderate dimensions and the patient's condition favourable, the sac should be freely opened, and after the contents have been reduced, steps should be taken to produce a radical cure. The operation adopted in such cases will be identical with that undertaken for the cure of non-strangulated herniæ, and is described below. Treves states that his results in treating these herniæ at the London Hospital have much improved since he has adopted this method in every instance. A free excision of omentum will almost always be necessary, and the management of the intestine must be conducted on the lines laid down at page 844. Great care must be taken not to return the gut still strangulated by bands or through apertures in the omentum. It is not often that strangulation of an umbilical hernia occurs during pregnancy, but, should it do so, the operation must be performed as usual; this condition does not complicate the case much, and instances are recorded by Astley Cooper, Lawrence, and others, of its successful performance at this period.

**Radical Cure of Umbilical Hernia.**—This, as already stated, is usually effected by the pressure of a simple pad in infants and children. The herniæ of adults usually occur in fat, flabby women, who are bad subjects for any operation, and consequently it is in but a small proportion of cases that the operation is justifiable. Adherent intestine in the sac is a serious complication, but if the omentum only is adherent and the gut reducible the operation is more practicable. If the hernia be very large it is not wise to operate, even if the patient survived the operation, the cure would almost certainly not be permanent. No operation for radical cure should be attempted without the most efficient antiseptic precautions.

For the radical cure of umbilical hernia the plan recommended by F. Treves is most efficient. Two curved incisions are made, which meet above and below in the middle line and include the greater part of the skin covering the hernia, the tumour being turned first to one side and then to the other as the incisions are made. The wound is next deepened on one side and the skin reflected from the base of the swelling until the aponeurosis is exposed just beyond the neck of the hernia. The same process is continued completely around the base of the hernia. "When this has been done, the hernia, covered by the perfectly undisturbed skin, will be entirely isolated from all the tissues outside the abdomen, and will be attached only by its neck." The margin of the opening in the aponeurosis is clearly defined. The sac is next opened in any part which appears to be free from adhesions and the contents reduced; if necessary, the opening must be enlarged in the middle line above and below. When the sac has been emptied, the opening into the abdomen is plugged with a sponge, and the sac with its coverings is excised at the edge of the opening. The latter is then closed with sutures of silkworm-gut, introduced with a curved Hagedorn's needle and made to include the aponeurosis and the peritoneum. The sutures should all be introduced before any are tied, and whilst they are being passed the intestines must be held back with a broad spatula. Finally, the skin wound is completely closed with sutures. The dressing should be covered with several broad strips of plaster, and an abdominal belt should be worn for at least several months after the operation.

Under no circumstances should an umbilical hernia be opened by a median incision, for the coverings are thinner here than elsewhere and the contents more frequently adherent to the sac. The free removal of omentum is almost always necessary, especially as it is usually extensively adherent to the sac. In dealing with adherent intestine it is wiser to return the piece of the sac to which the gut is fixed into the abdomen than to run any risk of damaging the gut in dissecting it away.

#### VENTRAL HERNIA.

By **Ventral Herniæ** are meant those protrusions of the intestine that occur through any part of the abdominal wall, except the inguinal, the femoral, or the umbilical apertures; they most commonly occur in the mid-line between the recti muscles, the linea alba appearing to have given way in this situation during parturition; and here they may attain an immense size. A case was once sent to me in which there was a long triangular gap through the upper part of the abdominal wall, extending from the umbilicus to the ensiform cartilage, through which a protrusion had taken place that was nearly as large as an adult's head. These ruptures have also been met with in the lineæ semilunares, and in the hypochondriac and iliac regions. When these herniæ form in the vicinity of the stomach, they are apt to occasion dyspeptic symptoms and much gastric irritation. These different protrusions have occasionally been met with as the result of injuries, by which the anterior abdominal wall has been lacerated; indeed they seldom take place below the umbilicus, unless arising from a directly traumatic cause, such as an ovariotomy wound.

It is by no means uncommon to meet with fatty tumours, sometimes of considerable size, in the linea alba above the umbilicus. They consist of

protrusions of subperitoneal fat through a rounded opening in the aponeurosis, and not uncommonly contain in their pedicle a small pouch of peritoneum which is due to the traction exerted upon it. It may be impossible to distinguish these protrusions from omental herniæ until it is found that the fat is extraperitoneal and not contained within a sac.

A rare kind of ventral rupture was described by Guthrie, in which, after a blow, the muscles of the abdominal wall have been absorbed or have yielded to a considerable extent, forming a broad and expanded tumour, without any distinct neck or pedicle. Sometimes this tumour may attain an immense size, stretching perhaps down to the knees, and containing even the gravid uterus.

The **Treatment** of ventral hernia must consist in supporting it by means of a broad belt and properly-constructed pad. Should it become strangulated, which I believe very rarely happens, owing to the width of the neck of the sac, the operation must be performed in the same way as for umbilical rupture, care being taken to divide the integuments cautiously, any aponeurotic investments, and the peritoneal sac if necessary; the stricture should always be divided upwards. In suitable cases a radical cure may be attempted by an operation similar to that for umbilical hernia.

**Lumbar Hernia** may conveniently be mentioned here. There are two positions in the loin through which the hernia may protrude. One is Petit's triangle, the space which often exists above the iliac crest between the borders of the external oblique and latissimus dorsi; and the other is higher up below the last rib where the aponeurosis of the transversalis is covered only by the latissimus dorsi. Apart from true hernia, bulgings of the abdominal wall may occur in the loin after the healing of abscesses or wounds. Macready has collected 28 cases of lumbar hernia. Of those cases in which the position of the hernia is noted, 11 occurred at Petit's triangle, 2 through the higher space above mentioned, 1 near the tip of the eleventh rib, and 1 near that of the twelfth. In 6 cases strangulation occurred. Three of these were successfully treated by taxis; 1 recovered and 1 died after operation; and another died, apparently untreated.

#### PELVIC HERNIÆ.

**Obturator Hernia.**—This rare form of hernia, in which the protrusion of intestine takes place through the thyroid foramen, was first noticed by Garengot, in the early part of the eighteenth century; since that time about 80 cases have been recorded. Its existence has rarely been ascertained before death; in fact, Lawrence doubted the possibility of recognizing the condition during life, in consequence of the small size which the tumour attains, and its being covered in and compressed under the pectineus muscle. But several cases are on record in which it was recognized during life. It generally occurs in persons above the age of fifty; in consequence, according to Gurlt, of the participation by the muscular structures covering the thyroid foramen in the general wasting of tissue which may occur at that time of life. Pimbet, who collected the records of all the published cases up to 1882, states that in 73, in which the sex was mentioned, 65 were women and 8 men.

**Symptoms.**—In obturator hernia the neck of the sac lies behind the

horizontal ramus of the pubes. The symptoms have in some cases sufficiently resembled those of strangulated femoral hernia to lead able Surgeons to suppose they had to deal with the latter affection. In addition, however, to the ordinary symptoms of strangulation, there are two special signs which may lead to the suspicion of the existence of this hernia, if not to its positive diagnosis. The first of these is a slight fulness and hardness in the upper part of the thigh to the inner side of the femoral vessels, often very indistinct, yet giving to the surface of the limb a different outline from that which is observed on the other side. The other is, pain extending down the inner side of the thigh towards the knee; or even, as in a case referred to by Birkett, as far as the great toe. This pain has been noticed in a large number of the recorded cases, and is due to the pressure of the hernia on the obturator nerve: it may also be increased by pressure with the hand over the thyroïd foramen, and according to Pimbet by forced external rotation of the limb. It does not

Fig. 811.—Obturator Hernia: *a*. Pubic Spine; *b*. Branches of Obturator Veins; *c*. Obturator Artery with a glass rod in it; *d*. Obturator Nerve; *e*. Obturator Membrane; *p*. Sac of the Hernia opened.

extend to the testis; but it may, as happened in a case which I have seen, affect the thigh to such an extent that the patient, to relieve it, flexes the limb on the abdomen. Roser has recommended, as a means of diagnosis, an examination of the interior of the pelvis, *per rectum* in the male, and *per vaginam* in the female. Most reliance, however, is to be placed on the symptoms which I have described. In a considerable number of cases the hernia has been a partial enterocoele.

**Treatment.**—Taxis has been employed in a few cases. In one instance, Roser reduced an obturator hernia in this way, the patient surviving; but, in another case under his care, death took place, a portion of the walls of the intestine remaining strangulated. Werner was successful in an instance in which, in addition to applying pressure externally, he introduced his hand into the vagina, and employed traction backwards and upwards. Welsch of Herrenberg reduced an obturator hernia by external pressure; the patient was apparently doing well, when, in a few days, an abscess appeared at the site of

the hernia, and he died in seven weeks. At the *post-mortem* examination, the end of the vermiform appendix was found projecting through the thyroid foramen, with its tip laid open by the suppurative process.

Operation for strangulated obturator hernia has been performed successfully by Obre, Bransby Cooper, and Lorinser of Vienna. In Obre's case, the patient was seized with symptoms of strangulation, but no tumour could be detected in any of the ordinary seats of hernia. "On uncovering the upper part of both thighs at the same time, the eye detected a slight degree of fulness in Scarpa's triangle on the right side; this triangle of the opposite limb was well marked with a hollow, or depression passing down its centre, but this was lost on the affected side, and the whole contour of this part of the limb was visibly fuller than that of the corresponding one. There was no tumour or circumscribed swelling; but, on standing over the patient, and using firm pressure with the ends of the fingers over the neighbourhood of the femoral artery, and a little below the saphenous opening, a distinct hardness could be felt (slight in its extent), giving an impression as if the sheaths of the vessels were being pressed on." Taking the dangerous state of the patient into consideration, Obre acted in accordance with the best rules of surgery; and, thinking that there might be a hernia deeply strangulated in the femoral canal, he made an incision downwards in this situation, but was disappointed on finding, when the saphenous opening was exposed, that there was no intestine confined there. As, however, a hard structure could be felt deeply at the inner border of the opening, the fascia lata was exposed, and the pectineus muscle divided to the extent of about two inches, when a hernial sac of about the size of a pigeon's egg, and containing intestine, came into view. In this operation the saphenous vein gave some trouble, lying in the course of the incision. The sac having been laid open, the stricture was divided upwards, during which part of the procedure the vein was accidentally cut, and required ligature; no other vessel was tied. The operation was perfectly successful. In Bransby Cooper's case, the patient, a woman aged forty-nine, recovered from the operation, but died of bronchitis before leaving the hospital. In Lorinser's case, the existence of the hernia was detected by vaginal examination. On cutting down on the hernia (on the eleventh day of the symptoms) the intestine was found gangrenous. A faecal fistula resulted, but subsequently closed; and the patient survived eleven months, dying at last of tuberculosis. In a considerable number of cases the operation was performed unsuccessfully.

When the diagnosis is clear the Surgeon may adopt the treatment successfully carried out by Obre, and expose the hernia by an incision in the thigh. If, however, the indications are very uncertain, it is better to perform median laparotomy, and if an obturator hernia be found, to reduce it from within. This was performed by Hilton in 1848, and again by Godlee in 1884, and by Beck in 1891. All three cases ended fatally. In Godlee's case the hernia was reduced without difficulty, but the patient, who was extremely collapsed at the time, died about twenty-four hours after the operation; in Beck's case the patient was old and died collapsed a few hours after the operation.

Besides the obturator, various other pelvic herniæ may take place, as into the perinæum, the vagina, or through the sciatic notch. These various forms of rupture are of extreme rarity, and present many difficulties in their diagnosis.

**Perinæal Hernia** occurs in the male as a protrusion of the recto-vesical

pouch, which appears in the perinæum either in the middle line, or to one side of it. According to Winckel and others, the existence of such a hernia in the female is not proved. The close connexions of the rectum and vagina, and the dense structure of the perinæum in the female, make it difficult to understand how such a hernia could occur, especially as the easily displaced vaginal wall would offer so little resistance to the descent of the hernia. The *treatment* of perinæal hernia would consist in the application of a specially-constructed truss; as the mouth of the sac is large, strangulation is not probable.

**Vaginal Hernia** has occasionally been met with; the tumour usually protrudes through the lateral wall of the vagina high up, and presents the ordinary characters of a hernia, such as impulse on coughing and reducibility. A vaginal hernia has been removed in mistake for a polypus. The *treatment* consists in retaining it with a pessary; a radical cure by operation has been successfully accomplished.

**Pudendal Hernia** was described by Astley Cooper as closely resembling vaginal rupture. It forms a swelling in the posterior part of the labium majus. It can be distinguished from an inguinal hernia by the anterior part of the labium and the external abdominal ring being free. The distinction between pudendal hernia and cyst of the labium can hardly be attended with any difficulty. The *treatment* consists in the use of a special truss or a pessary.

**Sciatic Hernia.**—This rare form of hernia was described by Astley Cooper as passing through the sciatic notch between the lower border of the pyriform muscle and the spine of the ischium. It lies in close relation with the sciatic nerve, and with the internal iliac vessels. In the case related by Cooper, the obturator artery passed above, and the vein below the neck of the sac. From the depth at which such a hernia would be seated, and its small size, it would probably escape observation during life; but, if detected, it might readily be retained by means of proper bandages and a pad. Should operation ever be required, laparotomy and reduction from within the abdomen would probably be the safest proceeding.

#### DIAPHRAGMATIC HERNIA.

**Congenital defect of the Diaphragm** is occasionally met with. It has consisted, in most of the recorded cases, of an aperture in this membrane, varying in diameter from an inch upwards; and amounting, in some rare instances, even to an entire absence of one or both wings of the diaphragm. Through these openings, the contents of the abdomen have been protruded; the stomach and small intestines being most frequently displaced, and the spleen and liver having been found in the chest in a tolerably large proportion of the cases. The hernia has mostly been observed in children at or soon after birth; but in several instances the subjects have lived to adult age, the hernia at last taking place apparently accidentally. In some of these latter cases, however, it may be a question whether the opening in the diaphragm was not the result of an accident, perhaps some time antecedent to the occurrence of the hernia. The opening has generally been found on the left side; sometimes, however, on the right.

Diaphragmatic hernia is sometimes of **traumatic** origin, being the result

of a wound or laceration of the diaphragm. It usually attains a large size, and may contain the stomach or the transverse colon with a portion of the omentum, which forms a tumour in the thoracic cavity, encroaching upon the lungs, and pushing the heart to one side. The hernia is not enclosed in a peritoneal sac, but has been found partially enveloped by the pleura. It occurs generally on the left side of the chest, but cases have been recorded by Percy and others in which the injury of the diaphragm was on the right side. The following case is a very good instance of this rare affection.

A man, seventy-four years of age, was admitted into University College Hospital. About twelve months before, he had fallen into an area about ten feet deep; he believed that he had injured his chest and head, as from that time he had suffered much from shortness of breath and occasional sensation of suffocation, had a hacking cough, and could not lie down without feeling some difficulty in breathing. At the time of the accident, he coughed up about three spoonfuls of blood. Ever since the accident, he had suffered much from dyspeptic symptoms and constipation, though previously he had experienced no inconvenience in this respect. About a month before admission, the difficulty in breathing increased; and four days before he came to the hospital, violent pain in the abdomen came on, and his bowels ceased to act, although he took a variety of aperient medicines, and had enemata containing croton oil. On admission, the abdomen was tensely distended, and tympanitic, with pain around the umbilicus; the tongue was coated with whitish-brown, moist fur; the pulse was small, quick, and somewhat resisting; there was nausea, but no vomiting. The skin was cool, and the countenance anxious; the bowels had not acted for seven days, but he had frequent desire to go to stool. He was ordered an aperient draught every third hour. As this had no effect, he was directed to take calomel and elaterium pills, and to have turpentine enemata, which afforded him some relief, though they brought away no fæces. The patient became more restless, the skin cold and flabby, the countenance more anxious, the breathing shorter, and the abdomen more tympanitic, and he died two days after admission, and nine from the commencement of the obstruction.

*Examination of the Body twenty-four hours after death.*—The abdomen was distended and tympanitic, and the peritoneum contained about six ounces of fluid, with here and there patches of recent lymph. The small intestines were not distended; the large were greatly distended with flatus, the cæcum extending into the cavity of the pelvis; the ascending and the transverse colon were much distended, and it was found that a large loop of the transverse and of the descending colon had passed through an opening in the tendon of the diaphragm into the pleural sac, and was there strangulated (Fig. 812). The colon below the stricture was contracted, and entirely empty. On opening the thorax, the loop of intestine, fourteen inches in length, of a pale slate-colour, and distended with gas, was found in the left pleural sac. It reached as high as the fifth rib, touched the pericardium, and was overlapped by the free margin of the left lung. Where strangulated, it was of a darker colour than elsewhere. The opening in the diaphragm, through which it had passed, admitted little more than the point of the fore-finger, and had a thin tendinous margin. The tenth and eleventh ribs, on the left side, were found to have been fractured; the latter was united by bone, but the tenth rib, at the seat of fracture, had formed a false joint.

Connected with this and with the intercostal space below it, was a firm adhesion about an inch broad and an inch and a half long, united by its other extremity to the protruded meso-colon and the diaphragm. The meso-colon

Fig. 812.—Diaphragmatic Hernia of Colon.

was firmly adherent to the upper surface of the diaphragm, close to the opening in it. The lungs were tolerably healthy. The right pleura contained three ounces, and the left eight ounces of serum.

## CHAPTER LXII.

## INTESTINAL OBSTRUCTION.

THE term **Intestinal Obstruction** as commonly used means a total arrest of the passage of fæces and flatus through the intestine, and in that sense it will be used here ; but by some writers it is applied also to interference with the free passage of the intestinal contents, and is qualified as *partial* or *complete*. Intestinal obstruction may arise from many pathological conditions, which it is important, if possible, to distinguish from one another, as they require different lines of treatment for their relief. Our knowledge of the various causes of obstruction of the bowels has been greatly increased by the work of Fagge, Bryant, Leichtenstern, and many others, and especially by the publication of an excellent monograph on the subject by F. Treves, containing, besides much original matter, a complete summary of all previous observations. Intestinal obstruction may be either *Acute* or *Chronic*, but this division does not agree accurately with one founded on pathological anatomy, as some forms of mechanical obstruction, especially intussusception, may run an acute or chronic course according to circumstances.

**ACUTE INTESTINAL OBSTRUCTION.**—The **Symptoms** common to all forms of acute obstruction are as follows : The patient who may previously have been in perfect health is seized with a more or less sudden feeling of something wrong having taken place in his abdomen, or he may be taken with *intense pain* at one point. This pain persists to a greater or less degree throughout the case, and is often violent and paroxysmal. *Vomiting* speedily follows, at first of the contents of the stomach, but after a time of stercoraceous matter. This is as a rule accompanied by an intense sense of nausea, which is not relieved by the act of vomiting. The quantity brought up is often enormous, and every drop of fluid taken is immediately returned. *Constipation* is complete, neither flatus nor fæces passing, and most commonly there is no sense of any desire to go to stool. In most cases before long *distension of the abdomen* sets in, the intestines being filled with flatus, but as a rule in acute obstruction the tension of the belly is not very great until after the third or fourth day. If the obstruction be high up in the bowel distension may be entirely wanting. If the patient be thin, the distended coils of intestine may be recognisable through the abdominal wall, but they can seldom be seen or felt rolling upon one another, nor are gurgling or rumbling noises commonly to be heard. *Tenderness* may be found localised in one spot in the abdomen, and it then probably indicates the seat of the obstruction. If peritonitis sets in, the tenderness becomes more general, and the abdominal walls become tense and rigid. In some forms a distinct *tumour* may be felt within the abdomen. The *Constitutional Symptoms* are very severe, collapse setting in early. Occasionally syncope may occur at the time of invasion. The tongue is coated with a foul creamy fur, ultimately becoming dry and brown. The mind remains clear

to the last. If relief be not afforded the patient rapidly emaciates, the depression increases, and death takes place usually under a week.

**Varieties and Causes of Acute Intestinal Obstruction.**—Acute intestinal obstruction may arise from—1, internal strangulation of the bowel; 2, volvulus or twist; 3, impaction of concretions or foreign bodies in the small intestine; 4, stricture of the small intestine becoming suddenly occluded, and 5, acute intussusception.

1. **INTERNAL STRANGULATION.**—This affects almost invariably the small intestine. It resembles in its main features ordinary strangulated hernia, differing solely in the fact that the cause of constriction is situated within the abdominal cavity, and not at an aperture in its wall. As a rule the strangulation is

FIG. 813. —Strangulation of intestine by a band attached to a diverticulum from the ileum.

less severe in internal obstructions than in external hernia, and gangrene of the gut is comparatively rare. In the majority of cases the constriction arises from a portion of gut slipping under or becoming entangled in a **band** passing from one part of the abdominal cavity to another. These bands are often many inches in length, usually rounded in form and from a tenth to a third of an inch in diameter. They are composed of fibrous tissue, and are often of considerable strength. From the fact that they are most commonly single, Gay described these under the name of "solitary bands." They are supposed to be formed, in many cases at least, by adhesions between two portions of the abdominal contents, resulting from localised peritonitis. Thus inflammation of a mesenteric gland may cause the adhesion of a neighbouring part of the mesentery or of a coil of the intestine, or a typhoid or tuberculous ulcer may cause the adhesion of two portions of the ileum. The fibrous adhesion thus formed is supposed to be gradually stretched and rounded by the

movements of the intestines. In other cases the bands are probably congenital, especially when connected at one end with the umbilicus or its immediate neighbourhood, and at the other with the mesentery. When the band is short, strangulation usually occurs from a coil of gut slipping beneath it, but when it is long and loose, it may form a noose, in which a portion of the intestines may be snared.

Internal strangulation may also be caused by **bands formed from the omentum**. These are commonly attached near the openings of the femoral and inguinal rings, more especially in cases in which a hernia has at some time existed. The adherent piece of omentum usually loses its membranous form, and becomes twisted into a firm fibrous cord, by which the gut may be pressed upon as above described.

**Meckel's diverticulum** from the ileum, the imperfectly obliterated vitelline duct, is another not uncommon cause of strangulation. The vitelline duct joins the ileum at a point between 18 and 36 inches from its termination (in the adult). Among the conditions which may be the result of an imperfect obliteration of the duct are the following:—1. The duct remains open throughout, and persists as a faecal fistula at the umbilicus; 2. The intestinal extremity persists in the form of a pouch-like projection from the gut, or as a long narrow diverticulum with a globular extremity; and 3. From the end of the diverticulum a fibrous band passes to the umbilicus, or forms a free whip-like process. Bland Sutton has shown that in rare instances the process of obliteration of the vitelline duct may be excessive and involve the lumen of the gut itself, thus giving rise to a constriction of the ileum, varying in degree between slight narrowing and complete occlusion. As causes of internal strangulation, the most important conditions are those in which the diverticulum ends in a fibrous band (Fig. 813), or in which its extremity becomes adherent to the mesentery or other coils of intestine, and thus forms a loop through which a coil of gut may pass.

Strangulation may also arise through **loops formed by the attachment of the vermiform appendix, Fallopian tube, or the pedicle after ovariectomy**, to neighbouring structures, such as the abdominal wall, the mesentery, the omentum, or the intestine.

Fig. 814.—Intestinal Obstruction from Internal Hernia.

In another form the gut is strangulated by passing through a **slit or aperture in the omentum or mesentery** (Fig. 814). In some cases these openings are possibly the result of injury, but probably they are more commonly congenital.

The above are the most common varieties of internal strangulation, but various other anomalous forms are mentioned by Treves, such as strangulation over, instead of under, a band, acute kinking from traction on an isolated band, or by an adherent diverticulum, &c.

Lastly, to this class belong certain very rare forms of **internal hernia**, in which the gut is strangulated in the foramen of Winslow, or in certain

peritoneal pouches. Among the latter, which have been carefully studied by Treves, are the fossa duodeno-jejunalis, the ileo-cæcal fossæ, and the inter-sigmoid fossa. The fossa duodeno-jejunalis is a pocket, which, when present, lodges the bend formed by the junction of the duodenum and jejunum. It is bounded in front by a fold of peritoneum, with a free horizontal upper border. A hernia into this pouch forms the "*retroperitoneal or mesenteric hernia*" of Astley Cooper. In this way an enormous sac, containing all the small intestines except the duodenum, may occupy the centre of the abdomen. The intersigmoid fossa lies in the left wall of the sigmoid mesocolon; it is directed downwards and to the left, and the fold which bounds it is caused by the sigmoid artery, which lies above and to the right of the pouch. A strangulated *sigmoid hernia* has been met with by Lawrence and Eve.

**Special Symptoms of Internal Strangulation.**—Internal strangulation gives rise to the most typical cases of acute obstruction. It is slightly more common in males than in females, and occurs most frequently between the ages of 20 and 40. In a considerable proportion of cases there is a previous history of peritonitis, or of obscure abdominal pains, and, in a smaller proportion, of previous attacks of partial obstruction. The onset is almost always sudden, the patient being able to tell the exact time at which he was seized with the symptoms. In a considerable proportion of cases there is some apparent immediate cause, such as running or jumping, straining at stool, or a violent action of the bowels, either as the effect of a purgative or from diarrhoea. The pain is usually severe and griping, and most commonly referred, as in ordinary strangulated hernia, to the region of the umbilicus. The vomiting sets in early, very speedily becomes stercoraceous, and is often very abundant. Constipation is complete, and there is no sense of a desire to go to stool. There is prostration from a very early period, and collapse sets in rapidly. The temperature is seldom raised; much more commonly it is sub-normal. Owing to the profuse vomiting and the rejection of all fluids taken by the mouth there is intense thirst, and the urine becomes very scanty. On examination of the abdomen at first there may be no distension, and it is possible sometimes to recognise fulness and some tenderness at the seat of the strangulation. Later on more or less distension sets in, but it is not usually very excessive. Dilated coils of intestine may be recognised if the patient is thin, but no peristaltic movements are visible except in very rare cases. Percussion as a rule gives a uniform tympanitic resonance over the whole abdomen.

Cases of internal strangulation, if left to nature, very rarely recover. Yet it occasionally happens that the obstruction, even when of the most acute character, may give way. Almost invariably, however, the symptoms continue, the prostration increases, the extremities become blue and cold, the pulse more rapid and feeble, respiration shallow and hurried, and death takes place usually under a week, the patient retaining consciousness to the last. If the strangulation is very intense the ordinary symptoms of peritonitis may develop as gangrene of the gut commences, but more commonly the gut is not held sufficiently tight to cause complete arrest of circulation, and peritonitis is wanting to the end.

2. VOLVULUS.—A twist of the intestine may occur in three ways. The gut is, in very rare cases, twisted on its own longitudinal axis; much more commonly a long loop is twisted on its mesenteric axis; and again, very rarely, the

neighbouring coils become twisted round each other. In whichever way it occurs the lumen of the gut is occluded, and the symptoms of intestinal obstruction set in. Volvulus may affect almost any part of the intestine, but by far the most common seat is the sigmoid flexure, so much so that it will suffice here to describe that form only. It is the only form of acute intestinal obstruction affecting the great intestine. In the sigmoid flexure it is invariably the result of great dilatation of the gut, possibly in some cases congenital, but commonly the effect of habitual constipation. In this way the sigmoid flexure may become greatly increased in length and in diameter, and the meso-colon becomes long and loose. In this condition it is easy to understand how it may become twisted on itself, either as a consequence of some movement or from accumulation of faeces in the upper part of the loop. When it becomes thus twisted complete obstruction results. The circulation in the actual twist is seriously interfered with, the gut becomes congested and almost invariably peritonitis sets in, commencing at the twist. Later on, if the patient lives long enough, sloughing and perforation may take place at the twist.

**Special Symptoms of Volvulus of the Sigmoid Flexure.**—The invasion is, in most cases, sudden, without severe collapse or shock, and accompanied by pain, not usually very intense, often intermittent and griping. Distension of the abdomen sets in very early, and forms the most marked feature of the case. This is caused almost entirely by accumulation of gas in the dilated sigmoid flexure, which may become so distended as to empty and compress the other parts of the intestine, and by forcing up the diaphragm may seriously impede respiration. The huge distended coils of the great intestine may be recognisable through the abdominal wall. Constipation is complete, neither flatus or faeces passing, but vomiting is not a very marked symptom, and rarely becomes stercoraceous. Tenesmus is an occasional symptom. The course of the disease is usually rapid. Symptoms of peritonitis appear at an early period, and, according to Treves, death takes place on an average about the sixth day. It has been known to occur on the third day from asphyxia caused by the pressure of the distended gut.

Volvulus of the small intestine, or of the great and small together, gives rise to much the same symptoms as strangulation by a band.

**3. IMPACTION OF FOREIGN BODIES IN THE SMALL INTESTINE.**—Foreign bodies may be divided into three classes :—

1. *Solid Foreign Bodies accidentally swallowed*, such as false teeth, plum-stones, &c., very rarely cause obstruction of the intestine directly, for anything which can pass the oesophagus can, as a rule, pass the remainder of the alimentary canal.

2. *Intestinal concretions or enteroliths* are of three kinds :—1. Laminated stony masses of a white or brownish colour, composed of magnesium phosphate, ammonio-magnesium phosphate, and organic matter usually formed round some small foreign body as a nucleus ; 2. Masses formed of indigestible husks or other vegetable refuse felted together and mixed with faeces and earthy matter ; and 3. Stones formed as a consequence of the long-continued and excessive administration of certain mineral drugs, especially chalk, magnesio, and oxide of bismuth.

3. *Gall-stones* far more commonly cause obstruction than the solid bodies above mentioned, and the accident is much more frequent in women than in

men. It is probable that in every case of obstruction from a gall-stone the calculus has found its way into the intestine by ulceration from the gall-bladder into the duodenum, and not by passing down the bile-duct. The shape commonly assumed by these large calculi is well shown in Fig. 815, taken from a stone removed from a case under the care of B. H. Allen of Hastings. The base of the stone is faceted as if it had lain in contact with another concretion in the gall-bladder. It is possible that the stone may increase in size after entering the intestine. Mayo Robson has pointed out that gall-stones may also cause obstruction by setting up localized peritonitis, or by inducing volvulus of the intestine.

A foreign body, when it causes obstruction, usually lodges in the lower part of the ileum, which is the narrowest part of the intestine.

The **Special Symptoms of Obstruction from a Foreign Body** are not very characteristic. The previous history may throw some light upon the case. If the foreign body is a gall-stone there may be a history of repeated attacks of hepatic colic, and of an illness with obscure pain in the region of the gall-bladder, probably unaccompanied by jaundice, occurring some days or weeks before the symptoms of obstruction commenced, and indicating the time at which the gall-stone passed by ulceration into the duodenum. After this there may be a history of obscure pains in the belly, usually worse after food. The invasion of the symptoms is sufficiently sudden to bring the condition within the class of acute obstructions, but it is not abrupt, nor is it accompanied by severe pain or collapse. The vomiting comes on gradually, is seldom very profuse, and may not become stercoraceous for many days. The constipation is complete, but in the great majority of the recorded cases there has been little or no distension of the abdomen. The coils of intestine cannot be recognised, nor is there any visible peristalsis. Such pain as there is may be referred to the region of the obstruction, but this is by no means always the case. By manipulation some tenderness may be detected, usually below and to the right of the umbilicus, and possibly, under chloroform, some fulness might be felt if the patient be not too fat.

Fig. 815. Gall-stone removed by operation from the ileum.

The result of the case depends upon the size of the foreign body and the point at which it is impacted. If lodged high up—a very rare condition—the symptoms are much more severe, and death occurs early. If low down in the ileum the patient may survive for from two weeks to a month. In other cases a gall-stone has been passed after as much as four weeks of complete obstruction. The size of the foreign body and its form are of much importance. If smooth and rounded it is more likely to pass. The stone figured above was rough on the surface, and measured  $3\frac{1}{4}$  inches in circumference. Larger stones than this have been passed after longer or shorter intervals of obstruction, but, on the other hand, death has been caused by a calculus measuring only  $2\frac{1}{4}$  inches in circumference. If death takes place it is caused either by exhaustion from vomiting or by ulceration and perforation of the gut at the point where the body is impacted.

#### 4. SUDDEN OCCLUSION OF A STRICTURE OF THE SMALL INTESTINE is

necessarily a very rare form of obstruction, as stricture of this portion of the alimentary canal is seldom met with. It is said, however, to occur as the result of cicatrisation of tuberculous ulcers, which tend to spread circularly round the gut. Typhoid ulcers, which are longitudinal, probably never cause contraction. Syphilitic, catarrhal, and peptic ulcers have also been described, but that they ever cause stricture is very doubtful. Treves mentions six cases of stricture after injury, four after strangulated hernia, and two after external violence. Cancerous stricture of the small intestine is more common than simple, but it also is very rare. Narrowing of the small intestine may also be caused by a coil being kinked and fixed in this position by adhesions, by chronic peritonitis often tuberculous, causing sometimes a matting together of many contiguous coils of gut, the lumen being narrowed possibly in more than one place.

The **Special Symptoms of Obstruction from narrowing of the Small Intestine** are not very definite. The patient has usually suffered, often for years, from occasional attacks of abdominal pain, commonly described as colic. These most frequently occur after meals, especially if some indigestible food has been taken. In some cases attacks of vomiting and obstruction have occurred and passed off, perhaps ending in diarrhoea, more than once before the final obstruction. The final attack closely resembles that already described as occurring in impaction of a foreign body. If the stricture is low down, the symptoms develop less rapidly.

**Stricture of the Ileo-Cæcal Valve** is a rare affection. Treves has collected 8 cases, 3 of which were simple and 5 cancerous. It generally gives rise to the usual symptoms of stricture of the lower part of the ileum, but in a case of carcinoma of the ileo-cæcal valve recently in University College Hospital, there was great distension of the abdomen, and an absence of vomiting, although complete obstruction had existed for two weeks before death. In these respects the symptoms suggested stricture of the large intestine rather than of the small.

5. **ACUTE INTUSSUSCEPTION.**—The invagination of one portion of intestine into another is a common form of intestinal obstruction, especially in children. It forms about 30 per cent. of all cases. The upper portion of the intestine is invaginated into the lower. To this rule a very few exceptions have been recorded. According to Leichtenstern, 44 per cent. of all cases are seated at the ileo-cæcal valve, the valve itself forming the apex of the invagination. The next most frequent seat is in the small intestine, especially in the lower jejunum, 30 per cent. occurring in this region. Eighteen per cent. are met with in the rectum, and in 8 per cent. the invagination has occurred in the lower part of the ileum, the invaginated portion passing through the ileo-cæcal valve, and being grasped by it.

An intussusception is composed of three tubes of intestine, one within the other. The innermost tube is spoken of as the entering tube. The middle or reflected tube is turned inside out, so that its serous coat is in contact with that of the entering tube. In the space between these two tubes lies the mesentery belonging to each, and the vermiform appendix in those cases in which the cæcum forms the reflected tube. The whole mass thus formed is termed the intussusceptum. The external tube is termed the ensheathing tube or intussuscepiens. It is most commonly thrown into numerous folds at its upper part, which can be straightened out by slight traction, thus giving rise to

apparent partial reduction of the invagination. The whole mass forms a rounded sausage-like tumour. On making an incision into it through the sheath the mucous surface of the reflected tube will be brought into view in contact with that of the sheath. On further cutting through the reflected tube a space is found between the serous coats of the reflected and entering tubes containing the mesentery (Fig. 816). In very rare cases double intussusceptions, composed of five layers, or triple, with seven layers, have been observed. An intussusception increases entirely at the expense of the sheath, the line of reflection between the entering and reflected tubes remaining unchanged. The length of the part invaginated varies greatly. When limited to the small intestine it is usually short—not more than two or three inches in length; in the

Fig. 816.—An intussusception dissected.

large gut as many feet may be involved. The intussusceptum is more or less severely strangulated at the point of the reflection between the reflected tube and the sheath. This usually seems in part to be caused by the closely-packed folds of the sheath at the neck of the intussusception. The entering and reflected tubes are therefore intensely injected with blood, and swollen, and the mesentery included in the space between them is in a similar condition. In some exceptional cases of intussusception of the colon there is little constriction; so little, in fact, that the lumen of the gut may not be completely occluded.

There is reason to believe that in very slight cases the intussusception may undergo spontaneous reduction. In other cases, when the strangulation is not sufficiently severe to cause gangrene of the intussusceptum, though it seriously

or completely obstructs the passage of faeces, death inevitably results sooner or later. If the strangulation is tight enough to cause gangrene, adhesions may form between the upper part of the entering tube and the reflection between the sheath and the reflected tube, the gangrenous intussusceptum may be cast off into the bowel, and recovery take place. Unfortunately, the patient usually perishes from exhaustion before this is accomplished.

The **Causes** of intussusception have given rise to much discussion, but the most reasonable view seems to be that the invagination commences as the result of irregular peristaltic action of the intestine. Nothnagel experimentally demonstrated this in the rabbit's intestine. He showed that the application of a powerful electric current to a portion of the gut caused a contraction extending a short distance below the point stimulated, and a considerable distance above it. At the same time the uncontracted bowel below rose up over the lower end of the contracted part, thus giving rise to limited intussusception. He also obtained somewhat similar results by paralysing a portion of the gut by crushing, but it is improbable that anything analogous to this occurs in the production of intussusception in the human subject. When the invagination has once commenced, the intussusceptum is passed on by the contraction of the bowel, like a mass of faeces or a foreign body. That irregular peristaltic action is the probable cause is further supported by the fact that in children it is sometimes due to the irritation of worms or the straining accompanying dysenteric diarrhoea. The intussusceptions of the dying, so commonly found in *post-mortem* examinations, are also probably the result of irregular peristaltic movements immediately preceding death. They are often multiple, and occur with equal frequency in the upward and downward direction.

In adults the invagination occasionally commences at the seat of a tumour.

**Special Symptoms of Acute Intussusception.**—The invasion is usually sudden, the patient feeling that something has gone wrong internally. In an infant there is usually screaming, evidently from severe pain. The symptoms of obstruction then develop. Vomiting soon sets in, but is not very severe, and rarely becomes stercoraceous till a late period unless the intussusception is in the jejunum. The pain is griping in character and intermittent. In almost all cases there is marked tenesmus, with the passage of blood and mucus from the bowel. This is one of the most important and characteristic symptoms. There is little or no distension of the abdomen, and the coils of intestine are not visible. The degree of collapse varies. In extreme cases the patient has been known to die in less than 24 hours from shock. More commonly it is not severe except in very young infants. In subacute cases the obstruction may not at first be complete; in fact, there may even be some diarrhoea, but this is rare. On examination of the abdomen, if necessary with the help of an anæsthetic, a tumour can usually be felt at the seat of disease. It is sausage-like in form, doughy to the feel, and becomes tense under manipulation from the peristaltic contraction of the gut composing it. It is tender, and the hardening during manipulation is accompanied by some griping pain. If the case be watched from the beginning, the tumour will be found to change its position as the invagination progresses: thus, when beginning at the ileo-cæcal valve, it will at first be felt in the right iliac fossa, subsequently in the umbilical region, and often at last in the left iliac fossa. If the intussusception be ileo-cæcal, or of the great intestine, it often descends low enough to be felt by passing the finger into the rectum, and not unfrequently it protrudes from

the anus, and may thus resemble a simple prolapse of the bowel. Such a condition is easily recognised by passing the finger beside the protruded gut into the rectum, which it is of course impossible to do in a case of prolapse. The nature of the tumour, when it lies in the rectum, may be recognised by feeling the opening in the apex of the intussusceptum, which has been compared to the os uteri.

The **Prognosis** in acute or subacute intussusception is very bad, especially in children under one year of age, of whom not two per cent. recover if the case be left to nature. The great majority die before the seventh day from shock and exhaustion. In older patients, recovery may take place by gangrene and subsequent elimination of the invaginated bowel. This is said to occur in about 40 per cent. of all cases. The chance of its occurrence steadily increases with the age of the patient. When it is about to happen, the discharges from the bowel become offensive, and finally the gangrenous gut is passed and followed by a motion. Separation of the gangrenous gut is, however, by no means always followed by recovery. According to Treves, 40 per cent. die from failure of the adhesions to prevent extravasation of fæces, from ulceration and perforation of the gut, from hæmorrhage or pyæmia. If elimination does not take place death is inevitable, unless it can be prevented by surgical interference.

**CHRONIC INTESTINAL OBSTRUCTION.**—A typical case of chronic obstruction is characterised by the gradual development and the want of intensity in the symptoms. The cause of this condition is seated almost invariably in the great intestine. In a few exceptional instances stricture of the small intestine has given rise to chronic obstruction, but in most of the recorded cases, as already stated, the sudden blocking of the narrowed lumen causes an attack sufficiently sudden in its commencement and rapid in its course to justify its inclusion amongst acute obstructions.

**Symptoms.**—In chronic intestinal obstruction there is usually a history of gradually increasing constipation, often alternating with diarrhœa. The motions often become gradually smaller, and are not uncommonly streaked with blood and mucus, and passed with much straining. At last the constipation culminates in complete obstruction, neither fæces nor flatus passing. It may not be for some days that the patient recognises that his bowels are obstructed, and he frequently first becomes aware of it by the failure of purgatives to produce a motion, and by some sickness with distension of the abdomen following their use. After a week or more, eructations, retchings, and even vomiting may set in. The abdomen gradually becomes distended, and the flatus passing from one part to another gives rise to loud rumbling and gurgling noises, with some gripping pain. The belly usually assumes a barrel shape, the flanks being distended and tympanitic. If the abdominal walls be thin, the distended coils may be felt and often seen through them, and peristalsis may be very evident. Not uncommonly the patient will say that he feels the flatus moving towards a certain point where it is obstructed in its passage, and then rolls back with a loud rumble. As the case progresses the vomiting increases in frequency, and at last, usually after two or three weeks, it may become fæculent. It is never, however, so abundant as in acute obstruction. The tongue is foul from the first, and towards the end becomes brown and dry. Loss of flesh is very evident from the beginning, and before death the emaciation may be extreme. If unrelieved by treatment death takes

place at periods varying from two weeks to two months, most commonly from exhaustion, but occasionally from perforation of the bowel and peritonitis. The gut may give way immediately above the occluded point, but more commonly perforation occurs in the cæcum, even when the obstruction is at some distance from that part.

**Causes and Varieties of Chronic Obstruction.—Stricture of the Large Intestine** is by far the most frequent cause of chronic obstruction. In the rectum, simple, syphilitic, and cancerous strictures are common, and will be described in the chapter on Diseases of the Rectum. In 44 strictures seated below the ileo-cæcal valve and above the rectum, Treves found that 28 were cancerous, 13 simple, and 3 of doubtful nature. Cancer occurs with about equal frequency in males and females, but simple strictures in this country are more common in females. In 98 cases collected by Coupland, Morris, Fagge and Treves, the situation of the stricture was as follows: sigmoid flexure, 58; descending colon, 11; splenic flexure, 7; transverse colon, 7; hepatic flexure, 9; ascending colon, 2; and cæcum, 4. The simple stricture of the great intestine is the result of the healing of some non-malignant ulcer, most commonly dysenteric, less frequently syphilitic. The malignant stricture is almost invariably a columnar carcinoma. Colloid is said also to be occasionally met with as a result of degeneration of a columnar carcinoma. Glandular cancer probably never occurs primarily in the great intestine. Cancerous tumours in the intestine are often of very slow growth. They tend to extend circularly round the gut, and thus to narrow its lumen. Secondary growths are frequently absent throughout. When they occur they affect the lymphatic glands, and less frequently the liver. As the growth advances it invades neighbouring parts, and at the same time degenerates and ulcerates in its centre. Thus, in some cases communications have been established between the bladder and the gut, or between the great and small intestine. Perforation is very rare, as adhesions form before the growth penetrates the wall of the gut. In all cases of stricture, whether simple or malignant, the gut is dilated above the narrowed part, and its muscular coat hypertrophied, a condition which can frequently be recognized by examination of the abdomen. Ulceration of the mucous membrane immediately above the stricture is rare, but in the cæcum it is very common, even when the obstruction is seated in the lower part of the colon. The formation of these "stercoral ulcers," as they are called, is apparently the result of the irritation and pressure of the accumulated faeces.

**Simple Tumours growing within the Bowel** very rarely cause obstruction. Tabular adenomata and papillomata are the most common simple tumours of the intestine, but if we exclude those growing in the rectum, they are extremely rare. Fibromata, springing from the submucous tissue, fibromyomata, lipomata and angiomas have also been described, but they are merely pathological curiosities.

**Narrowing of the Gut by pressure from without** is a more frequent cause of obstruction of the great intestine. Under this heading may be included pressure from inflammatory products, as in pelvic cellulitis or in perityphlitic or perinephritic abscess, and invasion or compression of the gut by malignant growths in neighbouring parts, as by a cancer of the tail of the pancreas, sarcomata in the iliac fossa, &c.

The **Special Symptoms of Narrowing of the Great Intestine** are the

same, whether the cause lies without or within the gut. They consist in gradually increasing difficulty in obtaining relief from the bowels. At first this is overcome by purgatives. The periods of constipation are frequently followed by diarrhœa. This alternation of constipation and diarrhœa always suggests the existence of some narrowing of the great intestine. In some cases the motions become gradually smaller, but this occurs only when the stricture is low down. In other cases the bowels act with great frequency, the motions being small in quantity and frequently loose. The passage of blood and mucus is an important sign of malignant ulceration. The patient at the same time suffers from dyspeptic symptoms, eructations, loss of appetite, and foul tongue. The complexion becomes muddy and unhealthy, and there is usually more or less loss of flesh. The abdomen becomes full, and the distended great intestine may often be recognized without difficulty. After these symptoms have existed for a longer or shorter time complete obstruction sets in with the signs already described.

**Mechanism of Obstruction of a narrowed Large Intestine.**—The final obstruction of the narrowed gut usually occurs as the result of the impaction of a hardened mass of fæces, or some indigestible material in the stricture. In other cases it apparently arises from kinking, bending, or twisting of the distended bowel above the stricture, for it is very common, after colotomy has been performed to relieve prolonged complete obstruction, for the fæces to pass freely again for some time by the natural passage.

**Prognosis.**—Chronic obstruction, if unrelieved, is, of course, ultimately fatal, either from exhaustion or from perforation of the gut, most commonly in the cæcum. It often happens, however, that the first attack passes off after one or two weeks' complete obstruction. This seems to arise from gradual softening of a fæcal mass impacted in the stricture owing to an abundant exudation from the irritated mucous membrane above the narrowed point. When the obstruction gives way it is usually followed by copious diarrhœa. If no relief is obtained, the duration of the case may vary from three weeks to two months. Much will depend upon the treatment. If the patient is properly fed, and not poisoned by powerful purgatives, life will usually be prolonged to six weeks or more without operative interference.

**Fæcal Accumulation.**—Obstruction from accumulation of hardened fæces occurs with infinitely rare exceptions in the great intestine only. It is most common in women, especially in those liable to hysteria. It is merely an exaggeration of habitual constipation. The gut, from being constantly distended, becomes partially paralysed and unable to expel its contents, relief being obtained only by the use of enemata and purgatives. A large fæcal mass accumulating under these conditions becomes gradually hardened by absorption of its more fluid constituents, and by pressing on and distending the gut leads to more complete paralysis of the part in which it is lodged. These masses are most commonly met with filling the rectum and sigmoid flexure, but they are not uncommon in the cæcum, and may be arrested at any part of the colon. The **Symptoms** are less severe than in other forms of obstruction. Vomiting may not come on till a very late period, and is rarely stercoraceous. The digestion and appetite become impaired, the complexion becomes yellow or earthy, there are unpleasant eructations, a foul tongue, and offensive breath. There is some loss of flesh. The abdomen becomes more or less distended, and coils of small intestine in active peristaltic movement are

sometimes visible. Under an anæsthetic, if the mass is lodged in the colon, it can be felt as a firm tumour, which, on pressure, can be indented with the finger like a mass of putty. If this sign is present, it is diagnostic of faecal accumulation, but it does not prove that there is no stricture below it. If the accumulation fills the rectum, it is recognized by digital examination.

**Results.**—Faecal accumulation is very rarely fatal. When it does cause death it is most commonly from ulceration of the mucous membrane, apparently from the pressure and irritation of the faecal mass, followed by perforation and peritonitis. The duration of obstruction from faecal accumulation is often extraordinary, authentic cases being recorded in which patients have recovered after having passed no motion for more than three months. *Enteroliths* have in very rare cases been known to cause obstruction resembling that by faecal accumulations.

**Chronic Intussusception.**—About 18 per cent. of all cases of intussusception run a chronic course, due to the slight degree of the strangulation, and the imperfect occlusion of the lumen of the bowel. Chronic intussusception occurs far more frequently in adults than in children. In 60 per cent. the invagination occurs at the ileo-caecal valve. In some cases it is associated with the presence of a tumour of the bowel. The *Symptoms* of chronic intussusception are often very anomalous. The invasion is not usually very sudden, and as the lumen of the bowel is not completely occluded, nor the strangulation sufficient to cause shock or gangrene of the gut, the other signs of intussusception may be more or less wanting. The constipation is not complete; there may even be diarrhoea, or alternate constipation and diarrhoea. Vomiting is slight and intermittent, and the pain paroxysmal and colicky. Tenesmus is absent in most cases; in about half there is no blood or mucus in the stools. There is usually little distension of the abdomen; but if the case last long enough some hypertrophy of the muscular coat of the bowel above the obstruction may take place and the coils may then be distinctly visible through the thin abdominal wall. In about half the recorded cases the characteristic tumour has been recognized. The general health suffers considerably, the appetite is bad, and the patient gradually loses flesh and strength. The duration of chronic intussusception is usually at least two or three months, and Treves mentions one case in which it extended to one year. The patient may die merely from exhaustion, or complete obstruction may set in and prove fatal. In some cases perforation of the gut above the obstruction has been the immediate cause of death. Recovery by separation of the intussusceptum is infinitely rare.

**Relative Frequency of the Various Forms of Intestinal Obstruction.**—Bryant has published the following statistics on this point, derived from the records of Guy's Hospital, and collected chiefly by the late Hilton Fagge. The obstructions caused by disease of the rectum and by chronic peritonitis are included. The total number of cases was 124. Of these 33 were acute, 76 chronic, and 15 were due to intussusception. Of the 33 acute cases, 1 was due to internal hernia, 7 to volvulus, and 25 to strangulation by bands. Of the 25 bands, 14 were old adhesions, 6 were connected with diverticula from the ileum, 2 with the vermiform appendix, 2 with the neck of a hernial sac, and 1 with the pedicle of an ovarian tumour. Of the 76 cases of chronic obstruction, 3 resulted from faecal impaction, 3 from pressure of tumours, 47 from stricture, and 23 from matting together of the intestinal coils from

chronic peritonitis or cancer. Of the 47 strictures, 2 were in the small gut and 45 in the large. To these 45 may be added 59 collected by Morris and Coupland. Of these 104 strictures of the great intestine, 78 were in the rectum and sigmoid flexure, 19 in the transverse colon, and 7 in the cæcum.

**DIAGNOSIS.**—The diagnosis of the cause of obstruction is of the greatest importance, for in certain forms there is no possibility of recovery except by surgical interference, and this must be adapted to the nature of the case.

In the first place, it is necessary, if possible, to exclude certain conditions, which, though not generally included under the name of intestinal obstruction, give rise to symptoms of a similar nature. The most important of these are simple intestinal colic, typhilitis, perforation of the vermiform appendix, and acute general peritonitis, which simulate acute obstruction; and lead colic, and chronic peritonitis which may resemble the chronic forms.

In simple intestinal colic vomiting is not a prominent symptom, and is never stercoraceous. Constipation is rarely complete, flatus, if not fæces, passing, and there is no collapse. The symptoms of perforation of the vermiform appendix will be given in the next Chapter.

**Acute General Peritonitis** is characterized by the marked tenderness of the abdomen, with rigidity of its walls. The vomiting is not so profuse, rarely stercoraceous, and occurs without straining or retching. The ejecta are usually dark-coloured. The constipation in peritonitis is very frequently incomplete, flatus, if not fæces, passing. In intestinal obstruction the temperature is usually subnormal; in peritonitis it is commonly elevated. The diagnosis is, however, confused by the fact that general peritonitis may occur as a complication of some forms of acute obstruction.

**Lead Colic** is usually easily recognized by the history of the case, the retraction of the belly, the absence of vomiting, and the blue line on the gums. The following case shows, however, that the symptoms may be very misleading. A man, aged thirty-eight, was admitted to the hospital for supposed intestinal obstruction. For six months he had suffered from increasing constipation and straining at stool. A fortnight before admission he first experienced severe pain in the lower part of the abdomen, extending to the right testicle. The abdomen was uniformly tender, but not distended. There was frequent bilious vomiting. The tongue was moist; temperature 100·6°; urine normal. The paroxysmal and colicky character of the pain led to an examination of the gums and the detection of a slight blue line. The pain subsided entirely after a hypodermic injection of morphine, and the bowels acted spontaneously on the third day.

**Chronic Peritonitis** is sometimes included as one of the causes of intestinal obstruction, and it no doubt does occasionally prove fatal in this way. When this happens the obstruction is due to matting together of the coils of intestine, or possibly to the formation of bands, and is rather an accident in the disease than an essential part of it. Chronic peritonitis is most commonly tuberculous, but it also arises in connexion with malignant growths, and sometimes without evident cause. In the tuberculous form there may be ascites; more commonly there is some fulness, with irregular hardness, or a doughy feel in the abdomen. There is slight elevation of temperature in most cases. Vomiting is often altogether absent, and is never stercoraceous. Diarrhœa is more common than obstruction, but cases do occur in which constipation is the most prominent symptom. I saw a case some years ago which terminated

fatally after more than six weeks' obstruction. The diagnosis is made by the peculiar feel of the abdomen, the presence of a small quantity of fluid, the gradual development of the disease, and possibly by the evidence of tubercle elsewhere. In simple and malignant chronic peritonitis, ascites is a marked symptom, and the condition is hardly likely to be confounded with intestinal obstruction. I have known of a case, however, in which obstruction was caused by a band formed in connexion with a malignant growth in the peritoneum. The abdomen was opened and the bowel relieved from the band, a large quantity of ascitic fluid being let out at the same time. The patient survived about six weeks.

Other conditions may sometimes be mistaken for intestinal obstruction. Thus, a case was sent into University College Hospital as intestinal obstruction which turned out to be stricture of the pylorus, the constipation being merely due to the fact that no food was passing into the intestine. In another case, uræmic vomiting was attributed to the effects of the pressure of a large renal tumour on the ascending colon. Such cases as these are usually easily distinguished by careful examination.

In any case of supposed intestinal obstruction occurring in a female the pelvic organs should be carefully examined, for there are various conditions, such as twisting of the pedicle of an ovarian cyst and ruptured pyosalpinx, which may cause very similar symptoms.

In all cases of acute obstruction all the apertures at which a hernia could protrude must be carefully examined as the first and most essential step in the diagnosis.

All the above conditions being excluded, and the case being recognized as one of genuine intestinal obstruction, the next question is to determine whether it is to be classed as acute or chronic. There is no difficulty in recognizing a typical case of either kind by attention to the symptoms already described (p. 894, and p. 897). Internal strangulation of all kinds, volvulus, and acute intussusception are typically acute; stricture of the great intestine, faecal accumulation, and chronic intussusception are typically chronic; obstruction from a foreign body in the small intestine, stricture of the small intestine, and some cases of intussusception, although usually presenting symptoms which would bring them into the acute class, may verge upon the chronic. In some cases of chronic obstruction of the great intestine, acute symptoms may suddenly develop from a twist of the gut above the obstruction.

The differential diagnosis of the various forms of internal strangulation and twist involving the small intestine is practically impossible, and these may be classed together. Impaction of foreign bodies, including gall-stones, volvulus of the sigmoid flexure, sudden occlusion of a stricture of the small intestine, and acute intussusception in a large proportion of cases, present sufficiently definite symptoms to make an accurate diagnosis possible. Among the chronic obstructions, stricture, faecal accumulations, and chronic intussusception may usually be distinguished from each other, but it is often impossible to determine the exact seat of the obstruction and its nature in cases of stricture. These facts being borne in mind, it is best to write down on a sheet of paper all the conditions above mentioned, and then to examine the patient methodically in the manner about to be described, noting every symptom under the disease to which it apparently points. In this way a diagnosis will probably be made, if it be possible.

The points which will engage the Surgeon's attention are :—1. The previous history. 2. The mode of invasion. 3. The general condition. 4. The character of the pain. 5. The character of the vomiting. 6. The duration and degree of constipation. 7. The physical examination of the belly. 8. Examination of the rectum. 9. The character and quantity of the urine.

1. The **Previous History** often throws much light upon the nature of the disease. In cases of *internal strangulation*, and in *intussusception*, the patient has usually enjoyed good health up to the time of the obstruction, although in some cases there is a history of a previous attack of the same kind. If the other symptoms seem to point to strangulation by a band, diseases likely to cause local adhesions in the peritoneum, such as typhoid fever, typhilitis, or ovaritis in the female, may be inquired for. In *Volvulus of the Sigmoid Flexure* there is a history of habitual constipation. In cases of *obstruction of the small intestine from impaction of a gall-stone*, there will be a history of prolonged pain and discomfort in the region of the gall-bladder during the time that the stone was making its way by ulceration into the intestine. In *stricture of the small intestine suddenly occluded* there is a long history of digestive troubles, attacks of colic, especially after food, and often of previous attacks of obstruction which have passed off. In chronic obstruction arising from *gradual closure of a stricture* there is a history of gradually increasing difficulty in obtaining relief from the bowels, with uneasiness and dyspepsia. Most commonly there have been periods of prolonged constipation followed by diarrhoea. These alternating periods of constipation and diarrhoea are very characteristic, and should always raise a suspicion of stricture, most probably in the great intestine. In *Fæcal accumulation* there has been chronic constipation of long duration.

2. **Mode of Invasion.**—In *Internal strangulation* the attack commences with severe pain, coming on so suddenly that the patient can state within an hour or less the exact time at which it seized him. In *Volvulus of the sigmoid flexure* the invasion is usually sudden, but commonly less so than in internal strangulation. In *Impacted gall-stone* the attack begins with uneasiness, increasing steadily in a few hours to actual pain. In *Obstruction of a stricture of the small intestine* the invasion is much like that of impacted gall-stone. In *Acute intussusception* the attack is usually very sudden. In all the *Chronic obstructions* except intussusception the symptoms develop gradually.

3. The **General Condition of the Patient.**—In *Internal strangulation*, *Volvulus*, and *Acute intussusception*, there is usually early collapse, with a small, quick pulse, and a subnormal temperature. Thirst is often a prominent symptom. In *Impacted gall-stone* and *Occluded stricture of the small gut*, collapse is not marked. In the *Chronic obstructions* there is no shock or collapse, and exhaustion comes on gradually. The tongue is foul in all forms.

4. The **Character of the Pain.**—In *Internal strangulation* it is most intense, often amounting to agony. It is usually referred to the umbilical region. In *Volvulus of the sigmoid flexure* it is less intense and paroxysmal. Later on acute tenderness is present from peritonitis. In *Impacted gall-stone* the pain is not usually severe, sometimes little more than uneasiness. In *Acute intussusception* the pain is severe and paroxysmal, often causing periodical screaming in children. In *Chronic obstruction from Stricture of the great intestine or fæcal accumulation* there is diffused uneasiness, and after a time

paroxysms of griping pain occur. In *Chronic intussusception* there is paroxysmal griping pain.

5. The **Character of the Vomiting**.—In *Internal strangulation* the vomiting sets in at once, is very frequent and profuse, and very soon becomes stercoraceous. In *Volvulus of the great intestine* it sets in later, is seldom profuse, and most frequently does not become stercoraceous. In *Impacted gall-stone* and *Occluded stricture*, it appears early and gradually increases in frequency, but may not become stercoraceous for many days. In *Acute intussusception* vomiting is often not a very prominent symptom, and does not become feculent for some days. In all *Chronic obstructions* vomiting is long delayed, moderate in amount, and does not become feculent until after two or three weeks. It is usually kept in check without difficulty by proper treatment and feeding.

Feculent vomiting, though one of the most characteristic symptoms of mechanical obstruction of the intestines, is occasionally present when apparently no such condition exists, disappearing after a time under the influence of opium, and, as above stated, in some varieties of actual obstruction it is altogether wanting.

6. The **Duration and Degree of Constipation**.—In *Internal strangulation* and *Impacted gall-stone* the constipation is complete, neither feces nor flatus passing, nor, except in a few cases of *volvulus*, is there any sense of a desire to go to stool. In *Acute intussusception* there is marked tenesmus, and blood and mucus, sometimes mixed with some fecal matter, are discharged. In these cases the constipation is sudden in persons previously regular in their bowels, and there is a sense of its dependence on a fixed cause. In *Volvulus of the sigmoid flexure*, the complete arrest of flatus and feces comes on suddenly, but there has been a previous history of chronic constipation. In *Chronic obstruction from stricture* the constipation is complete, but is gradually developed as an aggravation of previous partial obstruction. Unless the stricture be in the rectum there is rarely any tenesmus. In *Faecal impaction* the constipation is not always complete, flatus occasionally passing. There is usually a sense of a desire to defecate. In *Chronic intussusception* constipation is the exception; there may be tenesmus with the passage of blood and mucus, but this is by no means constant, as in the acute form.

7. The **Physical Examination of the Belly**.—(a.) **Inspection**.—The chief points to be observed are, the distension of the abdomen, the form it has assumed, the appearance of coils of distended gut, and peristaltic movements.

**Distension of the Abdomen**.—In *Internal strangulation* it rarely develops before the third or fourth day, and is seldom extreme. In *Volvulus of the great intestine* it appears from the commencement, and forms one of the most marked features of the case. It may be so great as to interfere with respiration and in this way cause death. In *Impacted gall-stone* distension is slight or wanting, and the same is the case in *Acute intussusception*.

In *Chronic obstruction from stricture* it gradually increases, and after one or two weeks may become excessive, causing much distress. In *Chronic intussusception* it is absent, unless the obstruction is complete.

The **Form of the Abdomen**.—When the obstruction is in the small intestine and acute, the distension is usually, in the early stages, most marked in the epigastric, umbilical, and hypogastric regions, the flanks being less distended. In obstructions low down in the great gut the distended colon on

each side fills out the flanks, giving the abdomen a barrel-shape. In some cases of strangulation by a band or internal hernia, the abdomen may be irregularly distended, one side or region being more prominent than the rest. Too much importance must not be attached, however, to the form of the abdomen, as it is often deceptive, and especially when the distension is great. In women who have borne children there is always great prominence in the umbilical and hypogastric regions, whatever the cause of the distension may be.

**Coils of Intestine visible through the abdominal walls** may be observed, when the patient is thin, in all forms of obstruction if there is much distension. In *Internal strangulation* this symptom occurs late if at all. In *Volvulus of the sigmoid flexure* the enormous size of the distended gut does not suggest a coil of intestine. In *Impacted gall-stone* and *Acute intussusception*, no coils are visible as a rule. In *Stricture of the small intestine*, as the gut is already dilated and hypertrophied, the coils readily become visible should obstruction occur. It is in *Chronic obstruction from stricture of the great intestine*, and in chronic intussusception, that the distended coils of small intestine are usually most distinctly visible.

**Peristalsis of visible coils** is most marked in *Chronic obstructions in the great intestine*. It may be taken as evidence that the gut is not paralysed by acute peritonitis; but beyond this it is of no great value.

**(b.) Percussion.**—By percussion we try to ascertain the condition of the colon. In the normal condition the different notes given by the stomach, colon, and small intestine, usually enable us to determine their positions, but in the distended abdomen the evidence thus obtained is often fallacious. The stomach is always concealed by the distended intestines. If the small intestines are much distended their note becomes indistinguishable from that of the colon. Extreme superficial tympanitic resonance, uniform in note and concealing the liver dulness, with a very pointed abdomen, indicates free gas in the peritoneal cavity either from actual or impending perforation. Hyper-resonance in each flank is usually a sign of a distended colon. Dulness in the flanks, disappearing on turning the patient on one side, is usually evidence of fluid, and may indicate that peritonitis is commencing. In a case in University College Hospital a few years ago, this sign was, however, found to be dependent on a loaded colon with a long meso-colon, which moved out of the flank when the patient was turned to the opposite side.

**(c.) Manipulation.**—By manipulation we estimate the degree of tension and the presence or absence of tenderness or tumour. In *Internal strangulation* it is very rarely that localized swelling or tenderness can be recognised. In *Volvulus of the sigmoid flexure* tenderness from peritonitis is an early symptom. In *Impacted gall-stone* an ill-defined hardness may occasionally be recognised, probably below and to the right of the umbilicus. In *Intussusception*, whether acute or chronic, the characteristic sausage-like tumour is usually to be found. In *Chronic obstruction from stricture of the great intestine* a tumour may be felt in exceptional cases, but much more commonly the results of manipulation are purely negative. In *Fæcal Accumulation* the mass can be felt and its putty-like consistence recognised. In all cases as soon as the distension becomes excessive, manipulation is useless. It may in the earlier stages be much facilitated by relaxing the abdominal walls by means of an anæsthetic.

8. **Examination of the Rectum** should never be omitted ; by it we ascertain the presence of strictures within reach of the finger, or tumours pressing on the rectum, and of faecal accumulations. In intussusception, we may feel the end of the invaginated intestine. Those whose hands are small enough to pass into the rectum—an uncommon condition in men—might possibly detect a malignant stricture in the sigmoid flexure.

If the stricture be seated at the upper part of the rectum, it may be recognised in some cases by a careful examination of the bowel with bougies, but this mode of examination is rarely of any value.

Another method of examination often employed is the administration of the largest possible enema, with the view of ascertaining whether the obstruction is low down in the great gut. This is very fallacious, as the abdominal distension is often so great that even when the whole colon is free, the patient cannot bear the injection of more than a few ounces of fluid.

Treves states that by careful auscultation of the abdomen during the administration of an enema it is sometimes possible to find the point of obstruction. If the colon is free, the fluid may be heard most clearly as it enters the caecum.

9. **The Quantity of Urine.**—It is frequently stated that in obstruction high up the quantity of urine secreted is diminished, owing to the lessened extent of intestinal surface capable of absorbing liquids. That scanty urine is commonly met with in these cases is undoubted, but this is probably due to the fact that the patient vomits all the liquid he takes.

By attention to the foregoing points, there may be no great difficulty in coming to a correct opinion as to whether the obstruction is in the large or small intestine. It may also be borne in mind that with the exception of twists of the colon and acute intussusception, all acute obstructions are seated in the small intestine, while the great majority of chronic are in the large. Yet cases do occur in which, though the obstruction be seated in the large intestine, and due to chronic stricture, the symptoms are acute probably from twist or kinking above the narrowed part, and thus errors of diagnosis will occur in spite of every precaution the Surgeon may take to avoid them.

**TREATMENT OF ACUTE OBSTRUCTION.**—Although it is a comparatively easy matter to indicate the treatment which should be adopted for the relief of the different varieties of acute intestinal obstruction described above, it is practically impossible to lay down any very definite rules for the treatment of a case in which the sudden onset of abdominal symptoms is suggestive of mechanical obstruction, but in which the character of the symptoms does not allow of a certain diagnosis. There can be no doubt that in many instances, if the exact condition could be accurately determined, the right treatment would consist in resorting at once to abdominal section and relieving the obstruction, and that medical treatment would be of as little use as in the treatment of an ordinary case of strangulated hernia. The differential diagnosis of the various forms of intestinal obstruction is attended with so much difficulty, and the similarity of the symptoms caused by other conditions is often so close that the greatest care is necessary in deciding between treatment by medical means and treatment by operation.

If a case has been seen immediately after the onset of the symptoms, and if on examination no cause of intestinal obstruction can be detected, the patient

must be closely watched and the effects of simple medical treatment noted. He should at once be confined to the recumbent position and the administration of food by the mouth stopped. Under no circumstances should purgatives of any kind be given, for if any cause of mechanical obstruction exists they can have no influence over it, and their only effect will be to increase the pain and vomiting and exhaust the patient. The only drug which is likely to be of any service is opium. This should be given in such quantity as to relieve the pain. If there is no vomiting a grain of solid opium may be administered by the mouth, but if, as so often happens, the patient has vomited almost immediately after the onset of the pain, morphia should be given hypodermically. Thirst may be relieved by sucking ice in very small quantity, or by sips of hot water.

Upon the course of the symptoms during the few hours after this treatment has been adopted the Surgeon will decide whether or not he has to deal with a case of true intestinal obstruction. He must avoid the serious mistake of regarding the case favourably because the urgent symptoms are relieved by absolute rest, the avoidance of food, and the administration of opium. In too many cases operative interference has been postponed until it has been undertaken as a last resource, and many valuable days have been allowed to slip away whilst the serious nature of the case has been masked by repeated doses of opium.

It is undoubtedly true that apparently desperate cases occasionally recover under the treatment by opium, but this should not induce the Surgeon to delay operation if the symptoms are such as to justify the diagnosis of internal strangulation or some other form of mechanical obstruction. The chances of success are as much influenced by delay in such cases as if the strangulation existed in an external hernia (p. 840), and, indeed, more so, for in all cases a varying degree of peritonitis sooner or later occurs, whilst the increasing distension of the intestines adds to the difficulty and therefore to the danger of the operation.

It remains to be considered whether any methods of treatment, other than operation, hold out sufficient hope of affording relief in acute intestinal obstruction to justify the Surgeon in delaying operation in order that he may employ them. With regard to *enemata* it may be stated that in all acute obstructions, except intussusception, they appear to be perfectly useless and to aggravate the patient's sufferings. In the same way the application of *ice* to the abdomen and the employment of *electricity* can hardly be productive of anything but harm. It seems scarcely reasonable to endeavour to relieve the obstruction at one time by arresting the peristaltic movements with morphia, and at another by stimulating them with electricity, and it may fairly be assumed that cases of supposed obstruction, which have been relieved by electricity, were due to faecal accumulation from paralysis of the muscular coat. The administration of *metallic mercury* in large quantities, with the view of overcoming the obstruction by its weight, is an ancient and barbarous treatment which cannot be of any use in genuine obstruction.

*Inversion of the patient, with massage of the abdomen*, is an ancient mode of treatment which has been employed with some success, and has recently been strongly supported by Hutchinson, who recommends that "abdominal taxis" be carried out as follows:—The bladder and rectum having been emptied, and the patient brought fully under the influence of an anæsthetic, the

Surgeon forcibly and repeatedly kneads the abdomen, pressing its contents vigorously upwards, downwards, and from side to side. The patient is then held up in the prone position by four men, and shaken backwards and forwards. He is next held feet uppermost, and shaken upwards and downwards, and copious enemata are given in the inverted position. Hutchinson recommends that the whole proceeding be carried out in an energetic manner for not less than half or three-quarters of an hour. In a case at University College Hospital, of extremely acute obstruction with violent stercoraceous vomiting, treatment of this kind was immediately successful; as the patient was inverted there was a loud gurgle, and a feeling like the reduction of a large hernia was perceived by the hand on the abdomen. I have also seen a case of obturator hernia—unrecognised during life—in which at the *post-mortem* examination it seemed probable that inversion and shaking would have effected reduction and so saved the patient. Hutchinson states that during twenty years' experience at the London Hospital he only opened the abdomen once for intestinal obstruction, and that for intussusception, and he could not remember a case in which the *post-mortem* made him regret not having operated. In the light of such facts the advisability of adopting this treatment in suitable cases, viz., in which the symptoms point strongly to strangulation by a band or internal hernia, and when there is no abdominal distension and no signs of peritonitis, must be considered. Seeing, however, how misleading the symptoms often are in these difficult cases, the majority of Surgeons will not regard inversion and abdominal taxis with sufficient favour to feel justified in delaying operation in order that they may adopt them.

*Puncture of the Intestines* with a trochar or the aspirator has been adopted in cases of great distension. This treatment is not free from risk, and has so rarely given more than temporary relief that it should not be adopted.

To sum up, therefore: As soon as the Surgeon has made up his mind that the case before him is one of acute intestinal obstruction due to some mechanical cause, the sooner he performs laparotomy the greater may be his hope of saving the patient.

It will be convenient in the first place to describe the operation as it is performed as an exploratory measure in a doubtful case, and subsequently to consider the appropriate treatment for the different conditions which may be met with.

OPERATIONS FOR INTESTINAL OBSTRUCTION.—Unless the patient's condition is so grave as to forbid a necessarily severe operation, **laparotomy** should be performed. All the rules already laid down for abdominal operations in general must be attended to (p. 819). After the anæsthetic has been administered, the bladder should be emptied, and if there has been stercoraceous vomiting, it may be advisable to pass a tube into the stomach, and wash it out with hot water. The incision should be made in the middle line below the umbilicus, and should be long enough readily to admit three fingers. When the peritoneum is reached, all bleeding must be carefully arrested, and the peritoneum divided in the whole length of the incision. In opening the peritoneum, it is very easy to wound the distended intestine beneath; this is best avoided by Tait's suggestion of holding forward the membrane with two pairs of forceps and dividing the fold between them. The Surgeon now proceeds to search for the cause of the obstruction.

This must, if possible, be done without allowing a free protrusion of the

intestines from the abdominal cavity. Three fingers of the right hand should be introduced, and the inner aspect of the umbilical, inguinal, femoral and obturator rings explored, and thus a small hernia, if present at either of these positions, detected. If nothing is found in this way, the plan which is usually adopted is as follows : The fingers are passed to the region of the cæcum and its condition determined. If it be distended, it proves that the obstruction is in the large intestine, and the fingers should explore the sigmoid flexure, where possibly the cause of obstruction may be found, or if the gut is empty it must be traced upwards. If the cæcum be collapsed, it proves that the obstruction is in the small intestine, and at the same time a tumour or intussusception might be felt at the ileo-cæcal valve, a gall-stone in the lower part of the ileum, or a constricting band at the brim of the pelvis. If, however, no such cause be found, the Surgeon should try to find the collapsed coils of gut below the obstruction, which, as Hulke showed, often lie in the pelvis, and he should follow them up until the obstruction is reached.

Greig Smith recommends a procedure somewhat different from that above described. Before introducing the hand, he advises that the coils of intestine which present at the wound should be carefully inspected by gently turning them first in one direction and then in another. Choosing the most dilated coil, this is "followed in the direction of increasing distension and congestion," which, according to Greig Smith, will certainly lead to the obstruction. Only two fingers need be used for this manipulation.

If by these various means the cause of the obstruction is still undiscovered, some of the distended coils of intestine must be allowed to escape and carefully protected with soft towels wrung out in warm carbolic lotion (1 in 40). The hand is then introduced for further examination, as only in this way, as Treves has shown, may some forms of internal hernia, such as that into the foramen of Winslow, be detected. The special treatment of the different varieties of obstruction will be considered separately.

After the obstruction, whatever may be its nature, is removed, the intestines, if not much distended, must be returned, and the wound closed and dressed as described at p. 820.

It has been very rightly urged that abdominal distension is in itself a serious symptom ; it is a powerful cause of shock, and by inducing paralysis of the bowel, it is often not relieved although the mechanical obstruction has been overcome. Most Surgeons will therefore agree with Greig Smith "that no operation for intestinal obstruction is properly completed if the patient leaves the operating table with a greatly distended abdomen."

He recommends the following treatment in cases of marked distension : The operation is completed as far as the introduction of the stitches whilst the patient is under the influence of the anæsthetic ; the patient is then allowed to recover consciousness. A loop of distended bowel is drawn out of the wound, and an incision made into it transversely to its long axis at a point most distant from the mesentery. The bowel is protected with warm flat sponges, and the contents allowed to escape into a suitable vessel through an india-rubber tube passed into the opening. The sides of the abdomen are gently kneaded by an assistant to favour the escape of the intestinal contents. At least half an hour will be occupied in this procedure ; and then, when the distension is thoroughly relieved, the incision in the bowel is sutured, and the

latter, after being cleaned, is returned. Finally, the sutures in the abdominal wall, which are already *in situ*, are tied.

After the operation, the abdomen must be well supported by a bandage, and the knees must be bent over a pillow. Opium must be continuously administered, and nothing but ice and barley-water allowed for twenty-four to forty-eight hours. Rectal feeding is sometimes necessary, and if there is much collapse, rectal injections of hot water have been found useful.

It sometimes happens that the patient's condition is so critical that the operation of laparotomy as above described is contra-indicated. Under these circumstances, **enterotomy** should be performed. This consists essentially in opening the first loop of distended bowel which presents itself on making a small opening into the abdomen. The incision may be made, as originally recommended by Nélaton, in the right iliac region, but more often a short incision is made in the middle line below the umbilicus. The first piece of distended gut that appears is attached to the edges of the wound with sutures, and opened by a small incision. Although this treatment can only be regarded as intended to relieve urgent symptoms, it has in some instances been followed by permanent relief. In the very urgent cases in which enterotomy is indicated, no general anæsthetic should be used, but, if necessary, cocaine may be injected at the seat of the incision as advised by Greig Smith.

**Special Treatment of the different varieties of Acute Intestinal Obstruction.**—In cases of *internal strangulation*, the constricting band should, if possible, be freely removed between two ligatures; if the constriction is produced by a patent Meckel's diverticulum, or the vermiform appendix, the gut may be simply released, and if the constricting tube be removed, its end must be closed with Lembert's sutures, or by a single ligature, if it is small. When the gut is strangulated through an aperture, this may need to be enlarged before reduction is possible, and it should then, if circumstances permit, be closed by one or more sutures.

If *volvulus of the sigmoid flexure* can be definitely diagnosed, it is probable that the best treatment consists in performing left lumbar colotomy, as there is not much hope of reducing the volvulus by abdominal section. If, however, the nature of the case has only been discovered by means of an exploratory laparotomy, reduction should be attempted, and has in rare instances been successfully accomplished in volvulus of the sigmoid flexure, cæcum, and small intestine. If necessary, the distended coil of intestine may be emptied by an incision, and further attempts made to undo the twist. If this be found impossible, a loop of distended intestine above the obstruction should be drawn into the wound, and enterotomy performed.

If a *gall-stone* be found, an attempt may be made to push it on into the large intestine, as has been successfully done by Clutton. Failing this, the stone should be cut out by a longitudinal incision in the gut; if the latter appear healthy the incision may be made directly over the stone, but if the gut be damaged the incision should be made in the dilated part above. The incision in the gut is closed with sutures in the ordinary way. Removal of the stone by an incision is probably safer than attempting to break it up by puncture with a fine needle as has been suggested.

If the case be one of *stricture of the small intestine*, which has suddenly become blocked, an artificial anus should be made above the obstruction, or intestinal anastomosis performed (p. 924). The conditions are usually too

unfavourable to allow immediate reaction of the strictured portion, but this may be attempted as a secondary operation.

**Treatment of Intussusception.**—There can be little doubt that spontaneous reduction occurs in many of the slighter cases of intussusception, but when the disease is fully developed the only possible mode of natural cure is by gangrene of the intussusception and its subsequent separation and expulsion. This mode of cure does not occur in more than a quarter of all cases. In children under 10 years of age, in whom 50 per cent. of all cases occur, recovery by separation of the intussusception is very rare, certainly not happening once in twenty cases. Under two years of age it occurs in less than 2 per cent. In these cases, therefore, unless the invagination be reduced by mechanical means, death is almost inevitable.

In all cases, as soon as the diagnosis is made, small doses of opium should be given to arrest peristaltic movement and thus to prevent the increase of the invagination. **Injection** should then be tried without delay. In order to do this the patient must be put fully under the influence of chloroform to prevent straining and to relax spasm in the bowel. Air or water may be injected by means of a common Higginson's syringe, the anus being caulked around the tube with wet wool; or when fluid injections are used they may be allowed to flow in through a tube attached to a vessel which is raised about three feet above the level of the patient's body.

Care must be taken not to use too much force or to carry the distension too far, as serious injury to the intestine has been known to result. At the same time the tumour should be grasped if possible through the relaxed abdominal walls and gently manipulated, as this seems in some cases to aid in reduction. In a case recently in University College Hospital, reduction was in fact effected by manipulation alone through the thin abdominal walls of a young child. As the inflation proceeds the tumour will be felt gradually to move in the direction of the cæcum, and at last to disappear, leaving perhaps a sense of fulness behind it due to the swollen state of the gut. Injection has been successful in a large number of recorded cases, especially in infants. It can evidently be of use only in the ileo-cæcal and colic varieties. In a case under my care in a child aged ten years, the patient not being anæsthetized felt "as if a bone broke" in the abdomen as the reduction took place. If injection fails after a proper trial, little will be gained by repeating it.

The changes of spontaneous cure are so small that, if injection has failed, laparotomy should be performed and an attempt made to reduce the invagination. This operation was first suggested by Nuck, and has been successfully performed in a considerable number of cases. The usual median incision should be made and the intussusception drawn well up into view, so that its condition may be seen.

Reduction must be attempted by a process of kneading and drawing down the sheath, rather than by forcibly attempting to drag out the entering tube. If reduction is impossible, the Surgeon has three courses open to him: 1. To open the bowel above the intussusception and leave the latter untouched; 2. To excise the intussusception and stitch the ends of the bowel into the wound, thus making an artificial anus to be subsequently dealt with if recovery follow; 3. To excise the intussusception and suture together the ends of the bowel. The first method is, as a rule, the only one available, on account of the patient's condition and the extent of the invagination. The

second course is the best to pursue if the patient's condition is favourable and the intussusception small. The last method involves too long an operation to render its employment often practicable in the acute forms of intussusception. Senn's method of intestinal anastomosis (p. 924) has, however, been successfully adopted, and Barker has suggested that in suitable cases it might be possible to excise the intussusceptum through an incision in the sheath after placing a row of sutures round the neck of the invagination.

**Results of Operation for Acute Intestinal Obstruction.**—Farquhar Curtis has collected 328 cases of laparotomy for acute intestinal obstruction performed between 1873 and 1888. Of these 102 recovered and 226 died, giving a total mortality of 68·9 per cent. It is very important to note that of the fatal cases 101 were in a desperate condition before the operation, and in 41 peritonitis or gangrene of the bowel existed. These figures show clearly the large share which delay takes in causing the high mortality. That the death rate is also largely influenced by the length of the operation is also shown by the same statistics. According as simple relief of the obstruction, the formation of an artificial anus, or resection of intestine and suture was practised, the mortality was 56·4, 66, and 86 per cent. respectively. The mortality is also considerably influenced by the nature of the obstruction: thus in strangulation by bands or apertures it appears to be about 60 per cent., in acute intussusception 76 per cent., and in volvulus 82 per cent.

**TREATMENT OF CHRONIC INTESTINAL OBSTRUCTION.**—As before stated, this most commonly arises from faecal impaction, the compression of the large intestine by a tumour, or its narrowing by a stricture; much more rarely it results from chronic intussusception.

*Faecal impaction* is most common in elderly women. When it is suspected, the rectum should be explored, and if it be found to be blocked up by a rounded mass of indurated and impacted faeces, the Surgeon must condescend to undertake the duties of the nightman, and empty the human cloaca of its fetid accumulations. This is best done by anaesthetizing the patient, then dilating the sphincter ani with the fingers, breaking down the indurated mass with a spoon or lithotomy scoop, and washing it away by copious enemata.

In *chronic intussusception* injection is seldom of much use, and laparotomy gives the best chance of life. The operation has been successfully performed by Howse and others.

If the obstruction arise from the gradual compression of the rectum by an *intrapelvic tumour*, or from *malignant or simple stricture* of the great intestine, purgatives will be worse than useless; they will irritate, will often induce vomiting, and will always considerably increase the patient's distress, and should not be repeated. The patient should be kept quiet in bed. His diet must be limited to the smallest amount, and must be exclusively liquid. Arrowroot or ground-rice cooked with water, with the addition of a little brandy or wine, may be given; mutton or chicken broth being occasionally allowed as a change. Milk is usually found to aggravate the symptoms, but sometimes is taken easily, in small quantities, with soda-water. Enemata may be fairly tried, but if they do not soon overcome the obstruction nothing is gained by persistently annoying the patient with them. In some cases the introduction of a long rectal tube, and the administration of an injection, in this way may bring about relief. If the stricture is within reach, a catheter can sometimes be introduced through it, by means of which a large olive-oil

enema may be administered, and in this way the obstruction may be overcome. If these means do not succeed, opium may be administered, and sometimes after some weeks, the obstruction may give way. H. O. Thomas, who paid considerable attention to this subject, states that this frequently occurred in his practice, and that he was able to prevent the early return of the obstruction by keeping the patient on the restricted diet already mentioned.

Although this simple treatment is often successful and affords at least temporary relief, operative interference is required in many cases of chronic intestinal obstruction. Leaving out of consideration the comparatively rare cases of chronic intussusception, the probabilities are that the obstruction is due to a stricture of the large intestine. Theoretically the ideal treatment of such a case would be to perform laparotomy and, if a stricture of the large intestine be found, to excise the diseased portion of the bowel and suture together the upper and lower ends. Such an operation hardly comes within the bounds of practicability when actual obstruction is present, although it may, in suitable cases, be undertaken subsequently, after the obstruction has been relieved by simpler means (see Chapter LIII.). Practically the treatment usually adopted consists in opening the large intestine above the obstruction (*colotomy*), but an alternative method in some cases consists in establishing a communication between some part of the bowel above the obstruction and that below, as suggested by Senn (*intestinal anastomosis*).

**Colotomy.**—The operation required to give exit to the intestinal contents is of two kinds. In one the intestine is opened by an incision opening the peritoneum through the abdominal wall, usually in the left iliac fossa. In the other it is opened in the loin by cutting between the layers of the meso-colon, being thus exposed where it is uncovered by peritoneum.

Colotomy may be required for the following conditions:—

1. Intestinal obstruction below the descending colon.
2. Volvulus of the sigmoid flexure.
3. Intense pain in defæcation, in ulcerated cancer of the large intestine or rectum.
4. Cancerous fistula between the rectum and bladder.
5. Congenital absence of the rectum.

It will be convenient to describe the two methods usually adopted and then to consider their relative advantages.

**Inguinal Colotomy.**—This operation, which is often known as "*Littre's Operation*," after the Surgeon who proposed in 1710 that in these cases the sigmoid flexure of the colon should be opened in the left iliac region. It was not, however, until 1776 that any operation of the kind was performed, when Pillore of Rouen was the first to make an artificial anus in the adult, for relief of retention of fæces; this he did, not according to Littre's method, but by opening the cæcum in the right iliac region. Fine, of Geneva, in 1797, opened the transverse colon in the umbilical region, in a case of retention of fæces produced by a "scirrhus" of the upper part of the rectum. Of late years the operation has been extensively practised, and various improvements suggested by Harrison Cripps, H. W. Allingham, Maydl and others.

Inguinal colotomy may conveniently be performed by the following method, which in most respects is identical with that recommended by Cripps. An imaginary line is drawn from the umbilicus to the anterior superior spine of the left ilium, and an incision two and a half inches long is made, crossing

this line at right angles an inch and a half from the spinous process and being half above the line and half below it. The layers of the abdominal wall, including the peritoneum, are divided in the usual way. If the distended sigmoid flexure does not at once present in the wound, the small intestine or omentum must be pushed aside and the colon—recognised by its longitudinal muscular bands and appendices epiploicæ—sought for. When found, the gut is drawn gently downwards so that the opening may be made as high as possible with the object of preventing subsequent prolapse. Two supporting sutures of silk are next passed through the longitudinal muscular band opposite the mesentery at a distance of two inches from each other. These are left long, and serve to steady the bowel whilst it is being attached to the skin. This is done by means of fine silk sutures, which include the edge of the skin and the serous and muscular coats of the bowel. About six of these will be required on each side: they should all be inserted before any are tied, and the part of the bowel which is left exposed should include about two-thirds of its circumference. Finally, one or more sutures may be required in order to bring together the angles of the skin incision. If the case is not urgent an antiseptic dressing is applied, a piece of protective being placed over the exposed bowel, and on the fifth or sixth day the latter is opened by cutting out a small elliptical piece of its wall.

In an urgent case, when the bowel needs to be opened at once, especial care must be taken in the process of suturing.

It is very important that, after the bowel is opened, a prominent spur (p. 858) should separate the upper and lower openings: this serves to direct the contents out through the artificial anus, and prevents them passing onwards into the bowel between the opening and the obstruction. To insure the formation of such a spur, several devices have been suggested. The most simple consists in drawing out the bowel until its mesentery is exposed, and transfixing the latter with a piece of glass rod, which is left resting on the abdominal wall. Instead of the rod, a suture may be passed through the mesentery and the skin on either side of the incision.

The suggestion to divide the bowel completely, close the lower end, and suture the upper into the opening in the parietes, cannot be recommended. It greatly increases the severity of the operation, and is likely to be followed by trouble from accumulation of discharges above the stricture.

**Lumbar Colotomy.**—In order to avoid wounding the peritoneum, Callisen, of Copenhagen, in 1796, proposed opening the colon from behind, in the left lumbar region, where it is not covered by peritoneum. He once attempted this operation on the dead body of a child; but, failing to reach the intestine without wounding the serous membrane, he seems to have abandoned all further idea of it. The operation was, however, subsequently practised and perfected by Amussat, and is frequently known as "*Amussat's Operation*." It affords an admirable illustration of the important practical application of an apparently trivial anatomical fact, viz., the relation of the layers of the meso-colon to the descending colon.

Amussat, when he was attending the celebrated Broussais for cancer of the rectum, of which he ultimately died, was led to reflect on the resources that Surgery offers in similar cases; and after making some experiments on the dead body, he became convinced that the operation proposed by Callisen, if somewhat modified, was not only practicable, but safe. He soon had an op-

portunity of putting this opinion to the test of actual practice in 1839, in a private case, at which he kindly invited me, then a student in Paris, to be present. The operation was perfectly successful.

Lumbar Colotomy may be performed as follows: If the operation is to be performed in the ordinary situation on the left side, the patient must be placed on his right side, with a firm folded pillow beneath the flank, so that the body may be slightly curved to the right, and the space between the last rib and the crest of the ilium on the left side made as wide as possible. The Surgeon then measures from the anterior superior to the posterior superior spine of the ilium, carrying the tape straight from one to the other, and not along the crest of the ilium. From the mid-point between the two spines (Heath), or half an inch behind it (Allingham), a vertical line is drawn upwards, as in Fig. 817. This indicates the line of the colon. In this line a point is taken exactly mid-way between the last rib and the crest of the ilium. An incision, either transverse or inclined slightly downwards and forwards (Fig. 817), is then made, passing through this point. It must be from three to four inches in length, half on each side of the vertical line. If the measurements have been

Fig. 817.—Line of Incision for Lumbar Colotomy. Dotted line indicates situation of Descending Colon

correctly taken, the posterior extremity of the incision will be at the edge of erector spinæ. In fact the edge of this muscle is practically a better guide than the vertical line just mentioned. The incision is steadily deepened through the skin and superficial fascia by light strokes of the knife. After these are divided, the external oblique comes into view in the anterior two-thirds of the wound, and the latissimus dorsi in the posterior third; these are divided by drawing the knife lightly along the wound, and the internal oblique is then exposed and cut through in the same way. The fascia lumborum now comes into view. This is the first important rallying point. It must be picked up carefully with the dissecting forceps, and opened with the knife held horizontally: the finger, guiding a probe-pointed bistoury, may then be introduced through the opening, and the fascia lumborum divided freely in the whole length of the wound. At this stage the last dorsal nerve and the artery accompanying it are usually divided, and the vessel must be twisted or tied. The incision through the fascia lumborum always opens the sheath of the quadratus lumborum, the external border of which must be freely notched if it obstruct the wound. In dividing the muscles, two points must be attended to: first, that these structures are cut through to the same extent as the skin, otherwise the Surgeon will continue to dig in a deep and

conical pit, and will fail to recognize the gut at the bottom of it; and secondly, to avoid drifting downwards towards the crest of the ilium, as the incision is deepened, from drawing the wound to one side with the left hand.

At this stage of the operation two copper spatulae must be put into the wound, by which it is drawn widely open. Some loose fat then comes into view, which must be carefully torn through with the fingers, no forceps or other instrument being used. In thin patients this fat is wanting. The fascia transversalis next appears. This is a very variable structure; in fat females it is scarcely recognizable, while in a thin male it is often so strong as to be mistaken for the peritoneum or the gut. It must be carefully torn through at the posterior part of the wound. The subperitoneal fat, varying in amount with the fatness of the patient, is then exposed, and must be torn through carefully with the fingers. The gut is now reached. If the operation is being performed for obstruction, the colon is tensely distended, of a greenish colour, and usually rises up into the wound. In cases in which this operation is being undertaken for relief of pain in cancer of the rectum, the gut may be collapsed. In this state, not only is it very troublesome to find, but the part uncovered by peritoneum is so small that it is difficult to make an opening without wounding that membrane. All these difficulties are at once overcome by distending the gut with air. Lund has invented an ingenious apparatus for this purpose, but the gut can easily be distended by means of an ordinary enema syringe, the anus being closed around the tube by a mass of wet or oiled wool pressed against it by the hand of an assistant. As the air enters the gut will be seen and felt rising up in the wound; and in most cases, if the transversalis fascia have been sufficiently torn through, it will rise up to the level of the skin. If from any reason this fails, the gut may be found by pushing the forefinger into the wound till the lower end of the kidney is felt, immediately in front of which the colon lies. Pressure on the abdomen will sometimes make it appear. In other cases it may be found by turning the patient on his back, passing the forefinger into the posterior part of the wound, and then seizing between it and the thumb the parts in contact with it. The patient is then rolled again on to his side and the gut drawn up into the wound. In whatever way the gut is seized, it must be drawn well up to the level of the skin. The subsequent steps of the operation will differ according as it is necessary or not to open the bowel at once.

If the opening of the gut can be delayed, the anterior and posterior parts of the wound should be closed with sutures including the muscles as well as the skin. The gut is then fixed to the edges of the latter with a series of fine silk sutures passing only through the muscular coat. Some Surgeons dispense with stitches altogether; and a convenient method suggested by Davies-Colley consists in transfixing the gut with two fine pins which rest on the skin. In any case the wound should be dressed antiseptically, and the bowel opened on the fourth or fifth day.

If it be necessary to open the bowel at once, the following method should be adopted: Two silk threads, each about two feet long, are passed through the gut and the skin and fat on each side of the wound in the following way. A curved needle is threaded on the suture; it is first passed through the skin and fat on one side of the wound, then longitudinally through the anterior part of the gut exposed, including about one inch of it; finally the needle is passed from the wound through the skin and fat opposite to the point at

which it enters on the other side. A similar thread is then passed in the same way, including the posterior part of the gut exposed. Care must be taken not to puncture the peritoneum with the anterior thread. An incision is then made into the gut between the two sutures, the finger introduced, the loops pulled out and divided and tied. Thus the gut is rapidly secured by four sutures immediately after being opened, and the faecal matter is prevented from running into the wound. More sutures may be put in afterwards, if necessary. Before the bowel is opened, the wound should be thoroughly sponged with chloride of zinc (gr. 40 to 3j) and well dusted with iodoform, and the posterior part over which the faecal matter will flow may be smeared with iodo-vaseline ointment or carbolic oil. The gut should be brought as far back in the wound as can conveniently be done. After the operation the anterior part of the wound may be closed with sutures, but the posterior should be left partly open, and, if necessary, a drainage-tube introduced to prevent any burrowing of pus in the loose subperitoneal areolar tissue. A pad of carded oakum, or some other absorbent material, is then applied and changed frequently. A piece of lint soaked in carbolic oil (1 in 10) may be applied next the skin, a hole being cut through it opposite the gut.

*Wound of the Peritoneum* is the most serious accident during the operation, as it may be followed by peritonitis, but it is by no means necessarily so. It may occur in three stages of the operation:—1, while dividing the fascia lumborum, from too free use of the knife; 2, the posterior reflection may be torn with the finger by using it as a hook to drag the gut up into the wound; 3, it may be punctured by the needles, or wounded by the knife in opening the gut. In rare cases free gas is met with in the peritoneal cavity, and this may lead to the peritoneum being mistaken for the gut. In some cases a complete meso-colon is met with, so that it is impossible to open the gut without wounding the serous membrane. In fat subjects the depth of the wound increases the difficulty of the operation, in some cases necessitating a crucial incision to give more space. Different Surgeons have variously modified the operation by making the incision vertical or semilunar instead of transverse, but the method above described is that usually preferred.

The patient will derive much comfort after the operation from taking powdered charcoal. It not only deodorizes, but also tends to harden, the faeces. When recovery has taken place, the aperture in the lumbar region may be kept supported and closed by means of a truss with a large pad.

After recovery two complications are not uncommonly met with—contraction of the artificial anus and prolapse of the gut. The first is best prevented by drawing the gut well up in the wound at the time of the operation. If there is a tendency to contraction it may be prevented by introducing a conical vulcanite plug, which must be constantly worn. Prolapsus is best prevented by a properly constructed pad, secured by an elastic belt.

The causes of death after colotomy are usually exhaustion, septicæmia, peritonitis from wound of the membrane, and occasionally secondary peritonitis from burrowing of pus in the subperitoneal fat towards the iliac fossa.

*Colotomy on the right side* is done in the same way as on the left and presents no difference requiring notice.

**Comparison of the Inguinal and Lumbar Operations.**—Although there has been a strong wave of opinion in favour of inguinal colotomy during recent years, the relative advantages of the two methods are pretty evenly balanced.

The inguinal operation is easier to perform than the lumbar, especially when the patient is fat and the colon empty. The fact of the peritoneum being opened in inguinal colotomy does not seem a practical drawback, especially as when possible the operation is performed in two stages, and it is said that the risk of peritonitis is less than when the peritoneum is accidentally wounded in the lumbar operation, as the uniform pressure of the anterior abdominal wall tends to prevent the entrance of faecal matter into the cavity. The fact that the sigmoid flexure is so often the seat of disease in malignant stricture is a very strong argument in favour of Amussat's operation in such cases. The argument that the iliac incision allows exploration in doubtful cases is not a strong one, for under these circumstances, a median laparotomy will usually be performed, and the Surgeon will choose between making an artificial anus at the median incision, or closing this and opening the colon in the loin. As far as the future comfort of the patient is concerned it may be pointed out that prolapse is more common after the anterior operation, and it is very doubtful whether an artificial anus at the groin is as conveniently placed as one in the loin. When colotomy is performed for congenital absence of the rectum, Littré's operation is preferable, as being much less difficult and more certain to reach the gut, which is often, in infants, attached by a long mesocolon in the loin.

The mortality due to the operation itself is certainly small, and, especially in the case of the lumbar operation, death is far more often the result of the unfavourable condition of the patient at the time when it is performed.

Fig. 815.—Intestinal Anastomosis with Senn's plates.

**Intestinal Anastomosis.**—This operation, as already stated, consists in making a permanent communication between the intestine above and that below an obstruction, and is available as a substitute for the formation of an artificial anus in certain cases in which for some reason the cause of the obstruction cannot be removed. For instance, in the treatment of malignant disease of the caecum causing obstruction, but too extensive for removal, *ileo-colostomy* has been performed and a communication established between the ileum and the ascending colon.

The difficulties of the operation were so great that it had rarely been

attempted until Senn, of Chicago, simplified the method by the use of decalcified bone plates, by which complicated suturing is rendered unnecessary and the operation proportionately shortened. The plates are oval in shape and measure  $2\frac{1}{2}$  to 3 inches in length, 1 inch in width, and  $\frac{1}{4}$  inch in thickness. They are perforated with an oval opening around which are four drill holes in which silk threads are attached. The two pieces of bowel to be united are drawn through a suitable incision in the abdominal wall, and a segment of each is emptied of its contents and clamped by the fingers of an

assistant. A longitudinal incision about an inch and a half in length is now made into each piece of bowel opposite the attached border. A plate is slipped into each and is turned so that its longer axis corresponds with that of the bowel. The end sutures attached to each plate pass out through the ends of the incisions in the bowel; the lateral ones, threaded on needles, are passed through the wall of the bowel opposite the middle of the incision (Fig. 818). When the corresponding sutures are firmly tied the plates are drawn together, and bring two large peritoneal surfaces into contact with a free opening in the centre of each between the two segments of bowel. Before tying the silk threads a few fine sutures are inserted in the peritoneum along the posterior borders of the plates (Fig. 818), and after the approximation is complete a continuous stitch may be placed in a corresponding position in front. Union rapidly occurs between the peritoneal surfaces and the bone plates are absorbed. A considerable number of successful operations have been performed by Senn's method and the various modifications of it which have been introduced, and intestinal anastomosis must be regarded as a definitely established line of treatment in suitable cases.

## CHAPTER LXIII.

## OPERATIONS ON THE PERITONEUM AND ABDOMINAL VISCERA.—TUMOURS OF THE GROIN.

## TAPPING THE ABDOMEN. PARACENTESIS ABDOMINIS.

THE abdomen often requires **Tapping**, either for general or encysted ascites. This operation, which is one of the simplest in surgery, may be performed as follows: The bladder having been emptied, the patient is seated on the edge of the bed or of a large chair, or if very weak lies on the side, and has a broad flannel roller, split at each end to within six inches of the middle, passed round the body in such a way that the untorn part covers the front of the abdomen, whilst the ends, which are crossed behind, are given to an assistant on each side, who must draw tightly upon them as the water flows. The Surgeon then, seating himself before the patient, and having ascertained that there is absolute dulness at the point at which he intends to operate, thrusts the trochar through the abdominal wall about two inches below the umbilicus. It was formerly customary to make a superficial incision with a scalpel through the skin and fat before inserting the trochar, but this is a needless complication. As the fluid escapes, the patient often becomes faint; but this may commonly be guarded against by continuing to draw upon the bandage so as to keep up good pressure on the abdomen. After all the fluid has escaped, the aperture must be closed with a strip or two of plaster supported by a pad and bandage, or a pad of iodoform or salicylic wool covered with collodion.

The siphon-trochar, Fig. 777, p. 758, will be found the most convenient instrument. It should not be too large lest the opening should leak after the operation. Should the situation of the accumulation of fluid in encysted ascites not allow its withdrawal by an aperture below the umbilicus, the abdomen may be tapped in any other convenient situation, except in the course of the epigastric vessels.

Ascitic fluid may also be removed by the aspirator, but in the abdomen this instrument presents no advantages over the ordinary siphon-trochar.

Southey, believing that a gradual withdrawal of the fluid is most advantageous, avoiding the risk of syncope and the necessity of bandaging the patient, has devised a small "drainage-trochar," which can be left in until the distension is relieved. The fluid flows steadily from it at the rate of from ten to twenty ounces per hour, through a fine india-rubber tube. This method of relieving ascites has been found very efficacious. It has no tendency to set up peritonitis, and is almost painless.

## LAPAROTOMY FOR PERITONITIS.

**Acute Peritonitis.**—Laparotomy for acute peritonitis may be undertaken with the object of removing such inflammatory products as are already present

in the peritoneal cavity, providing a free escape for any which may subsequently form, and in some instances remedying the cause of the inflammation, as by the closure of a perforation in the bowel. On account of the many varieties of acute peritonitis which are met with, and the diversity of its causes, it is impossible to speak of the results in general terms. Thus, whereas the treatment of a perfectly localized purulent peritonitis by drainage is often eminently satisfactory, the number of cases in which the diffuse septic form has been successfully dealt with is very small. Treves, who has recently brought the subject prominently before the profession, has pointed out the fallacy of general statistics in which cases of all varieties are grouped together. Thus of 119 cases of generalized purulent peritonitis recorded by Kreeke only 68 died; the greater number of the recoveries, however, occurred among the cases in which the cause of the peritonitis was unknown, or in which it started in the vermiform appendix; all the cases associated with hernia or with perforation of the stomach died.

It has already been stated in Vol. I. p. 876, that as a general rule operation should at once be undertaken in cases of peritonitis following injuries, and usually due to severe damage of one of the viscera. The same may be said of that form which occasionally results from operations on the abdomen, including those for hernia, although the hope of cure is very small. The results of operation for diffuse peritonitis following perforation of the stomach and intestines has been most unsatisfactory, but it gives the patient the only chance of life, and is therefore justifiable unless absolutely forbidden by the patient's condition. Those rare cases in which diffuse purulent peritonitis arises without any obvious cause, sometimes during the course of an acute specific disease, may be similarly treated.

Laparotomy for *perforative peritonitis in typhoid fever* has been attended with almost uniformly fatal results. Louis, in 1890, was able to collect 11 cases, but in some of these the evidence upon which the diagnosis was made is by no means satisfactory. Two cases recovered: one in which Mikulicz closed a perforation of the ileum with sutures, and another treated by Escher, in which the disease was thought to be typhoid, and in which perforation of the appendix with general peritonitis was present. It cannot reasonably be hoped that this treatment will ever be attended with much success, and the only hopeful cases are those in which an unhealed ulcer perforates during convalescence.

In dealing with a case of circumscribed purulent peritonitis free drainage must be established through a suitably placed incision, care being taken not to break down the adhesions by which the collection is shut off from the general cavity of the peritoneum. In cases of diffuse purulent peritonitis irrigation, as described at page 819, should be carried out, and then the cavity having been dried with sponges, a drainage tube is inserted. In cases where adhesions have already formed shutting off various collections of pus or turbid serous fluid, these must be gently separated to allow the fluid to escape. In no case should carbolic acid or perchloride of mercury lotions be introduced into the peritoneum, as they are dangerous if used in an efficient antiseptic strength. In some cases iodoform has been used with advantage, either applied in the form of powder or as an emulsion (Vol. I. p. 264).

**Tuberculous Peritonitis.**—The first instances in which this disease was successfully treated by laparotomy were cases in which the abdomen was opened

under a mistaken diagnosis. Thus in 1863 Spencer Wells operated on a young woman who was supposed to be suffering from an ovarian tumour; the abdomen was closed and the patient was alive and well twenty-two years afterwards. It was not, however, until 1884 that König first recorded some cases of tuberculous peritonitis in which laparotomy was performed as a definite mode of treatment. Since that time a large number of cases have been recorded in this country and abroad, and the results have been highly satisfactory. Of 131 cases collected by König in 1890, 107 recovered from the operation, and of these 30 were known to have remained well after varying periods of more than two years. By far the most successful results have been obtained in that form of tuberculous peritonitis which is attended with marked ascites, and the simple method adopted has consisted in opening the abdomen in order to allow the fluid to escape and then completely closing the incision without drainage. No satisfactory explanation has been suggested of the permanent cure which has followed this treatment. It must, however, be remembered that cases of tuberculous peritonitis not uncommonly recover under simple medical treatment, and that of all forms, the ascitic is the most favourable. These facts must be carefully borne in mind in endeavouring to estimate the real advantage of operative interference. In the purulent variety irrigation and drainage should be adopted, and localized abscesses may be similarly treated. The results which have been obtained in the dry forms of the disease, associated with extensive matting together of the intestines, have not been nearly so satisfactory. No operation should be undertaken if there is evidence of active tuberculous disease in other parts of the body.

In some instances the symptoms of tuberculous peritonitis have developed so acutely that the abdomen has been opened in the belief that intestinal obstruction existed. On the other hand actual obstruction may be caused by the kinking of adherent intestine. In a case of this kind under the care of Barker, the obstruction was caused by a loop of small intestine being firmly held down to the brim of the pelvis by a tough mass of lymph. The peritoneum was thickly studded with caseous tubercles, and the cavity contained a large quantity of clear fluid. The obstruction was relieved, iodoform emulsion freely used, and the abdomen closed. Six months later the patient appeared to be perfectly well, and there were no abdominal symptoms.

#### INFLAMMATION ABOUT THE CÆCUM.

Localised peritonitis in the region of the cæcum is of common occurrence, and, on account of the frequency with which it goes on to suppuration, surgical interference is not uncommonly required. No subject in abdominal surgery has received more attention than this during recent years, and among those to whom we are largely indebted for our increased knowledge concerning the inflammatory affections of the cæcum and its appendix may be mentioned Treves, Fitz, Bull of New York, and Fowler of Brooklyn.

The term "**Typhlitis**" is now employed in a general sense to include all varieties of inflammation localised to the cæcum or its appendix and the peritoneum which covers them. In a more restricted sense the name has been applied to inflammation of the cæcum, those cases in which the vermiform appendix is alone affected being distinguished as "*appendicitis*." This division is of little practical value, for in many cases it is impossible from the

clinical features to determine the exact seat of the inflammation. If suppuration occur around the cæcum or its appendix, a "*perityphlitic abscess*" results, which is in all cases primarily intraperitoneal; for, as Treves has shown, both the cæcum and the appendix are completely covered by peritoneum.

*Pathology.*—In the milder forms of typhlitis, which almost invariably recover under simple medical treatment, the condition which is thought to exist most commonly is an ulceration of the mucous membrane of the cæcum with secondary inflammation of the peritoneum covering it. The ulceration is probably induced by the irritation of hard faecal matter, which is especially liable to accumulate in this part of the intestine. Treves has, however, shown that equally mild attacks of typhlitis may be due to mischief in the appendix, and there is, in the opinion of some Surgeons, reason for thinking that in all cases the appendix is at fault. The pathological grounds for the belief that many of the milder cases of typhlitis occur independently of mischief in the appendix are necessarily scanty, for the disease almost always ends in recovery.

In the more severe forms, however, which frequently result in abscess, there is no doubt that the starting-point is almost invariably the appendix, and thus it is that in cases which end fatally the same fact is almost constantly observed.

Among the pathological conditions to which the vermiform appendix is liable, the most important are catarrhal inflammation, ulceration, and gangrene. Catarrhal inflammation of its mucous membrane is the most simple inflammatory affection to which the appendix is liable, and is probably predisposed to by the abundant lymphoid tissue which Bland Sutton has shown to exist in the mucous membrane. It may be productive of serious symptoms if the escape of the mucus into the cæcum is prevented by blocking of the base of the appendix, as by kinking, or by the scarring following ulceration. This results in localized peritonitis, and the condition in question has been shewn by Treves to be at least one cause of "relapsing typhlitis" (see p. 932). Ulceration of the appendix, ending not uncommonly in perforation, seems to be usually the result of the irritation of hard faecal concretions, and much less frequently of the presence of a foreign body, such as an orange-pip or a cherry-stone. Often a small hard body, looking at first sight like a fruit stone, proves to be nothing more than a laminated mass of faecal matter. The perforation which follows may occur acutely before peritoneal adhesions have formed around, in which case general peritonitis probably results. Often, however, the process is more gradual, and a localized intraperitoneal abscess is the result. Tuberculous ulceration and typhoid ulceration are rare causes of perforation of the appendix; and a case due to actinomycosis has already been mentioned in Vol. I., p. 1106. Gangrene of the appendix is believed to occur in some instances from strangulation due to twists.

Observations show that the pus obtained from cases of localized or diffuse peritonitis secondary to perforation of the vermiform appendix is rich in the bacterium coli commune (p. 817).

**Perityphlitic Abscess** being almost invariably secondary to disease of the appendix, its position varies with that of the process itself. Treves finds that in the adult the appendix usually lies behind the end of the ileum and its mesentery, and points in the direction of the spleen; not unfrequently it lies vertically behind the cæcum, whilst it may hang down into the pelvis, and may be found in contact with the sigmoid flexure, rectum, uterus, or bladder. Usually the abscess occupies the peritoneal cavity in the right iliac region above

the brim of the pelvis, and is bounded by adhesions uniting together the cæcum and small intestine. If allowed to extend it may burst into the general peritoneum, or may point in the anterior abdominal wall, or extend on to the thigh. In exceptional cases the pus may burst into the cæcum, or, entering the pelvis, has been known to discharge itself into the vagina, rectum, or bladder. In still more exceptional cases the abscess has crossed the middle line to the left iliac region, or has extended upwards behind the ascending colon, forming a large collection in the loin, which has been known to reach the diaphragm, and even to perforate it.

Of the complications of perityphlitic abscess the most important is diffuse peritonitis. This usually assumes a plastic form, the coils of intestine throughout the abdomen being glued together with firm yellowish lymph. There is, as a rule, but little fluid in the cavity, usually only a few ounces in the pelvis. In rare instances pyæmia has resulted from septic phlebitis and thrombosis of the iliac veins or their tributaries; and from infection of some of the mesenteric veins pyelphlebitis with suppuration in the liver has been known to occur.

*Symptoms.*—On account of the varied nature of the inflammatory affections in the region of the cæcum the symptoms of typhlitis differ considerably.

**Simple Typhlitis** unattended with suppuration is by far the most common form, and as a rule recovery takes place under simple medical treatment. Its probable pathology has already been considered, and the symptoms must be shortly mentioned here, in order that they may be compared with those of the severe forms which require surgical treatment, and because in some cases an apparently mild case may end in suppuration. The attack begins more or less acutely, with pain and tenderness in the region of the cæcum. The bowels are constipated, and there is often some vomiting, but this is not usually a marked symptom. There is commonly some elevation of temperature about the third or fourth day. A well marked swelling is felt in the region of the cæcum, the doughy character of which indicates that it is the result of fecal accumulation. Treves has pointed out that "a careful digital examination *per rectum*, and careful palpation of the iliac fossa, do not reveal any swelling that resembles a swollen appendix." After an attack of this kind the pain and tenderness and febrile disturbance subside in about a week, and the swelling rapidly and completely disappears. In comparatively rare instances the symptoms do not clear up in this satisfactory manner, but suppuration slowly occurs, the first evidence of this being the detection of a fixed indurated swelling above the outer part of Poupart's ligament.

**Perforation of the Vermiform Appendix.**—The more severe forms of typhlitis, which are in almost all instances dependent upon perforation of the vermiform appendix, differ much in their intensity. In rare instances the symptoms closely resemble those resulting from perforation of the stomach or intestine, although perhaps less rapidly developed and attended with less collapse, and death rapidly follows from diffuse septic peritonitis. More commonly the symptoms are as follows: The patient, usually a male under twenty years of age, has as a rule been in good health up to the moment of perforation, although occasionally there is a history of previous attacks milder in character. The first symptom is sudden pain, which may be referred to any part of the abdomen, but is usually felt chiefly in the umbilical region, perhaps shifting later to the position of the cæcum. Often the pain occurs

without evident cause, but it has been known to follow a violent effort or a blow on the abdomen. The pain is soon followed by nausea and vomiting, which is frequently repeated. There is constipation from the first, although it often happens that the patient has given himself a purgative after the invasion, and the bowels have responded to it. There is a very variable elevation of temperature, and sometimes an actual rigor at the onset. Irritability of the bladder or painful micturition has frequently been observed. The tongue rapidly becomes coated, and the patient's face assumes the characteristic "abdominal expression."

On examination it will usually be found that there is slight general fulness of the abdomen, and partial or complete absence of abdominal respiratory movements. Even at an early stage there may sometimes be noticed some increased fulness above Poupart's ligament on the right side, and here also the absence of respiratory movements may be most marked. Tenderness may be present only in the right iliac region, or if general, it is most marked there, and is accompanied by muscular rigidity which prevents deep palpation. McBurney states that the maximum tenderness is usually at a point midway between the umbilicus and the anterior superior iliac spine. Even when the abdominal wall has been completely relaxed by the administration of an anæsthetic no swelling can at first be felt, and when it develops it is fixed, and, as Treves has pointed out, forms an elongated hard mass "about the size of an adult thumb," and can often be detected *per rectum*.

The course of the symptoms after the first twenty-four hours differs according to circumstances. Sometimes the abdominal distension steadily increases without any increase in the symptoms referred to the cæcum; the vomiting persists, and the patient dies within a week of diffuse peritonitis. In other cases the swelling in the cæcal region increases, and assumes the definite features of an abscess, with localized and radiating pain, flexion of the right hip, and later, cedema of the abdominal wall. The chief varieties of the perityphilitic abscess have already been mentioned. In rare instances unmistakable symptoms of suppuration subside spontaneously, probably by the abscess discharging itself into the cæcum or some other viscus. In a case lately in University College Hospital the patient rapidly recovered after a free escape of pus from the vagina. In still another set of cases the acute symptoms subside, and an abscess slowly forms in the region of the cæcum, with very little pain or constitutional disturbance.

The **Diagnosis** of rupture of the vermiform appendix is in some cases easily made, the sudden invasion, the seat of the pain and tenderness, the vomiting, and the age of the patient pointing clearly to the nature of the case. On the other hand, great difficulty may be met with in some instances, and often the cause of the patient's symptoms has remained unrecognized until an exploratory abdominal section has been made. The most severe cases may simulate other forms of perforation, as of a gastric or duodenal ulcer, but as a rule the symptoms are less intense, and there is no history of preexisting evidences of such affections. In cases of ordinary severity there is often a close resemblance of the early symptoms to those of mechanical obstruction of the small intestine, especially internal strangulation. The course of the symptoms will usually serve to distinguish the two conditions: in rupture of the appendix the signs of peritonitis occur early and precede those of obstruction, whereas the reverse is the case in mechanical obstructions. It is obvious,

however, that if the doubt is great, the sooner an exploratory laparotomy is performed the better. The careful examination of the pelvic organs in the female is of the greatest importance, and the close resemblance of the symptoms and physical signs of a ruptured pyosalpinx must be borne in mind.

If the case be first seen after the development of a perityphlitic abscess the history will usually serve to distinguish it from other forms of suppuration, such as that due to bone disease. The chief difficulty is likely to arise when the abscess takes an unusual course, passing upwards into the loin or across to the left iliac region. A perinephritic abscess scarcely ever occurs without pus in the urine. In chronic cases the dense inflammatory swelling may be indistinguishable in the female from that due to pelvic peritonitis, and has also been confounded with a localized tuberculous peritonitis, and a solid tumour, such as a sarcoma in the iliac fossa.

*Treatment.*—In the mild forms of typhlitis the treatment is purely medical, and consists essentially in the administration of opium, a restricted fluid diet, the use of enemata, and the local application of hot fomentations. Surgical treatment in these cases is altogether uncalled for, except in the exceptional instances when comparatively mild symptoms are followed by suppuration.

In the more severe cases in which perforation of the appendix is suspected the early treatment will depend upon the intensity of the symptoms. If these be very severe, and the diagnosis from some other form of perforation or from intestinal obstruction be obscure, immediate operation is indicated. If the appendix be found perforated it should be removed, and the peritoneum thoroughly cleansed. Far more often, however, there are no definite indications for immediate operation, and this is deferred until called for on account of the presence of pus. The treatment from the first will be carried out on the lines above indicated for simple typhlitis, and operation will be required if the increase of the local symptoms indicates the occurrence of suppuration. An incision should then be made, and every care taken to reach the abscess-cavity without disturbing the adhesions by which it is localized. For this reason an incision in the middle line should be avoided, as in this way the abscess will be reached from the peritoneal cavity, and diffuse peritonitis very likely set up. Of the other two available incisions—a vertical one in the linea semilunaris, and an oblique one above the outer part of Poupart's ligament, as for ligature of the external iliac artery—the latter is the better, as it leads down to the abscess in a position farthest removed from the general peritoneal cavity. When the pus, which is often very fetid, is reached, a suitable drainage tube should be inserted, and all further disturbance of the part avoided. No special steps should be taken to see the appendix, and only if it at once presents and is non-adherent should it be ligatured and excised.

If it be found necessary to open the abscess through non-adherent peritoneum, strips of gauze should be carefully introduced around it before the pus is evacuated, and a drainage tube inserted. The favourable cases are undoubtedly those in which a localized abscess exists, and is not complicated with general peritonitis. If diffuse peritonitis is also present the chances of a favourable result are small. The only hope for the patient consists in providing free drainage for the localized collection of pus, and then irrigating and draining the general peritoneum through a median incision.

**Relapsing Typhlitis.**—In 1887 Treves first suggested the treatment of certain cases of relapsing typhlitis by excision of the appendix, and the opera-

tion has been performed by himself and others with great success. The operation is justifiable only in those cases in which there is good reason for believing the appendix to be at fault. This is best proved by the detection of the enlarged appendix during or between the attacks; the latter are severe, often frequently repeated, and occur independently of constipation or other conditions which favour the recurrence of attacks of simple typhlitis. The pathological condition which has been met with in those cases has been described at page 929. The operation for removal of the appendix should be undertaken only after all the symptoms of an attack have passed away. The procedure is often very difficult on account of the existence of firm adhesions. Treves recommends that the appendix be removed about half an inch from the cæcum, and that the mucous membrane be united by many fine sutures or a continuous one, and the outer walls by a second row.

#### REMOVAL OF PORTIONS OF THE INTESTINE.

**Enterectomy**, or the excision of a portion of the small intestine for disease, is said to have first been performed by Ramdohr in 1727. **Colectomy**, or removal of a portion of the large intestine, was first practised by Reybard in 1833; three inches of the colon were excised, the divided ends united by suture, and the patient recovered. In 1836 Dieffenbach removed a gangrenous portion of the intestine, and sutured the ends of the gut successfully in a case of strangulated hernia. Excision of a portion of the intestine remained one of the curiosities of surgery till within recent years, during which it has frequently been performed in this country and abroad.

Among the most important conditions for which resection of a portion of intestine may be required are: 1. For gangrene or ulceration, especially when resulting from strangulated hernia; 2. For ruptures or wounds of the intestine which are too extensive or in other ways unfavourable for a simple suture; 3. For the cure of artificial anus; 4. For irreducible intussusception; 5. For stricture of the intestine resulting from previous ulceration or the presence of a malignant growth. The question of the advisability of performing resection in the first four of the above conditions has already been discussed, but it is necessary here to consider the chief points concerning resection for stricture, especially of a malignant character. As malignant stricture almost invariably affects the large intestine, colectomy is the operation required, and has to be considered in relation with the alternative measures of colotomy and intestinal anastomosis (p. 919). If symptoms of intestinal obstruction are already present, the time is very unfavourable for resection, and colotomy should be practised. If, however, the condition of the patient will allow, the extent of the disease should be ascertained by an exploratory laparotomy. Should it be found of limited extent, and apparently uncomplicated by glandular enlargement, resection may be performed; but if the extent of the disease renders this impossible, intestinal anastomosis (p. 924) is an available method of treatment. Stricture of the small intestine, simple or malignant, is rare, but should such a case be met with uncomplicated by actual obstruction, resection should be practised. It thus appears that comparatively few cases occur in which excision of a strictured portion of the bowel is practicable, and when the disease is carcinomatous the chances of cure are small. In 1889 Kendal Franks collected 51 cases, including two of his own,

in which colectomy had been performed for malignant disease. Of these 20 died as a result of the operation, 29 recovered, and in 2 the result was not known.

Of the 29 cases which recovered the result was traced for a variable time in 20. In 10 death or recurrence of the disease was reported after periods varying from one to twenty-two months; in 9 no recurrence was observed after periods varying from two to ten months. Only one case was "cured," the patient being free from recurrence four years after Gussenbauer had removed four inches of the sigmoid flexure for carcinoma.

**Operation.**—The general directions for the performance of abdominal section given at p. 819 must be carefully attended to. The patient must be thoroughly under the influence of the anaesthetic; complete relaxation of the abdominal walls being a great assistance to the Surgeon. The incision must be made according to circumstances, the most convenient position being, as a rule, over the disease. The early stages of the operation are exactly the same as when it is undertaken for wounded intestine (Vol. I., p. 885 *et seq.*). The division of the intestine must be made well beyond the limits of the disease. After the resection has been performed the subsequent steps of the operation will depend upon circumstances. If the conditions are all favourable the ends of divided intestine may at once be united, and the continuity of the bowel re-established. This may be done by one or other of the methods of suture described in Vol. I., p. 885 *et seq.*, and for the same purpose the "Murphy button" has recently been employed with success (p. 943). If the ends of the divided bowel are of very unequal size, as in uniting the ileum and ascending colon after excision of the cæcum, the best method appears to be to close the ends completely with Lembert's sutures, and then perform lateral anastomosis as described at p. 924.

In many instances, however, it will be wiser to suture the two ends of the bowel into the abdominal wound, thus making an artificial anus, which may be treated by a subsequent operation (p. 859). This plan of treatment is open to less objection in the case of the large intestine than the small, and in some cases of colectomy a permanent artificial anus has been made by completely closing the lower opening and suturing the edges of the upper one into the wound.

#### OPERATIONS ON THE STOMACH.

**Perforation of Gastric Ulcer.**—When an ulcer, situated in a part of the stomach which is not surrounded by adhesions, perforates, the patient is seized with urgent symptoms, and usually dies within twenty-four hours. The diagnosis is as a rule easy, and may be made almost with certainty when sudden severe abdominal pain, followed rapidly by collapse and vomiting, supervene upon symptoms suggestive of ulceration of the stomach. Under these circumstances the only chance of life is afforded by operative interference, which should be undertaken with the least possible delay. An incision should be made in the middle line between the ensiform cartilage and the umbilicus, and this may be supplemented if necessary by another passing outwards below the left costal margin. The perforation, which is usually situated in the anterior wall of the stomach, must then if possible be closed by several rows of Lembert's sutures, so that a considerable peritoneal surface around the perforation may be brought together. The closure may be tested by injecting water into

the stomach through a tube. If this treatment be impossible, as in a case of Warrington Haward's, on account of the thickening around the perforation, the stomach should be drawn up to the wound and fixed there, as in the operation of gastrostomy. Finally, no pains must be spared to cleanse the peritoneum thoroughly by irrigation and sponging before closing the abdominal incision. After the operation rectal feeding should be adopted for about a week if possible, thirst being best relieved by very small quantities of hot water given by the mouth. Of 27 cases collected by Gilford of Reading in which laparotomy was performed for perforated gastric ulcer 6 recovered, the successful cases having been treated by J. W. Taylor, Barling, Kriege, Morse, Maclaren and Gilford. To these must be added cases operated upon successfully by Bennett, Morris, Nicholson, Jowers, Walters, and Pollard. The outlook must be regarded as practically hopeless if the operation is delayed until acute peritonitis is actually established.

In other cases, adhesions having formed before perforation occurs, a localized peritonitis results, with the formation of a *subdiaphragmatic abscess*, which derives much of its importance from its close resemblance to various conditions within the chest. Penrose and Lee Dickinson have recently recorded 10 cases of abscess beneath the diaphragm in connexion with perforating gastric ulcer. They find that the usual boundaries of the abscess are as follows: above, the arch of the diaphragm; on the right, the falciform ligament; below, the left lobe of the liver and part of the anterior surface of the stomach; in front, the abdominal wall with the stomach adherent to it; on the left, the cardiac end of the stomach, the spleen, and the diaphragm. Godlee has pointed out that such an abscess, if it contain gas, may readily be mistaken for a pyopneumothorax. It may be complicated by simple effusion into the left pleura, and without actually perforating the diaphragm may give rise to an empyema. The history of preexisting abdominal symptoms will serve as an important aid to a correct diagnosis. If the fact that the abscess is below, and not above the diaphragm, be overlooked, the Surgeon may make the serious mistake of opening the healthy pleura by a posterior incision. Godlee recommends that the abscess be opened by an abdominal incision parallel with and just below the left costal margin.

Operation has several times been undertaken for general peritonitis resulting from the rupture of an ulcer of the duodenum, but with fatal results. Dean has, however, successfully treated a case of this nature at the London Hospital. The ulcer was closed with sutures, and the patient recovered, but unfortunately death occurred two months later from acute strangulation due to adhesion between the omentum and the wound in the parietes.

**Pylorectomy.**—The possibility of removing the pylorus for cancer was first suggested by Billroth in 1877. Gussenbauer and von Winiwarter subsequently experimentally demonstrated the possibility of removing portions of the stomach from animals. The first operation on the human subject was performed by Péan in 1879; the patient however survived only five days. In 1880, Rydygier repeated the operation, but the patient died in a few hours. In 1881, Billroth performed the first successful operation. The patient was a woman aged 43; she made an uninterrupted recovery, and ate a mutton cutlet with the best appetite on the twentieth day after the operation. She died four months after the operation from cancer of the peritoneum and retroperitoneal lymphatic glands.

The operation is practicable only in cases in which the pylorus has not formed such adhesions to the surrounding parts as to prevent its being drawn completely from the wound. Before the operation the patient must be confined to liquid food for some days. Immediately before commencing the stomach must be thoroughly cleaned with tepid water by means of the stomach-pump. The incision through the abdominal wall must be transverse, or nearly so, in direction, placed over the tumour, and free enough to expose the parts thoroughly. In Billroth's cases the external wound was four to five inches in length, crossing the middle line above the umbilicus. The great and small omentum must be carefully separated from the parts to be removed, all bleeding vessels being tied as divided. The pyloric part of the stomach is then drawn from the wound and laid on a carbolized cloth or a flat sponge, the subsequent steps of the operation being conducted outside the abdomen. The stomach and duodenum are then cut through with scissors. After each stroke of the scissors, any bleeding point is secured. Before dividing the duodenum, a few threads must be passed through its serous and muscular coats, lest it slip back into the cavity of the abdomen. The stomach is then fitted to the duodenum, by the removal of a V-shaped piece of its walls, either in the greater and lesser curvature, or at one side only. Finally, the duodenum and the stomach are united by sutures inserted as already described, the stomach returned to the abdomen, and the wound closed. The operation takes from one to two hours, and fifty to sixty sutures may be required. Success depends upon attention to antiseptic details, and prevention of the escape of any of the intestinal contents into the abdomen. In some cases the divided stomach and duodenum have been closed separately with sutures and gastro-enterostomy performed in the manner described below. In the after-treatment no food is allowed by the mouth for two or three days, the patient being supported by nutritive enemata. Billroth allowed his patient sour milk on the third day.

Up to 1886 Billroth and his assistants, Wölfler and von Winiwarter, had excised the pylorus for cancer in 14 cases, with 8 deaths and 6 recoveries. Of the six who recovered, one was alive four years after, but in a dying state from cancer of the glands of the groin; a recurrent growth was cut out of the scar in the abdominal wall two years after the operation. Another patient remained well after two years. The rest died of recurrence under one year. Of three patients operated on for simple stricture, two died. These results are, however, quite exceptional. Kramer has collected the results of 72 cases operated on for cancer; of these 55 died directly from the operation. Of 10 cases operated on for cicatricial stricture, 4 recovered and 6 died. These results are not encouraging, and probably do not represent the real mortality. The chance of recovery from the operation is small, and recurrence is almost certain if the patient survives. It is doubtful, therefore, whether pylorectomy will retain a place amongst legitimate surgical operations.

**Gastro-Enterostomy.**—This operation was first performed by Wölfler in 1881, in a case in which pylorectomy was impossible on account of implication of neighbouring parts by the cancer. He therefore drew up a portion of the upper part of the small intestine, and applying it to the great curvature of the stomach, established a fistulous communication between them. In this country the operation has been successfully performed by A. E. Barker, H. Page, Jessett, Mayo Robson and others. Of 85 cases collected by Murphy

of Chicago 53 recovered. The earlier steps of the operation are the same as in pylorectomy. The stomach being exposed, a loop of small intestine is drawn up from below its cardiac end.

Various methods have been employed for attaching the jejunum to the stomach. Senn's bone plates have been successfully employed in a considerable number of cases. The plates are used in the manner already described and figured at page 924. Murphy's "button," which is available for all varieties of intestinal anastomosis, has also been employed in this operation; the method of using it will be described in the operation of cholecystenterostomy at page 943. Murphy has recorded seven cases in which this method has been employed by himself and others with only one death.

If gastro-enterostomy is performed with simple sutures, the best method is Barker's modification of Wölfler's operation. The omentum having been pushed over to the left, the first part of the jejunum and the middle of the anterior surface of the stomach are drawn out of the incision. The intestine should be emptied of its contents and occluded at two points in the way already described by means of two india-rubber tubes. A fold of the stomach is then pinched up and the empty gut applied to it, the two being held firmly together between the finger and thumb of the left hand. A longitudinal incision about one inch in length is then made in each, dividing the serous and muscular coats only. A line of interrupted sutures is then inserted uniting the posterior edges of the divided muscular and serous coats of the small intestine and stomach. The stitches must be continued at each end for about one inch beyond the incisions, passing through the muscular and serous coats, so as to fix the intestine firmly to the stomach. The mucous membrane may now be divided, and the rest of the operation finished in the usual way, a second row of sutures being afterwards inserted on both sides to give greater security. Gastro-enterostomy has given much relief in several cases, but it should not be undertaken if the patient can be kept in tolerable comfort by daily washing out the stomach.

Although it is only a palliative measure it is doubtful whether pylorectomy should ever be adopted in preference to it in the treatment of malignant stricture of the pylorus.

**Jejunostomy**, or the formation of a fistulous opening in the upper part of the jejunum after attaching it to the abdominal wall, has been performed amongst others by Golding-Bird, Pearce Gould, Ogston, and Mayo Robson. It seems in every way inferior to gastro-enterostomy, except that, as it can be very quickly performed, it may sometimes be available when gastro-enterostomy is not.

**Digital dilatation of the Pylorus for Simple Stricture, or Loreta's Operation.**—This operation was first performed by Loreta, of Bologna, in 1882. He exposed the stomach as if for pylorectomy, and opened it by a transverse incision between 5 and 6 cm. long near the pyloric end. He then inserted first the forefinger of the right hand, and, by a drilling movement passed it through the narrowed pyloric orifice. He then inserted the left forefinger also, and stretched with some degree of force. The opening in the stomach was immediately closed by Czerny's suture, the abdominal wound brought together, and an antiseptic dressing applied. The operation lasted considerably under an hour. The patient was fed by enemata till the fourth day, when a little food was given by the mouth. Loreta is said to have per-

formed this operation in more than 30 cases. It has been performed twice in New York, with a fatal result. Two successful cases have been performed in this country, one by Hagyard of Hull and one by F. Treves. In all the successful cases the patient has experienced great relief, and it is reported that there has been no case of recurrence of the stricture.

#### OPERATIONS ON THE LIVER.

Surgical procedures on the liver are required for the relief of abscesses, for the cure of hydatid cysts, and for some affections of the gall-bladder.

**Abscess of the Liver.**—Abscesses of the liver may be multiple or single. Multiple abscesses are usually the result of pyæmia, and admit of no surgical treatment. The single abscess generally occurs in patients who have lived in tropical regions, and is consequently often termed the "tropical abscess." The diagnosis of the disease belongs rather to the Physician than to the Surgeon.

It will be sufficient to mention here that the chief symptoms are fever, rigors, loss of appetite and health, occasional jaundice, with pain in the region of the liver, and sometimes in the right shoulder. The condition of the patient when he is seen in this country has been fully depicted by Godlee. He is sallow, partly from combined anæmia and mild icterus, and partly from the bronzing which is caused by the burning tropical suns; yellow jaundice is rare. He is thin, anxious-looking, and wasted; the abdomen is full and more or less motionless. The tongue is pale and furred, and the extremities tend to be cold and clammy. The liver is usually enlarged, sometimes considerably, and there is often a prominence at the epigastrium or a little to the right, or else in the lower part of the right axilla. If the latter, the liver dulness is raised, and the intercostal spaces slightly bulged, both these signs disappearing or becoming less marked when the patient turns on to the left side, unless the abscess is actually pointing. The amount of tenderness over the liver varies with the depth at which the abscess is situated. The elevation of temperature is usually slight. The bowels are as a rule constipated; the urine scanty and high-coloured.

The abscess, if unrelieved, most commonly comes to the surface, either in the epigastric region or through one of the lower intercostal spaces, usually in the axilla. It may, however, extend through the diaphragm and communicate with the lung, an accident which is often accompanied by hæmoptysis, and is followed by expectoration of blood-stained or chocolate-coloured pus; or it may burst into the pleura. More rarely rupture has taken place into the stomach or intestine, or into the peritoneum, with the production of general peritonitis, or more often of a localized subdiaphragmatic abscess.

**Treatment.**—If the existence of an abscess of the liver is suspected, the presence of pus should be ascertained by the use of the aspirator. This procedure is not altogether free from risk, and Godlee has recorded a most instructive case in which fatal hæmorrhage followed exploration of an enlarged liver with an aspirator needle, the enlargement being due to leucocythæmia, and not to abscess as was suspected.

When the presence of pus has been proved, the sooner the abscess is opened and drained the better; when possible, Fayerer recommends that this be done in front rather than behind. When the operation is performed in front, adhesions will usually be found between the liver and the abdominal wall, but

Godlee has pointed out that this cannot be foretold with certainty even when a prominent swelling exists. If after dividing the parietes the liver be found adherent, the Surgeon may at once proceed to open the abscess by passing a bistoury or dressing forceps along the aspirator needle with which the abscess has been found. The opening should be large enough to admit a drainage-tube the size of the finger. The free hæmorrhage usually stops quickly if the finger is passed into the track. If no adhesions exist between the liver and the abdominal wall, a ring of sutures must be introduced so as to fix the liver to the parietal peritoneum. Godlee recommends that fully curved Hagedorn's needles be used and the sutures passed deeply into the liver substance, in a double row and overlapping each other.

If necessary, the abscess may at once be opened in the centre of the circle surrounded by the sutures, but, if possible, this should be delayed for two or three days, when firm adhesions will have formed.

If the abscess be pointing at the side, the incision should, if possible, be made below the normal line of the pleura, according to Godlee, "roughly not more than two inches above the margin of the ribs in the mid-axillary line." When the opening is made above this line, no trouble will occur if, as usually happens, pleural adhesions have already formed. If, however, the pleural cavity be opened, the diaphragm should be carefully attached to the costal pleura by a circle of stitches before the abscess is opened through it. When the operation is performed through the chest wall a piece of rib should be removed, as in the treatment of an empyema (p. 759).

Patrick Manson, who has had a large experience in the treatment of tropical abscess of the liver, has devised a special form of trochar cannula which is pushed boldly into the abscess through a small incision in the skin after the position of the pus has been determined with the aspirator. A large drainage-tube, tightly stretched on a steel stilette, is then passed through the cannula; the latter is removed, and when the stilette is withdrawn, the tube by its expansion prevents any escape of pus except through its lumen.

**Hydatids of the Liver.**—A hydatid cyst is characterised by a gradual progressive enlargement of the liver, regular or lobulated in form, smooth on the surface and rounded at the edge. The general health suffers but little, there is no fever and no pain until the tumour reaches a considerable size, and causes local peritonitis with the formation of adhesions. When the tumour is very large, suppuration may take place. For a more detailed description of this disease I must refer the reader to works on medicine.

Surgical interference should never be undertaken until the tumour reaches such a size as to become a source of inconvenience to the patient. If any doubt exists as to its nature this may be cleared up by the use of the aspirator, the fluid of a hydatid cyst resembling nothing in the body except cerebro-spinal fluid (Vol. I., p. 100). The exploration of a doubtful abdominal tumour with the aspirator is by no means free from danger, and as a general rule a small exploratory incision is much to be preferred. The following are the chief modes of treatment which have been adopted in this disease:—

**Acupuncture.**—Many cysts have been cured after simple puncture by means of acupuncture needles repeated at short intervals. It appears that the fluid escapes through the punctures and is absorbed. This simple treatment has, however, very frequently been followed by suppuration, necessitating a free opening of the cyst to save the patient. It is said also that it may lead to

the diffusion of the parasites through the peritoneal cavity with the formation of new cysts. For these reasons acupuncture should not be practised.

*Electrolysis* has been tried in several cases, but presents no advantages over simple puncture.

*Tapping* has been very largely employed, chiefly no doubt on account of its simplicity, and has been attended with a moderate degree of success. It has been performed with a simple trochar or with an aspirator, and often the operation has been several times repeated. Of 411 cases collected by Thomas of Adelaide, 73 or 17·7 per cent. died, and in 97 others the treatment failed. The chief causes of death were exhaustion, peritonitis, and septic poisoning. The chance of success seems to be greater after aspiration than after simple puncture.

*Injection* with iodine, carbolic acid, and other substances has been employed, but does not seem to offer any advantages over simple aspiration. Of 18 cases collected by Thomas, 5 died.

*Drainage of the cyst* by means of a cannula inserted on a trochar and tied in has been successful in some cases. It is always followed by suppuration, and is attended with considerable risk of peritonitis.

*Opening the cyst by caustics* as recommended by Récamier was formerly frequently adopted, the object being to form adhesions between the opposed surfaces of the peritoneum before the cavity was reached. It is tedious and painful, and is now seldom adopted. Of 84 cases collected by Thomas 25 died, 55 were cured; in the others the result was unsatisfactory or not known.

*Incision and drainage with removal of the parasitic cyst* is the method of treatment which has given the most satisfactory results, and is most often adopted at the present day. This operation was first performed by Lindemann of Hanover. He divided the abdominal wall by a vertical incision under antiseptic precautions, and exposed the surface of the liver. The wound was then held open and a number of fine sutures passed attaching the peritoneum to the skin. Two strong threads were then passed through the cyst-wall parallel to the edge of the wound, by means of which it was drawn well out of the abdomen. It was then opened freely between the threads and the parasitic cyst cleaned out as far as possible. Finally the cyst-wall was closely sown to the skin, a large drainage tube inserted and an antiseptic dressing applied. This operation may conveniently be modified as follows: After exposing the cyst the peritoneum is plugged around with sponges, and the cyst partially emptied with an aspirator needle. It is then drawn well up into the wound and incised, the edges of the opening being held in several pairs of force-pressure forceps. The cyst-wall and its contents are next removed as thoroughly as possible with the finger or forceps, and finally the edges of the incision in the liver are carefully sutured to those of the skin incision, and a large drainage tube is inserted. Owing to the abundance of the discharge, and its highly putrescible character, the utmost care must be taken with the antiseptic dressing. Thomas in 1889 was able to collect 68 cases of hydatid of the liver in which this treatment had been adopted. Of these 7, or 10·29 per cent., died, and the remainder, nearly 90 per cent., were cured; septic complications were the most common cause of death.

Volkman advised that if there are no adhesions the operation should be performed in two stages, the surface of the liver being first exposed, and the wound plugged with carbolic gauze for five or six days till firm adhesions

have formed between the liver and the parietal peritoneum, when the cyst is opened and treated as above described. Other Surgeons have sutured the surface of the liver to the parietal peritoneum in order to ensure the formation of adhesions. The stitches may be inserted in the manner described at page 939.

The experience of those Surgeons who have extensively employed Lindemann's operation suggests that the performance of the operation in two stages is as a rule unnecessary. In some instances, hydatid cysts of the upper convex surface of the liver have been treated through a thoracic incision after removal of portions of one or more ribs. The same precautions against infection of the pleura should be adopted as in the treatment of an abscess (p. 938).

A suppurating hydatid cyst must be treated in the same way as a liver abscess.

**Resection of the Liver.**—The removal of a diseased portion of the liver has been practised in very rare instances. Tansini of Modena successfully excised part of the left lobe together with a hydatid cyst which was buried in its substance. The profuse hæmorrhage was arrested by ligatures and temporary plugging, and the wound was closed with catgut sutures. Terrillon successfully removed part of the right lobe, which contained several small hydatid cysts, by surrounding its base with an elastic ligature and leaving it to slough outside the abdominal wound. Lücke adopted similar treatment in a case of carcinoma of the left lobe of the liver, the removal of the lobe being completed with the cautery. The patient recovered, and the wound was healed in four weeks. Keen has successfully removed a cystic tumour attached to the border of the right lobe.

**OPERATIONS ON THE GALL-BLADDER.**—Great advance has been made during recent years in the surgical treatment of the various conditions which may arise from the presence of gall-stones in the gall-bladder and its duct, as well as in the common bile-duct. It is obvious, however, that only a certain proportion of cases of cholelithiasis require operative interference. Mayo Robson considers the following to be the most important conditions in which operation is indicated:—1. Repeated attacks of biliary colic apparently due to gall-stones, which, not yielding to medical treatment, are wearing out the patient's strength; 2. When there is evidence of suppuration in the neighbourhood of the gall-bladder set up by gall-stones; 3. Empyema of the gall-bladder; 4. Dropsy of the gall-bladder; 5. Obstructive jaundice due to occlusion of the common duct by gall-stones; 6. Acute or perforative peritonitis starting in the region of the gall-bladder.

The most favourable cases for operation are those in which dilatation of the gall-bladder results from the impaction of a gall-stone in the cystic duct; as the common duct is not obstructed there is no jaundice, and the fluid distending the cyst is not coloured with bile. In some cases the distended gall-bladder has been known to inflame, suppurate, and discharge externally, leaving a fistulous opening through which gall-stones have been discharged. The diagnosis of distended gall-bladder is not always possible; it is usually freely movable except at its upper attachment, and may resemble a renal tumour, or a hydatid cyst. The condition is infinitely more serious when the common duct is blocked by a calculus; obstructive jaundice results, and if unrelieved, is likely to prove fatal before any great dilatation of the gall-bladder takes place. The not unfrequent association of gall-stones and malignant

disease of the gall-bladder must be borne in mind, although a certain diagnosis in such cases is rarely possible except by an exploratory operation.

The following operations need consideration :—*Cholecystotomy*, or opening the gall-bladder ; 2. *Cholecystectomy*, or excision of the gall-bladder ; and 3. *Cholecystenterostomy*, or the establishment of a fistulous opening between the gall-bladder and intestine.

**Cholecystotomy** was first performed by Bobbs of Indianapolis in 1867, the patient recovering. In 1878 Marion Sims operated without success ; in 1879 Lawson Tait successfully accomplished the removal of the impacted gall-stone, and since then the operation has been performed in a large number of cases with success.

The operation is thus performed :—A vertical incision is made at the outer border of the right rectus, commencing above at the costal margin if the gall-bladder be not distended, or having its centre over the cyst if such exist. All the precautions usual in abdominal operations must be taken. If the gall-bladder be distended, the abdominal opening should be plugged around with sponges and the cyst emptied with an aspirator. As it becomes lax it is drawn well up into the wound. It is then opened freely, and its interior cleaned out with a sponge, any loose stones being removed. The finger is next introduced into the abdomen outside the gall-bladder, and the ducts examined for impacted calculi. These may be carefully extracted with a forceps or scoop passed into the duct from the gall-bladder and aided by the finger outside the duct. If this be impossible, the stone may be crushed with padded forceps or with the finger and thumb, or it may be broken up with a round needle passed through the wall of the duct, and the fragments then extracted. A last resource consists in incising the duct, and after the removal of the stone closing the incision with sutures, as successfully practised by Knowsley Thornton. The operation is completed by attaching the edges of opening in the gall-bladder to those of the upper part of the skin incision and closing the remainder of the abdominal wound in the usual way. A good-sized drainage-tube is then inserted, and an antiseptic dressing applied. If an escape of bile shows that the passages are clear, the tube can as a rule be removed after a few days. The fistula will usually close without any further operative treatment.

Klister, Roux, Meredith, and others have modified the operation by completely closing the opening in the gall-bladder with sutures, but as a general rule it seems to be far safer to adopt the method above described, as the danger of the stitches giving way appears to be considerable. *Cholecystotomy* is most difficult in those cases in which the gall-bladder is contracted and surrounded by adhesions. After the calculi have been removed it may be found impossible to draw the opening up to the abdominal incision. Under these circumstances it has been found that no harm results if a tube be passed into the gall-bladder and another into a neighbouring part of the peritoneum in case any extravasation should occur.

**Cholecystectomy**, or excision of the gall-bladder, was first performed by Langenbuch. It is an operation which is very rarely required, the most important indication for it being, that, as the result of stricture of the cystic duct, a fistula discharging mucus persists after *cholecystotomy*, or that as soon as the fistula closes, the gall-bladder again becomes distended. It is obvious that the operation should not be performed when a fistula discharging bile

is due to obstruction of the common duct. Robson believes that excision of the gall-bladder for malignant disease can rarely be called for, as the neighbouring parts are almost always implicated. The operation consists in carefully isolating the gall-bladder until the cystic duct is reached, which is ligatured with silk and divided.

**Cholecystenterostomy**, or the formation of a fistulous opening between the gall-bladder and the intestine, was first performed by Von Winiwarter in 1880. The operation may be undertaken in cases of jaundice due to some form of incurable obstruction in the common duct, and has been successfully performed by Mayo Robson and others in cases of incurable biliary fistula. The operation is carried out through an incision in the right linea semilunaris, and the communication should, if possible, be established with the upper part of the jejunum. Various methods have been adopted by different operators. Von Winiwarter sutured together the gall-bladder and jejunum around two circular areas, and at a second operation opened the adherent part through an incision in the bowel. In other cases the method of suture used by Wölfler in gastro-enterostomy (p. 937) has been successfully adopted.

In this operation, as in the various forms of intestinal anastomosis, different mechanical contrivances have been devised with the object of rendering the use of complicated methods of suture unnecessary. Thus, in two of the three successful operations performed by Mayo Robson decalcified bone bobbins were used. The bobbin is shaped like a cotton-reel, and the ends are inserted into the viscera to be connected through a small incision in the wall of each. Only two sutures are needed: an inner, to approximate the edges of the divided mucous membrane, and draw them tightly around the bobbin, and an outer, to include the serous and muscular coats. Murphy of Chicago has introduced an ingenious metal "button," which, like the bone bobbin, can be used in all forms of intestinal anastomosis or end to end approximation. The button consists of male and female halves, each composed of a hollow stem with an expanded cup-shaped extremity. The two halves when pressed together are held by two spring catches in the stem of the male portion, which hold upon a screw-thread in the stem of the other half. The separated halves of the button are inserted, one into the gall-bladder, the other into the intestine, through a short incision in the wall of each, and the margin of the opening is drawn tightly around the cylindrical portion of the button by means of running silk sutures previously inserted. The two halves of the button are then clamped together, and thus the serous coats are firmly approximated by a spring flange on the male half of the button. Adhesions form around, and eventually the button is liberated and passes on through the bowel.

The results of the operation appear to have been satisfactory, and the mortality not high. Murphy has collected 48 cases, of which 10 died. Of 28 cases in which the Murphy "button" was employed only 2 died, and in both of these the obstruction of the bile-duct was due to carcinoma of the pancreas.

#### SPLENECTOMY.

Vulpinus of Heidelberg has collected 117 cases of removal of the spleen, of which 59 recovered and 58 died. In 28 cases the operation was undertaken in leucocythæmia; of these 25 died directly from the effects of the operation, the most common cause of death being uncontrollable hæmorrhage resulting

from imperfect coagulability of the blood. In one of the three cases which recovered the leukaemic nature of the enlargement has been much doubted, and the other two cases died after thirteen days and eight months respectively from the effects of the general disease. These statistics show that the operation is not justifiable in leucocythæmia, and the same may be said of 3 cases in which the operation was performed for "chronic congestion," one for albumenoid degeneration, and one for syphilitic enlargement. If these be subtracted there remain 84 cases with 56 recoveries, giving a total mortality of 33 per cent. In 66 cases splenectomy was performed for hypertrophy with 24 deaths. Under this heading are included cases of simple hypertrophy associated with anæmia, enlargement of malarial origin, and cases of "wandering spleen," in which as a rule the organ is enlarged as well as displaced. In two instances recently recorded in this country by Bland Sutton and Malins, there was twisting of the pedicle. Of 5 cases of hydatid disease 3 recovered. Cystic spleen is very rare, and has usually been mistaken for an ovarian tumour; it has been removed four times with success. Of 4 cases of sarcoma 3 recovered, and of 3 cases of abscess all recovered. Vulpius's table contains only 2 cases of ruptured spleen, both of which died, but Nussbaum collected 26 cases of excision for injury with 16 recoveries.

The operation must be regarded as one of great severity, and should be reserved for cases in which all other treatment has failed or is impracticable. It should never be undertaken for hypertrophy unless the enlarged spleen is a source of much pain or discomfort, and the blood shows no leukaemia. The most favourable cases appear to be those of cystic disease and "wandering spleen," but in the latter affection splenectomy should be recommended only when the displacement is attended with severe pain, vomiting, or other symptoms.

The **Operation** has been performed through a median incision or through one in the left linea semilunaris. The greatest care must be taken not to tear the splenic substance, which is especially likely to happen if adhesions exist; traction on the pedicle must also be avoided. Immediately fatal hæmorrhage has in some cases resulted from the former accident. The pedicle may be transfixed and tied in two parts with silk, or the separate vessels may be seized in forceipressure forceps close to the spleen, and, after the removal of the latter is complete, tied separately.

In several cases the patient has been known to be in good health some years after the operation: thus, a woman, whose spleen was removed by Spencer Wells in May, 1888, was safely delivered of "a fine healthy boy" in December, 1891.

Examination of the blood before and after the operation has been made in a considerable number of cases; in some it has been normal, whilst not rarely there has been a somewhat rapid increase in the relative proportion of the leucocytes.

Enlargement of the lymphatic glands has been observed by Czerny, Kocher, and others. An increase in the red bone-marrow has been noted by numerous observers after extirpation of the spleen in animals, but the only observation in the human subject bearing on this subject is that of Riegner, who is said to have found a similar condition in a boy aged fourteen who died three weeks after the excision of a ruptured spleen.

## CYSTS OF THE PANCREAS.

In 1885 Senn of Chicago published an account of eleven cases of cyst of the pancreas, one of which was diagnosed and successfully operated on by himself. Since that time a considerable number of cases have been recorded, many of which have been treated by operation with complete success. A pancreatic cyst forms a tumour which may reach a great size, and contain several pints of fluid. It occupies chiefly the epigastric and left hypochondriac regions, and as it increases it tends to push the stomach forwards and upwards and the transverse colon downwards. It reaches the surface above the umbilicus, being covered in front by the great omentum. In addition to the swelling there is almost invariably abdominal pain, often with vomiting, and sometimes with jaundice from pressure on the bile-duct. In a considerable number of the recorded cases the appearance of the swelling has followed a more or less severe injury to the abdomen. Thus in Jacobson and Pitt's case the patient, a man aged twenty-one, had been kicked in the abdomen three years previously; he was confined to his bed for three weeks, and ever since had been liable to attacks of abdominal pain; and in a case recorded by Littlewood, of Leeds, the epigastric swelling was noticed two days after the patient was stamped on by a horse. The fluid contained in a pancreatic cyst is alkaline, and has a specific gravity of 1010 to 1020; it is generally turbid, of a greenish or brownish colour, and contains albumen with traces of the ferments usually present in pancreatic juice.

Little is known regarding the mode of formation of these cysts. When they are traumatic in origin it seems probable that laceration of the gland with hæmorrhage occurs, and that this is followed by escape of the secretion from the torn ducts. In the cases in which there is no evidence of injury it has been suggested that a retention cyst forms as the result of some obstruction of the duct. That the disease is simple in nature seems certain from the after-history of some of the cases which have been operated on, but it is important to note that in a case which was treated by Pearce Gould there was an infiltration of hard growth around the fistula which still existed three years after the operation, and enlargement of the inguinal and axillary glands.

The characters of the tumour have been sufficient in several cases to establish the diagnosis. In females the cysts have most commonly been mistaken for ovarian tumours; whilst among other conditions with which they have been confounded are hydatid of the liver, cysts of the peritoneum, and retroperitoneal sarcoma.

Jacobson suggests that in a doubtful case valuable information might be obtained by distending the stomach and colon with gas.

**Treatment.**—Although aspiration has produced a cure in some instances, and has frequently been adopted as a means of diagnosis, it is dangerous, and had better be abandoned in favour of an exploratory incision. In a case recorded by Cathcart, rupture of the cyst into the peritoneal cavity followed simple puncture. The treatment usually adopted has consisted in making a median incision above the umbilicus, and then exposing the cyst by dividing the omentum below the stomach. The contents are next partially withdrawn with an aspirator or trochar, and the cyst drawn up to the abdominal incision. Finally the cyst is opened, the edges of the opening sutured to the wound, and a

drainage-tube inserted. In more than one case a posterior opening has been made below the last rib of the left side. The connexions of the cyst will rarely allow complete removal, as practised by Clutton and others.

Nimier has collected 35 cases in which incision and drainage were practised; of these 29 recovered and 6 died, but only 3 directly from the operation. Partial extirpation was carried out in 8 with 7 recoveries, and complete extirpation in 6 with 4 recoveries.

I cannot leave this subject without an expression of admiration at the great advance that has of late years been made in the treatment of diseases of the abdominal viscera by surgical operation, and a recognition of the merits of those Surgeons who have led the advance in this department of our art, and of the vast importance of the results achieved by them. But whilst thus freely recording my admiration for the successes that have been obtained, I must add a few words of caution to aspirants for distinction in this great field of practice. I would venture to remind them that an operation is not necessarily justifiable because it is practicable; that every act of operative audacity is not a triumph of sound and legitimate surgery; and that a patient's life may possibly be prolonged on conditions less tolerable than death.

#### DISEASES OF THE UMBILICUS.

**Hæmorrhage from the Umbilicus** occasionally occurs in infants on separation of the cord. It is best treated by acupressure, a darning-needle being passed through the bleeding point and a piece of silk twisted round it.

**Ulceration of the Umbilicus** is occasionally met with after the separation of the cord in new-born children. It must be treated by cleanliness and the application of some simple ointment. In adults, especially when very fat and uncleanly in their habits, eczema followed by ulceration is not uncommon in the navel. It must be treated by syringing with boric acid lotion and the application of boric acid ointment. Sometimes a prominent fungating mass of granulations may form, which requires destruction with nitrate of silver. Soft and hard chancres have been met with on the navel, and a purulent discharge resulting from gonorrhœal infection is said to have been observed.

A **Polypus** is occasionally met with in children springing from the hollow of the umbilicus. It usually forms a pedunculated body of a red colour, and is about the size of a currant. On microscopic examination it is found to contain glandular tissue, and it is evidently developed from the vitelline duct. It may be removed with a fine ligature, or with a fine-pointed cautery.

**Dermoid Cysts** at the umbilicus are rare; they may be pedunculated. They should be removed.

**Squamous Carcinoma of the Umbilicus** is a rare disease. Should it occur the tumour must be removed freely, the abdominal cavity being opened if necessary, and the aperture being closed by sutures.

**Umbilical Fistulæ.**—*Fæcal fistulæ* at the umbilicus may arise from strangulation and sloughing of an umbilical hernia. They are also occasionally congenital, resulting either from a protrusion of a diverticulum from the ileum, or of a portion of the small intestine into the cord and its accidental inclusion in the ligature at birth. In other cases they arise from perforation of the small intestine by chronic ulceration, usually tuberculous, with the formation of a circumscribed abscess amongst the coils of the intestine, finally

discharging at the navel. The treatment of these fistulæ is extremely unsatisfactory. The application of the cautery to the orifice is of little use, and plastic operations almost invariably fail. If the disease does not give much trouble it is better treated by the application of a pad and attention to cleanliness. If there is a complete artificial anus after gangrenous hernia, a cure must be attempted by the means already described in the chapter on hernia. *Urinary Fistulæ* are very rare, and result from imperfect closure of the urachus. They are sometimes associated with obstruction in the urethra. An attempt may be made to close the fistula by a plastic operation. Any source of obstruction in the urethra or bladder must be dealt with. *Biliary Fistulæ* also have been met with; they usually result from inflammation of the gall-bladder, with adhesion to the parietes, and the burrowing of an abscess downwards.

#### TUMOURS OF THE GROIN.

Tumours of the groin may develop primarily in that region, or descend into it from the abdomen. In making the diagnosis the first point is to ascertain whether pulsation is present. *Pulsating* tumours are either aneurisms, pulsating sarcomata or fluid tumours with communicated pulsation. The distinction of these diseases is fully given at pp. 112 and 324, Vol. II. *Non-Pulsating Tumours* may be divided into the *reducible* and *irreducible*. The reducible tumours are either hernia, varix of the saphena vein, or abdominal abscesses passing under Poupart's ligament. The diagnosis of these various diseases is given at p. 880, Vol. II. In distinguishing the irreducible tumours, irreducible hernia must first be excluded. The remaining tumours may be fluid or solid. The fluid tumours are chronic abscesses of the lymphatic glands or cystic growths of various kinds. The diagnosis here is easy: the irregular hardened outline of glandular abscess, its rapid development, and softening from a previously indurated state, will distinguish it from the tense, clearly-defined outline, smooth and elastic feel of the slowly developing and very chronic cystic growth.

The *Solid* tumours may be enlarged glands, a retained testicle, or new growths. The new growths may be simple or malignant. When malignant they may be primary sarcomata or secondary carcinomata following primary disease of the penis or skin of the leg. The history of the case, the feel of the tumour, the rapidity of its progress, the extent of contamination of neighbouring parts, and the other signs that serve as diagnostic differences between simple and malignant growths, will enable the Surgeon to make the diagnosis with sufficient accuracy.

The *treatment* of most of these conditions has already been described, but a few words may be said here on the removal of solid or cystic tumours of the groin by operation. In undertaking such proceedings the relation of the growth to the great vessels must be carefully considered. If the tumour merely presses on the vessels, causing, perhaps, much solid œdema of the limb, the removal may be attempted, but if it seems to implicate and surround them and to be fixed to neighbouring parts it is wiser not to attempt any operation.

## CHAPTER LXIV.

## DISEASES OF THE RECTUM AND ANUS.

## CONGENITAL MALFORMATIONS.

BEFORE passing to the consideration of the more important **Congenital Malformations** to which the rectum and anus are liable, it may be well to recall very briefly certain stages in the development of these parts. Up to a certain stage the rudimentary genito-urinary apparatus opens into the hind-gut by means of the uro-genital sinus, and thus a true cloaca exists. Over the blind extremity of this cloaca a slight invagination of the epiblast occurs, forming the proctodæum, and by the absorption of the thin septum between the two, a cloacal orifice is produced. In the fifth or sixth week the genital eminence, from which the penis or clitoris develops, makes its appearance within the anterior margin of the cloacal orifice. A little later the orifice becomes divided into two parts by the gradual formation of a septum which extends downwards and separates the posterior, or anal, orifice from the anterior, or uro-genital. Thus the rectum and anus are completely separated from the genito-urinary apparatus, the further stages in the development of which need not be considered.

The following are the most important abnormal conditions of the rectum and anus:—1. Narrowing and partial closure of the anus. 2. Complete closure of the anus. 3. Anus present, but rectum wanting to a variable degree. 4. Anus and rectum wanting. 5. Anus present or absent; rectum opening into bladder, vagina, or urethra. In extremely rare cases absence of the rectum has been associated with want of development of the rest of the large intestine, or the anus has been found in an abnormal situation.

Reference to the mode of development of the part shows that the ordinary malformations cannot be explained by any simple arrest of the process. Thus, failure of the proctodæum to open into the hind-gut will not serve to explain those cases in which the anus is present but does not communicate with the rectum, for the proctodæum opens into the common cloaca of the hind-gut and uro-genital sinus. Hence the error of development must be looked for at a later stage, and probably consists in a secondary closure of the rectal part of the cloaca at the time when the latter becomes subdivided into its two portions. Doubtless an explanation of these cases in which the rectum communicates with some part of the genito-urinary apparatus must be sought for in the original communication between the uro-genital sinus and the hind-gut.

**1. Narrowing and Partial Closure of the Anus.**—The canal continues pervious, but not sufficiently to allow of the bowels being completely emptied, the anus usually merely admitting a full-sized probe. In some cases the

obstruction appears to depend upon constriction of the anal orifice, in others upon an imperfect septum stretching across it.

*Treatment.*—In slight cases the daily passage of a well-oiled finger into the bowel will prove sufficient. In more severe cases it may be necessary to notch the contracted anus with a probe-pointed bistoury and dilate it with bougies.

2. **Complete Closure of Anus. Atresia ani.**—The anus may be completely closed by a membranous septum stretching across it, usually having a raphe along the central line, and a slight depression, through which the dark meconium can be seen, and on which an impulse can be felt. This constitutes perhaps the most common form of malformation that is met with.

*Treatment.*—In this variety an incision must be made through the septum along the middle line, and across on each side, when the meconium will freely escape. The four angular flaps that are left must now be removed, and the aperture kept open by the introduction of a well-oiled plug.

3. **Anus present, Rectum wanting to a variable degree. Atresia recti.**—In the simplest form of this malformation the anus is perfectly formed, but at a distance of about half an inch or an inch from its aperture the rectum will be found occluded by a perfect membranous septum. This is a rare and somewhat puzzling malformation, as the infant will be found to labour under intestinal obstruction, and yet, on examination, the anal orifice will be found perfectly formed. The Surgeon will, however, detect the state of things by introducing a probe or the end of his little finger into the anus. The septum can readily be brought into view by inserting the nose speculum (Fig. 667), and throwing light up the bowel by means of a laryngeal mirror. In more severe cases the anal invagination is separated by a considerable distance from the *cul-de-sac* in which the rectum ends, or the latter may be entirely absent, the sigmoid flexure ending in a dilated pouch opposite the sacral promontory.

*Treatment.*—When the rectum is only occluded by a thin septum, the following operation will be found successful:—1. The child is put in the lithotomy position. 2. A trochar-cannula is then passed down to and pressed against the septum. 3. The trochar is next passed down the cannula and through the septum. 4. The trochar is then withdrawn, and the cannula left in. 5. A probe is passed through the cannula, which is then slipped out over it and along the probe, or a director which may be substituted for it, a narrow-bladed pair of dressing forceps is pushed up and opened out so as to dilate the opening in the septum. During this process, the retained faeces will have escaped. The aperture must be kept free by the occasional introduction of a bougie or of the finger.

In the more severe forms of this malformation, an incision must be made backwards from the anus to the coccyx and an attempt made to reach the rectum, or failing this colotomy is necessary, as in the next variety.

4. **Absence of Anus; Rectum more or less deficient. Atresia ani et recti.**—Every variety of this malformation is met with between the slightest form in which the rectum ends in a blind pouch close to the surface of the perinæum, and the most extreme form in which the rectum is absent and the colon terminates in a large pouch opposite the sacral promontory. The exact condition can rarely be recognised with certainty until the Surgeon has made an incision at the site of the anus in the hope of reaching the bowel. It has been pointed out that if the pelvis be abnormally

small and the tubera ischii too close together, it is probable that the rectum ends high up or is altogether absent. When the bowel comes low down into the pelvis, bulging may be noticed in the perinæum when the child strains.

*Treatment.*—In these cases the Surgeon must first make an attempt to reach the bowel from the perinæum, failing which, colotomy should be performed.

1. *Perinæal Incision.*—The perinæal incision has the advantage of being in the natural situation of the anus, and of being easily practised and usually successful in all those cases in which the anus only is imperforate, the rectum being present. In those cases in which there is congenital absence of the rectum this operation must necessarily fail. The operation is thus performed :—An incision about an inch in length should be carefully made from the point of the coccyx forwards. The dissection requires to be carried with caution to a considerable depth along the mesial line; and the Surgeon taking the curve of the sacrum and coccyx for his guide, and bearing in mind the relations of the bladder and large vessels in the neighbourhood, carefully proceeds in search of the gut, which may be found at a considerable depth from the surface. A probe may be passed into the urethra of a male child, or the vagina of a female, to serve as a guide to the position of these canals. The danger of wounding the bladder must also be considered, and may be materially lessened by emptying this viscus by pressing over the pubes before commencing the operation. In four instances of this kind on which I have operated, it was necessary to proceed to a depth of at least an inch and a half before the bowel was reached; which, on account of the narrowness of the wound and the small size and important relations of the parts is not an easy matter. When the gut is reached it must be punctured and the meconium allowed to escape.

It is of the utmost importance both for the immediate result of the operation and for the prospect of ultimate success that the gut should be brought down and fixed to the lips of the external wound. Unless this be done, the line of incision between the gut and the aperture in the integuments will degenerate into a fistulous track, which will have a tendency to contract, and will be a source of much subsequent trouble. If the gut can be brought down to and sutured to the opening in the integument, this source of inconvenience will be removed, and the patient will be saved all that danger which results from the passage of the meconium over a raw surface. This, however, can be done only when the intestine terminates at a comparatively short distance from the surface. If it be impossible, the track should be kept dilated with bougies; or a gum-elastic or pewter tube, through which the fæces are allowed to escape, may be fixed in the part.

If the Surgeon fail to reach the bowel through the perinæal incision, there is no alternative but to perform colotomy.

2. *Colotomy.*—Both the inguinal and the lumbar methods have been practised in these cases, and although there is no strong balance of evidence for or against either operation, the preference must be given to the inguinal incision (p. 924).

The principal objections to the lumbar operation are that the space between the last rib and the iliac crest, especially in a fat infant, is very limited, and that the colon is often misplaced, and still more frequently possesses a long meso-colon. In performing the inguinal operation, the

opening of the bowel may be postponed for twenty-four hours if the child's condition will allow. Should lumbar colotomy be undertaken, it must be borne in mind that the kidney is relatively very large, extends far outwards, may be enveloped in very little fat, and may thus easily be wounded. The mortality after colotomy in these cases is necessarily high : thus of 52 cases collected by Ball, 24 recovered, 27 died, and in one the result was not known. In 34 cases the inguinal operation was performed with 17 recoveries, 16 deaths, and one doubtful result ; in 17 cases the lumbar operation was performed with 7 recoveries and 10 deaths. In one fatal case the method was not stated.

**5. Absence of Anus ; Opening of Rectum into Bladder, Urethra, or Vagina.**—This class includes a considerable proportion of all cases of malformation of the rectum and anus, and necessarily presents much difficulty in treatment. When the communication is with the bladder there is little hope of reaching the bowel from the perinæum. Colotomy is therefore required, and Ball has suggested that it might be advisable completely to divide the colon, suture the lower opening, and convert the upper one into the artificial anus. When the communication is with the urethra there is more hope of success by the perinæal incision ; and cases have occurred in which, although the whole of the meconium with flatus had escaped *per urethram*, yet, on opening the rectum, the abnormal communication has gradually closed.

When the rectum opens into the vagina the communication is in the posterior wall, usually just above the vaginal orifice. The opening may be surrounded by a sphincter sufficiently developed to prevent the constant escape of fæces, or it may consist only of a small track communicating with the rectum above its blind extremity. In the latter case the bowel should be opened in the perinæum, and if necessary when the child is older steps must be taken to close the vaginal opening. When the opening into the vagina is represented by an anus provided with a sphincter, an attempt may be made to separate this from its abnormal connexions, and transplant it to the perinæum.

**Dermoids** have occasionally been met with in connexion with the mucous membrane of the rectum, the most conspicuous symptom in some recorded cases having been the projection of a bunch of long hairs from the anus. The explanation of the occurrence of dermoids in this position is not clear, but according to Bland Sutton they illustrate the close affinity of mucous membrane and skin, and the readiness with which one merges into the other. The only treatment consists in the removal of the growth.

Dermoid cysts are also sometimes found between the rectum and the sacrum, and are then supposed to arise from an unobliterated portion of the neurenteric canal. In a case of this kind operated on by Page, of Newcastle, the cyst was of very large size, and was successfully removed by an incision between the anus and the coccyx. After emptying the cyst of atheromatous matter and hairs, it was easily withdrawn by gently separating it with the fingers. It extended upwards above the brim of the pelvis, but did not implicate the peritoneum.

## INFLAMMATION AND ULCERATION.

Simple inflammation of the rectum, unaccompanied by ulceration, is not common, and most frequently results from the presence of large accumulations of faecal matter, or the irritation due to growths and other causes. It may be the result of true dysentery. Ball and others describe an acute catarrhal inflammation, which is not unfrequently met with, especially in children. It gives rise to tenesmus, the passage of small quantities of blood and mucus, with a sense of heat and weight about the pelvis, and sometimes irritability of the bladder, and a tendency to prolapse due to swelling of the mucous membrane and submucous tissue. An intense form of rectal inflammation occasionally results from infection with gonorrhoeal discharges.

**Gonorrhoeal Proctitis** may result from direct infection, but it more commonly arises secondarily as the result of inoculation with the discharges from gonorrhoeal vaginitis. It causes acute congestion and swelling of the mucous membrane, which may be so marked as to lead to a certain amount of prolapse. Associated with this is a more or less abundant purulent discharge. Ulceration of the mucous membrane is said to be rare. The most marked symptoms are burning pain in the part, especially intense during defaecation, and tenesmus. The *Treatment* should consist in rest in the recumbent position, the use of hot baths, and the administration of saline aperients. Ball recommends the use of a suppository containing five grains of iodoform and a third of a grain of extract of belladonna; and if there be much tenesmus, a simple enema of starch and opium. Weak injections of nitrate of silver are useful if the disease becomes chronic.

**Ulceration of the Rectum** is met with in a variety of different forms. The painful ulcer or fissure *in ano*, malignant ulceration, and that due to syphilis, will be subsequently considered. Extensive ulceration may occasionally result from dysentery.

**Simple Ulcer** of the rectum is not unfrequently met with just within the anus. In some cases it probably arises as the result of injury, but when of long standing and callous in nature, it is probably connected with a congested condition of the mucous membrane. Such an ulcer has aptly been compared with the varicose ulcer of the leg, and has been called by Rokitsansky the "haemorrhoidal ulcer." It gives rise to very little pain, and is usually attended with slight discharge of blood and mucus.

The *Treatment* should consist in regulating the bowels and keeping the patient in bed. Iodoform ointment may be applied with a special introducer, and often a suppository containing fifteen grains of subnitrate of bismuth will be found useful. If simple methods fail an anaesthetic should be given, the sphincter dilated and the ulcer scraped.

**Tuberculous Ulceration** of the rectum is not common, except the limited form, which is frequently present around the internal opening of a tuberculous fistula. The primary deposit in such cases probably occurs in the submucous tissue. In rare instances the ulceration is progressive and attended with much surrounding thickening; to such a form the term "lupoid" has been applied. Harrison Cripps has described two cases of this nature, in which the resemblance to carcinoma was very close. The *Treatment* consists in thoroughly scraping the surface and applying chloride of zinc (40 grs. to 3j) and iodoform; or excision of the ulcer may be required.

## STRICTURE—SIMPLE, SYPHILITIC AND MALIGNANT.

**Stricture** may be met with in any part of the large intestine, but it occurs with very varying degrees of frequency in different portions of that gut. Excessively rarely met with in the ascending or transverse, of unfrequent occurrence in the descending colon, it becomes more common in the sigmoid flexure, and very frequently occurs at about the junction of this portion of the colon with the rectum. In the rectum itself it is most commonly found either at the upper part from four to six inches above the anus, or else a little above that aperture.

The frequent passage of small quantities of liquid fæces, with occasional constipation, should always lead to a suspicion of stricture.

It is of three kinds : 1, the *simple*, dependent on simple thickening of the intestinal coats ; 2, the *sypilitic* ; and 3, the *malignant*, consisting of a cancerous growth of the walls of the gut.

**Simple or Fibrous Stricture** of the rectum is most commonly situated within easy reach of the finger, about three inches from the anus. It most commonly occurs in elderly people, and with special frequency in females. It may result from any condition which leads to the formation of cicatricial tissue in the wall of the bowel. Thus it may follow injury of the part, especially if attended with sloughing and loss of substance as sometimes happens during parturition. A common cause is the contraction following the healing of ulcers of various kinds such as those due to chronic dysentery, chancres, and possibly tuberculous ulceration. Harrison Cripps believes that the frequent spasm induced by the irritation of ulcers and other conditions in the rectum takes an important share in gradually causing actual organic stricture. In some cases the narrowing is really caused by inflammatory thickening outside the gut, especially in women who have suffered from pelvic cellulitis after labour. In such cases the stricture is seated just within reach of the finger.

The **Symptoms** of simple stricture of the rectum consist at first of some difficulty in defæcation, the patient being obliged to strain at stool. Often there is a history of alternating diarrhœa and constipation. The stricture becomes temporarily blocked by scybala, and when these escape an attack of spurious diarrhœa follows, the liquid matter which is passed being largely mucus poured out by the irritated mucous membrane above the stricture. When the stricture is quite low down the fæces may be flattened, narrowed or furrowed, but in most instances this symptom is not noticeable. There is very commonly pain in defæcation, with occasional passage of some mucus or blood ; and dyspeptic symptoms, with flatulent distension of the abdomen, are apt to come on. As a rule the stricture is within easy reach of the finger, so that its precise situation and diameter can be ascertained. The examination should never be made with the patient leaning over a chair, as in this position the gut is drawn up, and the stricture may then be taken out of reach. A stricture beyond the reach of the finger may be examined by the introduction of a well-greased bougie, attention being paid to the curve which the rectum makes laterally, as well as from before backwards. The information gained in this way is very uncertain, as the point of the instrument is apt to hitch in folds of the mucous membrane, or opposite the promontory of the sacrum : and thus there may seem to be a constriction, which in reality does not exist. Unless great care be taken the mucous membrane may actually be lacerated, and the instrument even forced into the peritoneal cavity. In other

cases a small bougie will appear to pass, when in reality its point, meeting with an obstruction, curves downwards into the rectum.

In cases of long-standing stricture of the rectum, the bowel below is often considerably dilated. Bryant, who first called attention to this so-called "ballooning of the rectum," suggests that it results from atrophy of the muscular coat due to arrest of peristalsis at the stricture, and the distension of the atrophied bowel below by retained flatus.

The **Progress and Termination** of a simple stricture vary in different cases. Many persons who present all the symptoms of this simple stricture of the rectum will live on in very good general health through a long series of years. In others the contraction may go on increasing until at last complete occlusion takes place. This condition usually comes on slowly, and after the occlusion is complete, life may continue for several weeks; but in some instances it seems to take place rather suddenly, and with all the symptoms of acute intestinal obstruction, death occurring in a few days. This is probably always due to volvulus or kinking of the dilated bowel above the stricture. Abscess occasionally forms in the neighbourhood of the stricture; and, passing down into the pelvis, may burst either into the ischio-rectal space, or into the vagina, or may present upon the nates. The discharge of pus from this source, as well as from the mucous membrane lining the stricture, which falls into an ulcerated state, may induce extreme emaciation and hectic, to which the impairment of nutrition consequent upon the disturbance of digestion adds materially.

**Treatment.**—The bowels should be kept moderately open, but purgation carefully avoided, as it is a source of much irritation. Castor-oil, Carlsbad salts, or saline aperient mineral waters in small doses suit best. The diet should be carefully regulated, and the strength kept up. An occasional enema will often give considerable relief. Small glycerine enemata are especially useful.

The *surgical* treatment of simple stricture of the rectum consists in dilating the canal at its constricted point. If this be within reach of the finger, the dilatation can readily be carried out. If it be above the upper part of the rectum, and the stricture be tight, it is extremely difficult to introduce the proper instruments with certainty. When the stricture is low down, so that the end of the finger can be introduced into it, it may readily be dilated by introducing a rectum-bougie every second day, and gradually increasing the size of the instrument. If the stricture yield but slowly, and be very tight and indurated, I have found it a convenient plan to introduce a sheathed probe-pointed bistoury into it and to notch it towards its posterior aspect, where this may be done without danger to the peritonæum. A tent of compressed sponge should then be introduced, and left in for twelve hours. On its withdrawal, bougies may more readily be passed; or the dilatation may be carried on by means of tents. When the stricture is above the reach of the finger, a good deal of management will be required to make the bougie enter it. This is best done by placing the patient on his left side, and using a moderate-sized elastic bougie, softened in warm water and well greased, which must be passed without the employment of any force. When once the Surgeon has introduced one, others can readily be made to follow in the same track. The great danger in introducing a bougie high up is that of mistaking the obstruction offered by its point coming into contact with one of the valvular folds of mucous membrane present in this situation, for that of the stricture, and, by pushing on the instrument, perforating the bowel—an

accident that would probably occasion fatal peritonitis. During the introduction of bougies, the bowels must be kept regular by means of laxatives, and the occasional use of enemata. If much pain or irritation be occasioned by their use, opium should be administered internally or in the form of suppositories. Though a simple stricture of the rectum may be much relieved by the use of bougies, it is seldom, I think, cured by this means; there being a great tendency in it to contract as soon as the treatment is discontinued.

Dilatation may sometimes conveniently be effected by the use of Todd's dilator (Fig. 819). This is introduced closed, covered with a thin india-rubber sheath, so as to avoid nipping the mucous membrane. It is then expanded to the required extent by pressing on a trigger in the handle.

In very obstinate cases of stricture in which simple dilatation has failed, *linear proctotomy* may sometimes be practised with good results. This is done by freely dividing the stricture, the wall of the rectum below it, and the sphincter with a probe-pointed bistoury. The division should be made exactly in the middle line behind. Bleeding may be arrested by ligatures, and the wound should be plugged with strips of gauze, and subsequently irrigated daily with warm boric acid lotion.

If complete obstruction occur, purgatives must on no account be given. An endeavour should be made to relieve the patient by the use of enemata of olive-oil, and the strength should be supported by a diet that is nourishing, at the same time that it leaves little or no solid residue. Opium in small doses frequently given will relieve the pain and prevent sickness; under this treatment the bowels may eventually act after a considerable lapse of time. In a case to which reference has already been made, the obstruction gave way after it had lasted for about five weeks, some hardened faeces with bloody mucus being discharged and speedily followed by abundant motions. Should the obstruction, however, continue, and the patient consequently be in imminent danger of death, colotomy should be performed.

**Syphilitic Stricture of the Rectum** is met with usually within easy reach of the finger, and chiefly in young women under thirty, rarely in men. The pathological changes to which it is due have already been described in the Chapter on Syphilis, Vol. I., p. 1155. The fact that this disease is almost exclusively met with in women has led to the idea that it may be due to direct infection of the bowel or to extension of disease from the vagina, but there is no evidence to support this view. It is always a tertiary affection, and is seldom associated with any affection of the vagina. It is almost exclusively met with amongst the poorer classes, and in hospital practice. To the finger introduced into the bowel it feels as if there were an irregular thickened cicatricial constriction of the mucous membrane. This may be limited to the lower part of the bowel, but frequently extends beyond the reach of the finger. The examination causes the patient the most intense pain, as there is often ulceration in the constricted region. Sometimes under proper treatment the ulcers may be made to heal, and then the dense irregular cicatricial bands alone will be felt. There are usually evidences

Fig. 819. — Rectum-Dilator.

of constitutional syphilis. I have seen these syphilitic ulcerations extend into the vagina, so as to establish a recto-vaginal fistula. In one case under my care death resulted from perforation of the upper part of the rectum into the peritoneum. The motions are usually passed with much pain, and are mixed with blood and pus. The general health is at first good, but gradually gives way under the pain and the exhaustion from loss of blood and discharge.

**Treatment.**—The patient must be put under the usual constitutional treatment for syphilis. If ulceration is still present the best treatment consists in passing bougies of cocoa-nut butter, each containing about four to five grains of iodoform, into the rectum once a day. If this do not succeed, similar bougies, containing a small quantity of bichloride of mercury, not exceeding  $\frac{1}{16}$  of a grain, may be used instead. In many cases nothing succeeds so long as the diseased surface is irritated by the passage of faeces, and then colotomy must be performed as the only means of giving relief. Should the ulcers heal without necessitating colotomy, the cicatricial contraction resulting from them may be treated in the same way as a simple stricture. The extent of the disease usually, however, makes this form of stricture extremely intractable.

#### **Carcinoma of the Rectum — Malignant Stricture.**

—The form of cancer met with in the rectum is almost invariably the Columnar Carcinoma. Its structure has been fully described in the Chapter on Tumours (Vol. I., p. 1074). In the rectum it varies somewhat in structure in different cases. In some the epithelial structure is very abundant, the growth being composed of a closely-packed mass of tubes resembling enlarged crypts of Lieberkühn, between which lie the vessels, supported by a delicate connective tissue closely infiltrated with small round cells. In others the glandular element is much less developed, the fibrous stroma being more fully developed, and showing in some cases a tendency to contract like

that of a scirrhus. All degrees may be met with between these two extremes. The clinical features vary with the structure. The softer varieties grow more rapidly, implicate surrounding structures more widely, and tend to infect the lymphatic glands and internal organs, but lead to a less complete stricture of the gut. The firmer varieties grow slowly, and often exist a long time without giving rise to secondary growths, while from their tendency to contract they cause great narrowing of the gut. The softer forms usually appear as flat cauliflower growths springing from the inner surface of the gut, and tending in most cases to spread circularly round it. They are usually extremely painful, and bleed readily when examined. They slough early, and cause extensive destruction of the bowel. The firmer varieties form hard,

nodulated growths projecting into the gut, greatly narrowing its calibre. They ulcerate slowly and bleed less readily.

True *scirrhus*, that is to say, glandular carcinoma, with firm fibrous stroma, is said to have been met with in the rectum. If such be the case it is certainly very rare. *Colloid cancer* also, arising apparently from colloid degeneration of a columnar carcinoma, has been met with, but is exceedingly rare.

The tumours described as *Encephaloid* have probably been soft malignant sarcomata commencing in the gut or in its coats, but these cases are so rare that it is impossible to speak with certainty as to their structure.

Carcinoma is usually seated from three to five inches above the anus, and may implicate a considerable portion of the bowel, extending upwards rather than downwards, giving rise to considerable contraction, ending in some cases in complete occlusion of the gut.

**Symptoms.**—Cancer of the rectum is met with chiefly in middle life, but sometimes does not occur until advanced age. Both sexes are equally liable to it; if anything, it is more frequent in women than in men.

It is very insidious in most cases in its early manifestations. A sense of

Fig. 821.—Cancer of Upper Part of Rectum. At x perforation leading to fatal Peritonitis took place, during administration of an Enema.

uneasiness, a tendency to diarrhoea, a slight discharge of blood or mucus, a feeling as if the patient had piles, are usually the only early evidences of the development of this distressing disease. After a time the rectal pain becomes very severe. There is now a constant feeling of pain and weight in the gut, with a sensation as if the bowels had not been completely relieved, together with the discharge of mucus, blood, or pus, and some flattening of the fæces. The patient experiences most intense suffering during defæcation, in consequence of the passage of fæces over the raw and ulcerated surface. This pain is not confined merely to the diseased part, where the sensation is of a burning character, but usually radiates round the loins and down the thighs, and is so severe that the patient looks forward to each action of the bowels with the greatest dread, and restrains it as long as possible. The whole nervous system at last participates in this continually recurring suffering; the countenance becomes anxious; the spirits are depressed; sleep and digestion are destroyed. The patient's condition is indeed truly miserable, between the dread of excessive suffering when the bowels act, on the one hand, and the fear of impending obstruction on the other. In many instances he is worn out by this suffering, occasionally combined with the cachexia induced by the contamination of the

system and the development of secondary visceral growths. Not unfrequently the misery is much increased by the formation of fistulous openings in the bowel, and communication between it and neighbouring parts, such as the vagina, bladder, or urethra, with cancerous implication of them. Flatus as well as faeces thus get entrance into the bladder or vagina: the flatus passing out with a rush, the faeces sometimes obstructing the urethra, and often very seriously irritating the bladder, producing strangury and great pain.

On examination of the rectum with the finger, the conditions will be found to vary much in different cases. The growth is hard and irregular, usually extensively ulcerated, and has a raised well-defined edge, which is everted and may even overhang the surrounding mucous membrane. The growth may be limited to one aspect of the bowel, so that its whole outline can be felt, but frequently it surrounds the gut, and the finger enters the contracted lumen in the centre of the mass. In such case the circular growth is often more or less prolapsed into the part of the rectum below it, giving to the finger a sensation not unlike that of the cervix uteri, the narrowed lumen being felt at the apex of hard projecting mass. When the growth is low down, the anus is often unusually patulous; when high up, the condition of "ballooning of the rectum" is often the first thing which attracts attention on introducing the finger (p. 954).

Death may put an end to the patient's sufferings in several ways: by exhaustion from pain and continuous discharge, together with constitutional cachexia; by perforation of the cancerous mass, which, ulcerating through at some point, opens into the peritoneal cavity, or by hæmorrhage, inducing fatal collapse; and in other instances by faecal obstruction, as in the case of simple stricture. The reason why intestinal obstruction is not more common than it is in cancer of the rectum is, that in many cases the diseased mass ulcerates and necroses more rapidly than it grows into the bowel, and thus an irregular chasm is left in its centre, through which the faeces pass.

**Treatment.**—This must necessarily in a large proportion of cases be merely palliative. The bowels must be relieved by occasional doses of castor-oil or by emollient enemata. The patient's sufferings may in many cases be much relieved by limiting him to a diet composed solely of material not likely to leave any solid residue, such as carefully prepared and strained arrowroot, and meat-broths of various kinds, to which a little brandy or wine may be added. If the patient at the same time be kept warm in bed in the recumbent position so as to economise force as much as possible, he may maintain his strength fairly well on a comparatively small quantity of food. Small doses of opium may be given to relieve pain. On this diet one action of the bowels about every three weeks will be quite sufficient. It will usually occur spontaneously without the necessity of administering a purgative. If there is much pain, hypodermic injections of morphia, often to a large amount, are required to lessen the patient's distress.

As further palliative treatment *Colotomy* may be required. This operation is performed for one of three reasons:—1. To relieve the intense agony resulting from the passage of faeces over the ulcerated cancerous mass; 2. To relieve the suffering and discomfort occasioned by the faeces passing into the bladder or vagina; 3. For the relief of more or less complete obstruction giving rise to distension of the abdomen, with retained faeces. Colotomy as a palliative has proved most successful in affording the desired relief; by its

means life may be prolonged as well as rendered more endurable. Attempted dilatation by means of bougies, the application of caustics, or crushing the tumour by means of the finger-forceps, as recommended by Amussat, are worse than useless. They cause great pain and irritation, hasten ulceration, and aggravate the disease.

**Excision of the Tumour.** **Partial excision of the Rectum** or **Proctectomy** is an operation which has lately been revived with considerable success. Récamier, Vidal, and others attempted the removal of the tumour when near the anus by ligaturing its base and allowing it to slough away, but excision of a portion of the rectum was first performed, according to Velpeau, by Faget in 1739. He took away an inch and a half of the circumference of the gut and cured his patient. The operation was revived in 1826 by Lisfranc, who operated in nine cases, with five recoveries. The operation, however, fell again into discredit until, in 1854, Chassaignac introduced the *écraseur*, and applied it to the removal of rectal growths. Since then Nussbaum, Volkmann, Czerny, Kraske, and others in Germany, and Holmes, Allingham, Harrison Cripps, Ball and others in this country, have done much to revive the operation. The cases suitable for removal are, according to Cripps, about one in five of those that come under observation. The conditions which are favourable for operation are the following:—The patient must not be too old, and must be in fair health; the growth must be so situated that the finger can be passed beyond it, and it must be freely movable, not having implicated surrounding parts or glands. The most favourable cases are those limited to one side, especially the posterior. It is an important question how far the dissection can be carried upwards without wounding the peritoneum. Cripps states that in the male the distance from the recto-vesical pouch to the anus is two and a half inches when the bladder is empty, and an additional inch when it is distended. In the female the distance from the recto-uterine pouch to the anus is somewhat greater.

The removal of a malignant growth from the rectum is accomplished as follows:—If it be very small, and situated very low down, it may be possible to bring it into view by forcible dilatation of the anus with the two first fingers of each hand. After this the anus will usually be sufficiently relaxed to allow of the affected portion of the gut being seized and drawn out to such an extent as to allow of the free removal of the growth by the *écraseur* or scissors. Cases in which this is practicable are, however, very rare.

The removal of a portion of the bowel, including the whole circumference, or a considerable part of one side, can be safely performed only when the anus has been enlarged by incision. The operation is thus performed: The rectum having been thoroughly cleansed with an enema immediately before the operation, the patient is placed in the lithotomy position, and a curved sharp-pointed bistoury, guarded by the left forefinger, is passed in at the anus; the handle is then raised so that the point is made to pierce the gut and appear superficially close to the tip of the coccyx exactly in the middle line; the parts between the coccyx and anus are then divided by a single cut. If more room be required during the operation it may be obtained by removing the coccyx. The bleeding must now be arrested, and a stout ligature may be passed through on either side, by which the wound may be held widely open. An incision is then carried from the margin of the wound on one side in a curved direction round the anus to a corresponding point on the other side. If the anus itself

be healthy this may be made at the junction of the mucous membrane and skin. The gut can now be separated posteriorly without any difficulty by means of the finger, aided by the scissors, at the attachment of the levator ani. When the sides are separated the gut must be drawn backwards and separated by careful dissection from the vagina in the female, or urethra and prostate in the male. To avoid wounding the urethra in the male, a large silver catheter should be passed at this stage of the operation, which will be clearly felt from the wound. The gut having now been separated it may be cut away by means of scissors. During the operation bleeding must be arrested, by the use of forcipressure forceps. The hæmorrhage can in this way easily be kept under control, and seldom causes any great trouble. Having completed the excision, most Surgeons follow Cripps's advice and make no attempt to bring down the mucous membrane to the anus; the stitches are very likely to give way, and burrowing of septic matter is more likely to occur than if the whole wound is left open. Volkmann and Czerny, however, recommend the use of sutures in order to lessen the amount of raw surface and therefore the subsequent tendency to stricture. If sutures be used they should include not only the skin and mucous membrane but should be passed deeply, as Ball suggests, through the surrounding tissues. The posterior incision should be left freely open. The wound should be thoroughly sponged with some antiseptic solution, chloride of zinc (gr. 40 to 3j) being by far the most efficient. It may then be dusted with iodoform.

The after-treatment consists in well syringing the wound once or twice a day with some antiseptic solution, and the application of iodoform. The bowels must be prevented from acting for ten days or a fortnight by proper diet and the administration of opium. Healing takes place slowly, and the mucous membrane becomes drawn down considerably towards the skin. Stricture almost necessarily results if the whole circumference of the bowel have been removed. To obviate this, Cripps recommends that a large bougie should be passed daily after the first fortnight, and allowed to remain in position for some hours daily. This should be continued for a month, and then the bougie passed once daily for a year or longer. Incontinence of feces is more rare. Cripps states that it occurred in seven cases out of thirty-six, and in six others there was a slight escape when the motions were liquid.

Removal of a part of the circumference is a much more successful operation. It is performed in the same way as that just described, but the healthy mucous membrane and the corresponding part of the anus must be preserved uninjured, a longitudinal incision with scissors being carried up the bowel on each side of the morbid growth. It is seldom followed either by incontinence of feces or serious stricture of the bowel.

Wound of the peritoneum is a serious but not necessarily fatal accident. If the opening be small and within reach, it must be closed by sutures. If this cannot be done, according to Bardenheuer the patient is given the best chance of life by the introduction of a full-sized drainage-tube into the peritoneal pouch from the rectum.

The mortality of the operation is considerable, but has been much reduced during recent years. Ball has collected 175 cases with a death-rate of 16.5 per cent. Harrison Cripps has performed partial excision of the rectum 38 times with only 3 deaths. Of the 35 patients who recovered, the subsequent history of 7 was not known; in 10 there was recurrence within a year, and in

5 after periods varying from one to three years; 1 died in a year without recurrence. In 12 no recurrence had occurred:—3 under one year, 1 after eighteen months, 1 after two years, 1 after three years, 2 after four years, 1 after five years, 2 after six years, and 1 after twelve years.

Cancer of the rectum is not uncommonly met with too high up, as Volkmann says, to be reached from below by the operation above described, and too low to be reached by laparotomy. For these cases, Kraske, of Freiburg, devised the operation which goes by his name. The patient is placed on his right side, and an incision is made in the middle line from the second sacral spine to the anus, which need not be divided. The gluteus maximus on the left side is then separated with an elevator as far as the edge of the sacrum, and the coccyx is excised. The great and small sacro-sciatic ligaments are next in the same way separated from the sacrum, and the left side of the wound forcibly drawn outwards with a strong spatula. If more room is required, a portion of the lateral mass of the sacrum may be cut away with a chisel. If the bone is cut in a line commencing on the left edge at the level of the third posterior sacral foramen, and running in a curved direction inwards and downwards past the third foramen and through the fourth to the left cornu of the sacrum, no important nerves or other parts need be wounded. The anterior division of the third sacral nerve is protected, and the sacral canal is not opened. The gut now comes so fully into view that it can be removed as high as its junction with the sigmoid flexure. The lower part of the bowel may be preserved, if it is healthy. In this operation the peritoneum will probably be opened in most cases. Should this happen, the opening must be plugged with a sponge or some antiseptic wool until the operation is completed. The edges of the wound in the peritoneum should then be accurately brought together with silk sutures, after which, if the anal portion of the gut has been left, the upper part may be brought down and sutured to it anteriorly, the posterior part being left open for drainage. Complete suture of the upper end to the lower has seldom succeeded.

Bardenheuer has operated in a somewhat different way in similar cases of high disease. A median incision is made from the posterior border of the anus to the middle of the sacrum, and the soft parts are reflected from the back of the bone. The sacro-sciatic ligaments are cut through and the sacrum divided transversely at the level of the third sacral foramen. The hand can now readily be introduced into the pelvis, and the subsequent steps of the operation are essentially the same as in Kraske's method. The upper part of the rectum is drawn down and sutured to the anal portion, or if this is impossible, it is sutured into the wound. Ball, of Dublin, has employed this method with success in four cases. Of the cases in which König operated by Kraske's method the mortality was 12 per cent.

**Intussusception of the Rectum** as a consequence of a malignant growth is a very rare condition. In two cases of this kind under the care of Barker in University College Hospital the tumour projected from the anus with each action of the bowels and bled freely. Digital examination showed that the reflexion of the rectal wall was situated about three inches from the anus. A double row of stitches was passed through the entering and reflected layers, and the apex of the intussusceptum including the tumour was cut away. Both patients made a rapid recovery.

**Carcinoma of the Anus.**—The anus is rarely affected by extension of

caucereous growths from the rectum. More commonly the disease is primary, and it is then always squamous carcinoma (Fig. 396, p. 1072, Vol. I.). It forms a nodular projection, often resembling a swollen external pile, for which I have more than once seen it mistaken. It ulcerates later than the same disease in other situations, the mass often reaching the size of a pigeon's egg

Fig. 822.—Papillary Polypus of the Rectum ( $\times 200$ ).

Fig. 823.—Large Papillary Polypus of the Rectum.

before the surface gives way. If limited in extent it may be excised by an operation similar to that for removal of the lower part of the rectum.

**Sarcoma of the Rectum** is very rare. Rokitsansky has described a nodular form of spindle-celled sarcoma. I have seen such growths forming arge and somewhat pale tuberous masses projecting into the interior of the

Fig. 824.—Polypus of the Rectum with Pedicle, removed from child 7 years old.

Fig. 825.—Polypus of the Rectum cut open, showing cysts lined by Columnar Epithelium.

gut and even protruding through the anus, giving rise to the same train of local symptoms as characterize cancer of the gut, but with less pain. In such cases as these the disease may, if limited or pedunculated, be removed by the *écraseur*. By means of this instrument I have removed from the inside of the gut a tumour of this kind nearly as large as a man's fist. Recurrence may of course be expected, but the patient will get relief for a time.

**Papilloma or Villous Tumour.**—Large papillomata, the papillæ of which branch repeatedly, and are covered by columnar epithelium, are occasionally met with in the rectum. They closely resemble carcinoma, but are recognized by their slow growth and by their being pedunculated. They cause hæmorrhage and some obstruction of the bowel. They can readily be removed by the *écraseur* or by ligature, and seldom return. The accompanying figure (Fig. 823) represents a pedunculated mass which was removed from the rectum of a man by Marshall. Fig. 822 is taken from a portion of the same growth.

**Adenoma.**—This is most commonly met with as the simple polypus of the rectum in young children. The adenomatous polypus is usually single and is attached to the lower part of the rectum by a slender pedicle. Its surface is usually smooth, but it may be lobulated (Fig. 824) or papillary, and may contain cysts. Its structure is that of a tubular adenoma, the glandular spaces, which exactly resemble the crypts of Lieberkühn, lying in a fibrous stroma, which may compose the bulk of the growth. In children hæmorrhage is the most common symptom, and to this may be added tenesmus and prolapse of the bowel. It may give rise to some irritability of the bladder and thus simulate stone. Polypi are easily removed by the application of a ligature, or by twisting through the pedicle if it be long.

**Fibroma.**—This occurs as the simple fibrous polypus, which is occasionally met with in adults. Ball believes that these usually arise by gradual changes in an internal pile. They are most common near the anus, and in some cases are found associated with a small intractable ulcer at the point at which the free end touches the gut. They are best removed by ligature of the pedicle.

**Angioma.**—A specimen of extensive *nævus* of the rectum is preserved in the Museum of University College. The patient, a man aged forty-five, was under the care of A. E. Barker. He had suffered from occasional rectal bleeding since boyhood, and died of copious hæmorrhage.

#### RECTAL FISTULÆ.

**Fistulous openings** occasionally occur between the rectum and the bladder in men; or between this gut and the vagina in women.

**Recto-Vesical Fistulæ** are not common, and usually result either from cancerous ulceration, establishing a communication between the rectum and the bladder; or from a wound of the gut during the operation of lateral lithotomy. In rare cases they arise from tuberculous abscesses in the *vesiculæ seminales* or prostate, opening into the rectum and bladder simultaneously. In these cases the urine escapes *per anum* in greater or less quantity, occasioning constant irritation or excoriation, with a sort of spurious diarrhœa; and the wet state in which the patient is kept by the dribbling of urine gives rise to an offensive ammoniacal odour about him. If the communication between the rectum and bladder be cancerous, *feculent* matter and *flatus* pass through the opening, and escape from time to time by the urethra; perhaps even more abundantly than the urine does *per anum*. There is this difference, therefore, between the traumatic and cancerous fistulæ, viz., that when traumatic the chief escape is from the bladder into the rectum; when cancerous, of the contents of the rectum into the bladder. It is remarkable how little irritation is often set up by this admixture of *feces* with urine in the bladder.

The fistulous aperture in the rectum, if traumatic, can readily be detected by passing the finger into the gut, or examining its interior with the speculum ani; when cancerous it is too high up for this.

*Treatment.*—If the fistula be cancerous, nothing can be done in the way of treatment beyond keeping the parts clean, or diverting the fæces by colotomy; but if it be traumatic in its origin, of small size, and more especially if it be recent, its closure may occasionally be accomplished by touching it with nitrate of silver, or with the thermo-cantery through a speculum ani. If this fails, an attempt may be made to close the opening by an operation, which will consist in freely exposing the opening by dilatation of the sphincter, paring the edges of the opening and drawing them together with sutures passed deeply with a curved needle. If, however, the fistula is of old standing, and the aperture large, repeated attempts to close the opening will often fail; and the only mode of treatment that can be adopted will be to introduce a grooved staff into the bladder, and cut through the sphincter upon this, thus laying the parts into one, and converting the anal into a perineal fistula.

**Entero-Vaginal Fistula.**—It has happened that a communication has been set up between the small intestine and the vagina, an artificial anus in fact forming in this cavity. These cases, however, are very rare, and may indeed be looked upon as incurable. Roux and Casamayor endeavoured to establish, by a deep and difficult dissection, a communication between the small and large intestine; but the operation, as might have been expected, proved fatal.

**Recto-Vaginal Fistulae** may arise from two causes: 1st, sloughing of the recto-vaginal septum, in consequence of undue pressure exercised upon it during parturition; and 2nd, its perforation by syphilitic ulceration. They may be ranged in two classes: those consisting of a button-hole opening (and these are often syphilitic), and those complicated with more or less extensive laceration of the perinaeum. The size of these fistulous openings when uncomplicated with rupture of the perinaeum, varies greatly; in some cases there is merely a small perforation, in others there may be loss of the greater portion of the posterior wall of the vagina. Whatever their size, they are necessarily sources of very great discomfort and annoyance to the patient. The recognition of the disease is easy; the escape of the fæces and flatus into the vagina being obvious, and examination with the finger or speculum at once detecting the seat and extent of the aperture. As there is just the possibility of a communication existing between the vagina and the small intestine, it may be useful to bear in mind that, in this case, the matter that escapes is yellower and less stercoraceous than when the rectum is opened.

The **Treatment** of the non-syphilitic fistula will vary according to the position of the aperture, and whether or not it is complicated with lacerated perinaeum.

If the fistula is high up in the recto-vaginal septum an attempt may be made to close it from the vagina. The opening having been fully exposed with retractors, the edges are freshened by dissecting away the surrounding tissue down to the rectal mucous membrane. Silver wire sutures are then inserted in such a way that they pass beneath the whole extent of the wound, and other superficial ones may be made to include the mucous membrane only. Pozzi advises that the sutures be inserted in whichever direction there is the least tension, which in the case of a large opening is usually transversely.

When the fistula is low down and complicated with a ruptured perinæum, an incision should be made vertically downwards from the opening, completely dividing all the tissue between the rectum and vagina. The case is then treated as one of complete rupture of the perinæum. (See Vol. I., p. 899.) If, although the fistula is low down, the perinæum is intact, it is not advisable to divide it in the way above described. The opening may then be closed by turning up a vaginal flap and applying sutures in the manner described in Vol. I., p. 900. The preparation of the patient for operation and the after-treatment must be carried out on the same lines as in the ordinary operation for ruptured perinæum.

When the recto-vaginal fistula is of syphilitic origin, there is usually some degree of stricture of the rectum associated with it, and an extensively excoriated and diseased state of the vaginal mucous membrane. In these cases the sufferings of the patient are often very great, and the only means of relief open to the Surgeon is the performance of colotomy.

**Entero-vesical Fistulæ.**—A fistulous communication may be established between the intestine at some point above the rectum and the bladder. The fistula usually forms between the sigmoid flexure of the colon and the upper and left lateral part of the bladder. Less commonly the small intestine is involved, and very rarely a communication exists with more than one portion of the bowel.

Harrison Cripps, who has collected 63 cases of recto-vesical and entero-vesical fistulæ, finds that the fistula is far more frequently the result of some simple inflammatory affection than of malignant disease. Indeed, in no less than 45 cases the fistula was due to simple causes, among which the most frequent was an abscess, probably due in the majority of cases to perforation of the bowel by fragments of bone or other foreign bodies.

The symptoms preceding the formation of the fistula vary with its cause. Thus, if it result from an abscess, there may be an acute onset with abdominal pain, fever, and possibly a rigor. A localized tender swelling may then develop in the lower part of the abdomen, and suddenly the urine is found to contain stinking pus, followed after a day or two by the passage of fæcal matter and flatus by the urethra. In other cases, when the fistula results from malignant disease or other chronic affection of the bowels there may be a long antecedent history of intestinal symptoms, followed by irritability of the bladder. In endeavouring to decide whether the communication is with the lower part of the large intestine or with the small intestine, the exact character of the fæcal matter entering the bladder must be carefully examined. If the opening is low down in the large bowel, milk injected into the rectum may be found to enter the bladder, or if injected into the bladder may be found unchanged in the rectum.

The *treatment* in the early stages should consist in clearing out the bowels with castor-oil, and then locking them up for 10 or 14 days with opium, so as to give the fistula a chance of closing, if it be not due to malignant disease. Should this fail, the bladder must be washed out twice daily, and if the patient's sufferings increase so as to render life a burden, colotomy may be resorted to if it is the great intestine that communicates with the bladder, or cystotomy may be done, and thus a wider outlet for fæces, urine, and flatus afforded through the perinæum than the urethra permits. Cripps has suggested that in favourable cases it might be possible to close the opening into the bladder by suprapubic cystotomy.

## PRURITUS ANI.

**Pruritus Ani** is often an extremely troublesome affection, the itching and general irritation about the anus being almost unbearable. In some cases it is due to the presence of external piles or worms. In others it results from a permanently moist condition of the skin around the anus. In others again it is due to eczema. Excess in alcoholic stimulants, habitual constipation, and other conditions may give rise to it; but frequently the most careful investigation fails to detect any cause. The *Treatment* must have reference to the cause if one can be found. If there be an external pile, the removal of it; if worms, their expulsion will probably cure the condition. If it is due to eczema, boric acid ointment with a drachm of extract of belladonna added to each ounce will frequently bring about a speedy cure. If there is a mucons discharge the frequent application of boric acid lotion may give relief. Chronic constipation must be treated by the habitual use of saline aperients, or of the aperient mineral waters, as those of Pullna and Friederichshall. In some cases it seems to depend on gout, and the treatment for that disease removes the pruritus. In other cases arsenical preparations will be found useful, together with the local application of chlorinated lotions or those containing hydrocyanic acid. Sometimes tar applied by means of a piece of oakum gives complete relief, but in many cases nothing succeeds.

## ULCER AND FISSURE OF THE ANUS.

This disease, though trivial in point of size and in its pathological relations, is of great practical importance, on account of the excessive local pain and great constitutional irritation to which it gives rise. Ulcer and fissure commonly exist together, though it by no means unfrequently happens that the two conditions occur separately. The ulcer is usually of small size, seldom larger than a threepenny-piece, situated between the folds of the mucous membrane in the lower part of the rectum, just above the ring formed by the sphincter, and is usually met with towards the posterior part of the gut. Occasionally more than one ulcer exists in this situation. If a fissure accompany the ulcer, it commonly leads from this across the face of the sphincter to the verge of the anus; but in many cases one or two fissures, sometimes even three or four, exist without any ulcer. The fissures are usually slightly indurated and cord-like, extending merely through the mucous membrane, scarcely, if at all, implicating the deeper structures; and not unfrequently their external termination is concealed by a small red pile—the so-called “sentinel pile.”

**Pathology.**—The view which is usually held concerning the pathology of the painful fissure of the anus is as follows: A small tear in the mucous membrane is caused by the passage of a hard motion. This is extremely painful, because it crosses the “white line” of Hilton, which corresponds to the junction of the skin and mucous membrane, and is the position at which the numerous nerve filaments which supply the skin of the anus become superficial. The constant pain causes spasm of the sphincter, and this in its turn prevents the healing of the ulcer. It is not uncommon to find a small polypoid growth immediately above the ulcer, hanging down upon the raw surface and apparently concerned in maintaining the disease.

A different explanation of the mode of origin of the painful fissure has

recently been suggested by Ball. From a study of frozen sections, Symington of Edinburgh has shown that normally the anus is in reality a closed canal nearly an inch in length. At the upper end of this, where the skin and mucous membrane join, are several little muco-cutaneous folds—the anal valves. Ball explains the formation of the painful fissure thus: “During the passage of a motion one of these little valves is caught by some projection in the faecal mass and its lateral attachments torn; at each subsequent motion the little sore thus made is reopened and possibly extended, the repeated interference with the attempts at healing ends in the production of an ulcer, and the torn down valve becomes swollen and oedematous, constituting the so-called pile, or, as it sometimes has been called, the ‘sentinel pile’ of the fissure.”

Small cracks and fissures, often multiple, are not unfrequently present at the margin of the anus of syphilitic subjects, especially women. In persons who have been the subjects of the chronic dysentery of hot climates, I have several times noticed a peculiar form of patchy ulceration within the rectum, of an extremely irritable and very intractable character.

The **Symptoms** of ulcer or fissure of the anus are very characteristic. The patient complains of pain, usually of a severe burning character, on the passage of a motion, especially if a hard one; it commonly occurs at the time of defaecation, but occasionally commences a few minutes afterwards, and continues from half-an-hour to several hours. This pain is very severe, and peculiarly wearing and burning; it is generally most felt opposite the sacro-iliac articulation, but not unfrequently radiates round the pelvis or down the thighs. In many cases it produces a good deal of continued irritation about the genito-urinary organs, giving rise, in the male, to symptoms of spasmodic stricture, a frequent desire to urinate, tenderness about the prostate, and seminal emissions. The pain is sometimes so severe that the patient avoids defaecation as long as possible, and with this object even abstains from taking sufficient food. Very commonly in women, the pains produced by the rectal disease simulate those occasioned by uterine irritation; and in both sexes they may after a time become continuous, and be attended with constant uneasiness in sitting, so that the patient is obliged to raise the hip of the affected side. There is often a streak of pus or blood on the faeces, and commonly a good deal of mucous discharge, with some tenesmus on defecation; but in some instances these symptoms are altogether absent, and the patient suffers no local inconvenience except from the pain. The constitutional irritation is often great; the countenance becomes pale and careworn, and the expression is indicative of constant suffering.

This affection most commonly occurs in women, especially in those of a weakly constitution and subject to chronic constipation. In some cases it seems to have arisen from injury during labour. When met with in men, it is most frequently seen in debilitated subjects.

The typical fissure may always be detected by everting the mucous membrane of the anus, and turning aside the pile which covers the lower end of the crack. During this examination it will usually be found that the sphincter is in a more or less spasmodically contracted state, admitting the finger with difficulty. An ulcer within the orifice of the anus will be felt with the finger as a small, soft, velvety patch; on touching it the patient will usually complain of acute and burning pain. It may be brought into view by examining the rectum with a speculum (Figs. 826 and 827), but an anæsthetic will usually be required to do this.

The **Treatment** of fissure or ulcer of the anus in its early stages, may sometimes be successfully conducted by the application of nitrate of silver, and the use of an anodyne or astringent suppository. I have found the following a very useful suppository in this and many other painful affections of the anus : 2 grains of extract of belladonna, 2 grains of the acetate of lead, and 4 of tannin, made up with a little cocoa-butter. This may be used every night ; the bowels should at the same time be kept gently open with castor-oil, or the lenitive electuary. In those cases in which the disease is of long standing these means will not suffice, and it is necessary to have recourse to a very simple operation. This consists in dividing the affected mucous membrane through the ulcer or fissure, with possibly some of the subjacent fibres of the sphincter, by which the part is set at rest, and cicatrization speedily takes place. The relief after the operation is usually immediate ; indeed, after its performance, a patient who has been suffering severely for months or

Fig. 826.—Anal Dilator.

Fig. 827.—Spectrum Anal.

years, will often get complete and almost instantaneous relief. The merit of introducing this plan of treatment into surgical practice is due to Brodie. Boyer had previously recommended that the sphincter should be cut completely across, in order that its action might be paralysed ; but Brodie found that the ulcer could be made to heal as readily by the limited incision above mentioned. The operation is done by introducing the left forefinger into the rectum, guiding along it a straight probe-pointed bistoury, and then cutting downwards and outwards, carrying the knife about the eighth of an inch in depth. No dressing is required after this operation ; but, if the incision do not readily heal, it should be touched with nitrate of silver. The patient's bowels should be well opened before the operation, and a dose of castor-oil may be given on the second or third day after it. During the process of cicatrization it will often be advantageous to give iron, and to put the patient on a nourishing diet. As a substitute for incision, forcible digital dilatation of the anus under an anæsthetic has of late been extensively practised with very good results. The floor of the fissure is usually torn somewhat deeply, so that the effect resembles that of incision.

In a considerable number of cases Ball has obtained equally good results by simply snipping off with scissors the small "pile" at the lower end of the fissure

which, as already stated, he looks upon as a torn down anal valve. Ball compares this treatment with that by which a so-called "torment" at the side of the finger-nail is cured by shaving off the little tag of skin.

**Spasmodic Contraction of the Sphincter Ani** is usually associated with fissure or ulcer of the anus, or inflammatory irritation of some neighbouring organ; but occasionally it occurs without this complication, and in all cases it may be connected with a neuralgic condition of the part. In hysterical women neuralgia and spasm are especially apt to occur; though it is not improbable that, in many of the so-called cases of neuralgia of the anus, some positive disease, such as a small ulcer or fissure, may be detected on close examination, as I have several times been able to verify. The *Treatment* of contraction of the sphincter, whether associated with neuralgia or not, consists in the employment of local sedatives, especially the extract of belladonna, gr. j. to gr. ij., as a suppository; the bowels being kept relieved by enemata and confection of senna. Should these means fail, the patient must be anaesthetized, and the sphincter forcibly dilated with the fingers.

**Atony of the Rectum** is common in middle age, in those who lead sedentary lives, and especially in women. It is a consequence of habitual constipation, and in its turn aggravates that condition, the walls of the rectum becoming expanded and pouch-like. It may occasion the retention and impaction of hardened fæces. A mass of clayey consistence, and as large as the foetal head, forming in the rectum and interfering seriously with defæcation, becomes a source not only of great discomfort but of serious ill-health. Like all retained excreta it slowly poisons the system, giving rise to foul breath, dirty greyish complexion, and mental depression. The *Treatment* of atony of the rectum consists in scrupulous care in emptying the bowels by the administration of cold enemata. If impaction of fæces have occurred, this is to be remedied only by putting the patient under chloroform, forcibly dilating the sphincter with the hand, and breaking down the hardened mass with a lithotomy scoop or spoon, washing it away with enemata, and thus clearing out the bowel.

#### ABSCESS AND FISTULA.

Abscess not unfrequently occurs in the vicinity of the rectum and anus. It may either be superficial, being confined to the muco-cutaneous structures, and presenting the ordinary characters of acute subcutaneous abscess; or it may be deeply seated, forming in the ischio-rectal fossa. It is these ischio-rectal abscesses that are of most practical importance. They are of two kinds—Acute and Chronic.

**Acute Ischio-rectal Abscess** forms deeply in the fossa, with throbbing, shooting, and stabbing pains through the anus, rectum, and perinæum; on examination, a hard brawny substance may be felt in the areolar tissue by the side of the gut, either by examination from without, or by exploration through the rectum. It speedily softens, and will, unless an outlet be made for it, burst either externally, or into the cavity of the gut, or both ways. (See Vol. I., p. 958.)

**Chronic Ischio-rectal Abscess** occurs insidiously in persons of a broken or strumous constitution. Without much pain or local inconvenience, a collection of pus forms, which is usually limited to one side of the ischio-rectal fossa, but in other cases acquires considerable magnitude, extensively denuding the rectum and then spreading widely on the nates. This kind of purulent

collection may form in this as in any other situation in the body, as the result of congestion or of some local irritation. I have several times seen it follow kicks, blows, or bruises of the lower part of body, or as a consequence of lowering of the vitality of the mass of adipose tissue in the ischio-rectal fossa in a weakly person from sitting on a cold stone, or standing for a long time in cold or snow. In other cases the mischief appears to originate around the prostate and an abscess forming in this situation may find its way down by the side of the rectum. Brodie attributed these abscesses, and the consequent fistuliform perforations of the mucous membrane; and although I think he exaggerates the frequency of this mode of production of the abscess, yet there can be no doubt that, in some instances at least, it occurs as the result of perforation of the bowel—either by ulceration from within, by the formation of a fissure by some foreign body, as a fish-bone, transfixing it. These abscesses are common in young adults, not unfrequent in middle age, but rare at either the extremes of life. I have, however, seen several cases in children—between three years of age—and the affection may occur in septuagenarians.

In the *treatment* of these abscesses, the principal point is to prevent extension and denudation of the gut. In order to do this the abscess must be opened as early as the formation of pus can be ascertained to have taken place, by making a free incision into the ischio-rectal space by the side of the bowel. Unless this is done, the pus may either burst into the interior of the gut, or spread widely upon the nates. The pus that is let out is always extremely offensive, even though not mixed with any feculent matter; the close neighbourhood of the bowel appearing to determine some change in it that renders the smell stercoraceous. After the evacuation of the abscess the patient recovers easily, and thinks that all is well, the discharge gradually lessening and the cavity contracting; but it does not close, and a fistula is left, in which feculent matter, perhaps, accumulates from time to time, giving rise to fresh outbreaks and extensions of the disease.

**Anal Abscess.**—Besides the two forms of abscess just described as occurring in the ischio-rectal fossa, another is commonly met with to which the term “anal abscess” may be applied. It commences in the submucous tissue of the gut immediately above the anus. Its cause is not always evident. It may result from suppuration taking place beneath an inflamed pile, from wound of the mucous membrane by some solid body such as a fish-bone, or from the formation of a caseating tuberculous nodule in the submucous tissue. The pus formed burrows downwards between the mucous and muscular coats of the bowel till it reaches the anus; here it passes out beneath the skin and forms a small rounded swelling at the margin of the anus. If unrelieved it burrows still further in the subcutaneous tissue. The pus in this case is superficial to the sphincter. These abscesses may be acute or chronic; in the chronic they are frequently tuberculous, advancing slowly and containing thick curdy pus. They usually burst both internally and externally, and are the most common cause of the ordinary fistula in ano. By early opening and dressing with wet boric lint and frequent bathing with a concentrated solution of boric acid they can sometimes be got to heal without leaving a fistula; if they are tuberculous this seldom happens, and the best treatment is to open them thoroughly open into the bowel, to scrape the surface well with a spoon, and to dress them with iodoform ointment.

**Fistula in Ano.**—The sinus left by the contraction of the cavity of an ischio-rectal or anal abscess constitutes a fistula in ano; an affection that

tracted a good deal of attention from the frequency of its occurrence, and from the difficulty of curing it without having recourse to operation.

**Extent.**—When following an anal abscess the fistula is very limited, being merely the sinus left in the submucous areolar tissue of the anus after the bursting of the superficial collection of pus in this situation, extending to a short distance up the gut inside the sphincter. This constitutes the most common variety of the disease. In a fistula resulting from an ischio-rectal abscess the track passes outside the sphincter in the surrounding areolar tissue, tending always as high as the upper margin of that muscle, and frequently reaching to a considerable distance up the side of the gut. Most frequently the lower and external aperture of the fistula is single, and is situated by the side of the anus in the ischio-rectal fossa, just beyond the sphincter; but not infrequently the aperture is in the perinæum, or posteriorly in the coccygeal region. Occasionally there is a fistulous opening on each side of the gut; or several openings may exist, and then sinuses extend from these upwards and inwards to a considerable distance, undermining the integuments of the perinæum about the buttocks, even stretching away towards the trochanters, and opening at a great distance from the bowel. These extensive fistulæ and sinuses are frequently connected with stricture of the gut; but they may occur without this in old and neglected cases of the simple disease.

The fistulæ are usually oblique, but straight in their direction from a point half an inch or an inch from the anal aperture, running upwards to above the sphincter. In some cases they are tortuous; and, occasionally, when opening at a distance from the gut, and extensively undermining the integuments, they are angular, having, as it were, an elbow at that point where the superficial sinus meets the deep fistula. This peculiarity will prevent the passage of a probe through their whole length until the external sinus has been slit up, and the commencement of the deep track reached, and may lead to the supposition the fistula being more superficial than it really is.

**Varieties.**—Fistula in ano is said to be **Complete** when it communicates at one end with the rectum, and opens by the other upon the external surface. It is said to be **Incomplete** when it has only one aperture, whether that be external or internal.

**Complete Fistula** is the most common form. It probably arises in the majority of cases from some source of irritation seated within the bowel, by which the mucous membrane of the rectum has been perforated, and an abscess is formed in the submucous areolar tissue or outside the gut. The external opening in this form of fistula is usually from half an inch to an inch from the margin of the anus; though it may be seated at a greater distance than this, upon the hip. It is commonly small, and has a vascular granulation projecting from or occluding it; and a thin purulent discharge usually drains away from it in small quantities, moistening the surrounding integuments. An internal opening is usually situated just above the sphincter, where the rectum begins to expand. But the fistula does not terminate at this internal aperture; for in the majority of cases it runs up a considerable distance higher into a kind of *cul-de-sac*. The internal aperture may readily be detected by introducing a blunt curved probe into the fistula; when, by a like management, it may be carried through the inner opening. In some cases, the existence of this may be ascertained by examining the interior of the rectum with a speculum, and by injecting water into the external opening.

**Incomplete or Blind Fistulæ** may be of two kinds. When there is no

collection may form in this as in any other situation in the body, as the result of congestion or of some local irritation. I have several times seen it follow kicks, blows, or bruises of the lower part of body, or as a consequence of the lowering of the vitality of the mass of adipose tissue in the ischio-rectal fossa in a weakly person from sitting on a cold stone, or standing for a long time on ice or snow. In other cases the mischief appears to originate around the prostate, and an abscess forming in this situation may find its way down by the side of the rectum. Brodie attributed these abscesses, and the consequent fistulae, to perforations of the mucous membrane; and although I think he exaggerated the frequency of this mode of production of the abscess, yet there can be no doubt that, in some instances at least, it occurs as the result of perforation of the bowel—either by ulceration from within, by the formation of a fissure, or by some foreign body, as a fish-bone, transfixing it. These abscesses are most common in young adults, not unfrequent in middle age, but rare at either of the extremes of life. I have, however, seen several cases in children—two or three years of age—and the affection may occur in septuagenarians.

In the *treatment* of these abscesses, the principal point is to prevent extensive denudation of the gut. In order to do this the abscess must be opened as soon as the formation of pus can be ascertained to have taken place, by making a free incision into the ischio-rectal space by the side of the bowel. Unless this be done, the pus may either burst into the interior of the gut, or spread widely upon the nates. The pus that is let out is always extremely offensive, even though not mixed with any faeculent matter; the close neighbourhood of the bowel appearing to determine some change in it that renders its smell stercoraceous. After the evacuation of the abscess the patient feels easy, and thinks that all is well, the discharge gradually lessening and the cavity contracting; but it does not close, and a fistula is left, in which faeculent matter, perhaps, accumulates from time to time, giving rise to fresh outbreaks and extensions of the disease.

**Anal Abscess.**—Besides the two forms of abscess just described as occurring in the ischio-rectal fossa, another is commonly met with to which the term "anal abscess" may be applied. It commences in the submucous tissue of the gut immediately above the anus. Its cause is not always evident. It may arise from suppuration taking place beneath an inflamed pile, from wound of the mucous membrane by some solid body such as a fish-bone, or from the formation of a cascating tuberculous nodule in the submucous tissue. The pus thus formed burrows downwards between the mucous and muscular coats of the bowel till it reaches the anus; here it passes out beneath the skin and forms a small rounded swelling at the margin of the anus. If unrelieved it may burrow still farther in the subcutaneous tissue. The pus in this case lies superficial to the sphincter. These abscesses may be acute or chronic; when chronic they are frequently tuberculous, advancing slowly and containing thick curdy pus. They usually burst both internally and externally, and are the most common cause of the ordinary fistula in ano. By early opening and dressing with wet boracic lint and frequent bathing with a concentrated solution of boracic acid they can sometimes be got to heal without leaving a fistula. If they are tuberculous this seldom happens, and the best treatment is to lay them thoroughly open into the bowel, to scrape the surface well with a sharp spoon, and to dress them with iodoform ointment.

**Fistula in Ano.**—The sinus left by the contraction of the cavity of an ischio-rectal or anal abscess constitutes a *fistula in ano*; an affection that has

attracted a good deal of attention from the frequency of its occurrence, and from the difficulty of curing it without having recourse to operation.

**Extent.**—When following an anal abscess the fistula is very limited, being merely the sinus left in the submucous areolar tissue of the anus after the bursting of the superficial collection of pus in this situation, extending to a short distance up the gut inside the sphincter. This constitutes the most common variety of the disease. In a fistula resulting from an ischio-rectal abscess the track passes outside the sphincter in the surrounding areolar tissue, extending always as high as the upper margin of that muscle, and frequently stretching to a considerable distance up the side of the gut. Most frequently the lower and external aperture of the fistula is single, and is situated by the side of the anus in the ischio-rectal fossa, just beyond the sphincter; but not unfrequently the aperture is in the perinæum, or posteriorly in the coccygeal region. Occasionally there is a fistulous opening on each side of the gut; or several openings may exist, and then sinuses extend from these upwards and outwards to a considerable distance, undermining the integuments of the perinæum about the buttocks, even stretching away towards the trochanters, and opening at a great distance from the bowel. These extensive fistulæ and sinuses are frequently connected with stricture of the gut; but they may occur without this in old and neglected cases of the simple disease.

The fistulæ are usually oblique, but straight in their direction from a point half an inch or an inch from the anal aperture, running upwards to above the sphincter. In some cases they are tortuous; and, occasionally, when opening at a distance from the gut, and extensively undermining the integuments, they are angular, having, as it were, an elbow at that point where the superficial sinus meets the deep fistula. This peculiarity will prevent the passage of a probe through their whole length until the external sinus has been slit up, and the commencement of the deep track reached, and may lead to the supposition of the fistula being more superficial than it really is.

**Varieties.**—Fistula in ano is said to be **Complete** when it communicates by one end with the rectum, and opens by the other upon the external surface. It is said to be **Incomplete** when it has only one aperture, whether that be external or internal.

**Complete Fistula** is the most common form. It probably arises in the majority of cases from some source of irritation seated within the bowel, by which the mucous membrane of the rectum has been perforated, and an abscess has formed in the submucous areolar tissue or outside the gut. The external opening in this form of fistula is usually from half an inch to an inch from the margin of the anus; though it may be seated at a greater distance than this, as upon the hip. It is commonly small, and has a vascular granulation projecting from or occluding it; and a thin purulent discharge usually drains away from it in small quantities, moistening the surrounding integuments. The internal opening is usually situated just above the sphincter, where the rectum begins to expand. But the fistula does not terminate at this internal aperture; for in the majority of cases it runs up a considerable distance further into a kind of *cul-de-sac*. The internal aperture may readily be detected by introducing a blunt curved probe into the fistula; when, by a little management, it may be carried through the inner opening. In some cases, the existence of this may be ascertained by examining the interior of the bowel with a speculum, and by injecting water into the external opening.

**Incomplete or Blind Fistula** may be of two kinds. When there is no

internal perforation, a mere sinus having been left by the bursting of an abscess, the fistula is termed *blind external*. When there is only an internal aperture, it is called *blind internal*. The blind external fistula is readily recognized by its being found that the probe does not penetrate the interior of the gut. The blind internal is not so readily detected; but in this case it will generally be found that the patient suffers from an occasional discharge of pus from the interior of the bowel; that there is a tender and brawny patch on one side of the anus; and that the pus may be made to escape from the anus by pressing upon this part. On passing the finger into the rectum, the internal aperture in the gut through which the pus exudes may readily be felt. In most cases the opening can be seen by the help of a speculum, and a hooked probe passed into it.

**Treatment.**—Operative interference is usually necessary. It is true that in some rare instances the fistula may be made to close under the influence of constitutional remedies, aided, perhaps, by stimulating its interior with nitrate of silver, or by touching it with a probe dipped in nitric acid. This kind of treatment is, however, successful only in the blind external fistula, several instances of which I have seen recover in this way. Occasionally in elderly people a blind internal fistula will be found, which, falling into a very chronic state and discharging little, is a source of but very trifling discomfort, and will continue for years without giving rise to serious local inconvenience, or in any way disturbing the general health. In such cases, I believe, there is often far less risk in leaving the fistula untouched than in subjecting the patient at an advanced period of life to the dangers of an operation. When the fistula is complete, the only plan of treatment that offers any chance of success is to lay it freely open into the bowel; so that if it pass external to the sphincter, this muscle, which tends to prevent the closure of the sinus, will be paralysed, and the fistula, being laid open from the bottom, will heal by granulation. Various plans have been devised for the division of the fistula, and much ingenuity has been expended in attempts to discover simpler and less painful modes of effecting this than by the knife, but hitherto without success.

The **Operation for fistula in ano** should not be performed indiscriminately in all cases and at all periods of the disease. If the fistula be dependent upon stricture of the gut, and more especially if this be of a malignant character, it is evident that no operation can be attended with a chance of success, and none should be attempted. So, also, if the patient be cachectic and broken in health, more especially if he be suffering from tuberculous disease of the lungs, it is well to improve his constitutional powers before undertaking an operation, lest the wound that results may not heal. The most important question connected with the operation for fistula, is the propriety of performing it in tuberculous subjects in whom the disease is especially apt to occur. The co-existence of fistula with pulmonary phthisis was at one time believed to retard the progress of the latter disease. I have, however, in several cases found considerable advantage result from operating for fistula in the early stages of phthisis, or in suspected cases of that disease, the patient's health having considerably improved after the healing of the fistula. But in advanced phthisis, no operation should ever be practised; as the wound will not heal, and the patient must be weakened by the additional discharge.

The operation for *complete* fistula should be performed in the following way: The bowels having been well cleared out the day before with a dose of castor-

oil, and an enema administered on the morning of the operation, the patient should be laid on his left side, with the nates projecting over the edge of the table. A flexible probe-pointed director is passed into the external opening and along the track into the rectum, a finger being introduced into the bowel to guide the director through the internal opening. The point of the instrument is then brought out of the anus, and the tissue which lies on the director is completely divided. Care should be taken to cut directly and not obliquely on to the director, lest a flap be left which will interfere with the healing of the wound. The hæmorrhage in ordinary cases is trivial, but when the track passes deeply, as in a fistula resulting from an ischio-rectal abscess, vessels of considerable size may be divided. In such a case the division of the tissues on to the director should be made by successive short cuts, and any vessels which bleed should be secured with forcipressure forceps and afterwards ligatured.

When the external aperture or apertures of the fistula are at some distance from the gut, the integuments being undermined to a considerable extent, perhaps thinned, soft, and bluish, all the superficial sinuses should be slit up with a probe-pointed bistoury; and, in those cases in which the course of the fistula runs more or less at a right angle to that of the external sinus, it is necessary to do so before the deep or internal fistula can be reached, through which the sphincter must be divided. If the fistula be a *blind external* one, it must at the time of the operation be made complete, by pushing the end of the director through the thinned structures that intervene between its extremity and the interior of the gut; and the operation must then be completed in the way described. The Surgeon must not be too ready to conclude that the fistula has no internal opening, as it is important that it should be laid open if it exists. A careful search with a probe should therefore be made in all cases in which an internal aperture is not at once found. If it be a *blind internal* fistula, a speculum should be inserted, and a bent probe passed through the inner opening of the fistula into the canal. The end of this, which can be felt externally, must be exposed by a puncture made through the integuments with a scalpel, and the operation concluded in the ordinary way.

When there is an internal aperture into the gut, this will usually be found just above the sphincter; the fistula, however, may not terminate here, but frequently extends up by the side of the gut for an inch or two. In these circumstances, what should be done with the *cul-de-sac* above the inner aperture? If it be laid open, an extensive wound will be inflicted, which may implicate some of the hæmorrhoidal vessels, and thus give rise to dangerous bleeding. Hence I think it a safer practice for the Surgeon to content himself with the division of all the parts intervening between the inner aperture of the fistula and the verge of the anus; the sinus which is left usually contracting and closing without difficulty when this has been done. In some cases, however, it happens that this *cul-de-sac* is not readily obliterated, but gives rise to a good deal of trouble in consequence of the occasional accumulation of pus in it, and the thickening of its aperture into the bowel causes spasmodic contraction of the sphincter and a kind of rectal stricture. This inconvenience gradually subsides in most cases, under the use of astringent injections or the introduction of a probe coated with nitrate of silver.

If the integuments around the fistula have been much undermined so as to leave loose flaps at the edges of the incision, the cure will be materially hastened by cutting these off. The unhealthy granulation tissue lining the

fistula, especially in tuberculous cases, should be scraped away with a sharp spoon and the raw surface cleaned with a sponge moistened with some chloride of zinc (gr. 40 to 3j), care being taken that this does not touch the healthy skin of the anus. Iodoform should then be freely applied to the raw surface and a narrow strip of boric lint inserted, after the introduction of a half-grain morphia suppository. A pad of wool is then put on and a T-bandage applied. This dressing may be left unchanged for three days. The wool can then be removed without difficulty or fear of bleeding. The bowels should be kept confined for three or four days by small doses of opium. After the first dressing the wound may be dusted daily with iodoform and a fresh piece of lint applied to it. It should be well washed at each dressing with a concentrated solution of boric acid or some other antiseptic. If there is any swelling and pain, lint soaked in a warm solution of boric acid may be applied externally and covered with oiled silk. Care must be taken to prevent the bridging over of granulations, if necessary by the occasional introduction of a probe. If the wound is slow in healing, red wash must be applied. After the wound has completely united, a notch will usually be left by the side of the anus, which may give rise to some inconvenience for a time by the occasional involuntary discharge of a little intestinal mucus, and some flatus. This happens especially in those cases in which the incision has been made anteriorly to the anus into the perinæum. Should an inconvenient or dangerous amount of hæmorrhage occur at the time of the operation, the wound should be plugged with iodoform wool, and a firm pad applied by means of a T-bandage. Should profuse bleeding, in consequence of the division of some of the hæmorrhoidal vessels, come on a few hours after the operation, all coagula should be cleared away, the gut washed out with ice-cold water, and then securely plugged either with a piece of compressed sponge, or with a lithotomy or œsophagus tube, surrounded by lint soaked in a solution of perchloride of iron, and pushed into the bottom of the sinuses that have been laid open.

#### HÆMORRHOIDS OR PILES.

By **Hæmorrhoids** or **Piles** is meant a morbid condition of the blood-vessels of the anus and lower part of the rectum, especially of the veins of the submucous or subcutaneous areolar tissue, giving rise to greater or less intumescence of the part, which may or may not be attended with a discharge of blood. Surgeons are commonly in the habit of classifying piles, according as they bleed or not, into **Open** or **Blind**; or, according as they spring from above or below the verge of the anus, into **Internal** or **External**; the internal being always within the gut, the external habitually protruding out of or around the anal aperture. The first may either bleed or not; the latter are always blind. To this division into external and internal, B. Cooper added an intermediate variety, the **Intero-External**, which is partly within and partly without the anus. These divisions are of great practical importance, as the treatment is very materially modified according as the hæmorrhoid is situated above or below the anal verge.

**Predisposing Causes.**—We must look to the peculiar arrangement of the veins of the rectum as directly predisposing to the occurrence of piles. The lower part of the rectum and the margin of the anus are composed of a plane of muscular fibre and a muco-cutaneous surface, with an intervening stratum

of loose areolar tissue, in which a close net-work of tortuous veins is situated. The blood, from this plexus of hæmorrhoidal veins, finds its way into the general system through two distinct channels. By far the greater portion of it is carried into the inferior mesenteric vein, and thence into the vena portæ, through the superior hæmorrhoidal vein, which may be looked upon as the extreme radicle of the portal system; and some passes into the internal iliac vein through branches that accompany the middle and inferior hæmorrhoidal arteries. We may, therefore, look upon the hæmorrhoidal plexus as being placed midway between the portal and general venous systems, but as belonging rather to the portal than to the systemic veins. In these arrangements we see all the elements that would predispose to congestion, and consequent dilatation of the vessels of a part. There is a large and intricate plexus of veins in which, as in all similar net-works, there is a tendency for the blood to circulate slowly; the natural tendency to stasis being much increased by the dependent position of the part, and by the absence of valves in the superior hæmorrhoidal vein and in the vessels into which it pours its contents, the whole pressure of the column of blood in the portal system may be brought to bear upon the hæmorrhoidal plexus. The circulation through the portal system is likewise subject to much interference in consequence of obstruction in the liver and elsewhere, and in these changes the blood in the hæmorrhoidal plexus also participates; and, were it not for the provision that exists by which this plexus may free itself to a certain extent from over-distension by its communication with the internal iliac through the medium of the middle hæmorrhoidal vein, piles would be much more frequent than they even now are. Another great cause of hæmorrhoidal enlargement is to be found in the want of support that the veins of this plexus experience on their mucous aspect during defæcation. Situated as they are in areolar tissue, between a plane of muscular fibres on one side, and yielding mucous membrane on the other, when distended by the constriction which they undergo during defæcation, they necessarily give way on that side on which they have the least support, being forced down, together with the mucous membrane under which they ramify, and which has a natural tendency to become slightly everted during the act of defæcation.

**Age** exercises considerable influence in predisposing to piles. This disease is not unfrequently met with in young men of eighteen or twenty years of age; more especially if they be of a relaxed temperament with languid circulation, and be obliged to lead a more sedentary life than is natural. After this period, the liability to the disease diminishes until middle age is reached, when it becomes more marked than at any former period of life, owing to the more active operation of those causes that tend to impede the return of the portal blood.

**Sex** appears to exercise greater influence on the occurrence of hæmorrhoids at particular periods of life, than on the general liability to the disease. It certainly appears to be more frequently met with in men at an early age, than in young women; but at a later period of life, the disease occurs with nearly equal frequency in the two sexes. The comparative exemption of young women is readily accounted for, by the periodic discharges from the uterus preventing the congestion that might otherwise occur in the parts in its vicinity. The greater frequency in females at a later period of life is attributable not only to the pressure of the gravid uterus on the veins, but also, after the cessation of the menses, to the congestion that is apt to be set up

in certain organs of the female economy, and to the retardation of the portal circulation by the accumulation of fat and by other causes.

**A sedentary life** with indolent habits constitutes, perhaps, the most powerful predisposing cause of the disease; more especially if habitual high living be conjoined with want of exercise. Indeed, the luxurious habits of the more opulent classes exercise a considerable influence on the occurrence of this disease, which is much more frequent amongst them than in persons in the humbler walks of life.

**Alcoholic excess** is amongst the most common causes of piles, owing to the hepatic congestion to which it gives rise. If it be carried to the extent of causing cirrhosis of the liver the condition becomes aggravated. Under these circumstances bleeding piles may serve as a sort of safety-valve to the overloaded portal circulation, and should on no account be interfered with. So important is this that in all cases of piles, before undertaking an operation, the symptoms of cirrhosis—morning vomiting, failure of appetite, intermittent diarrhoea and occasional jaundice—should be inquired for.

There are a number of minor conditions which are commonly looked upon as predisposing causes of this disease, though it is extremely difficult to determine the precise share that each has in its production. Amongst these may be mentioned intemperance in food; residence in warm, moist, and relaxing climates; the use of soft and warm beds, or the opposite condition of sitting on a cold stone or damp cushion. Over-excitement of the generative organs also will occasion it.

**Exciting Causes.**—Amongst the exciting causes may be mentioned *local irritation* of any kind. Thus, in some people hard riding will bring on an attack of piles. The *habitual use of drastic purgatives*, more especially of aloes, rhubarb, &c., is well known to occasion the disease; though it must be observed that individuals, who make habitual use of these remedies, often labour under some of those obstructions of the abdominal viscera that have already been noticed as conducing to piles. The existence of other *diseases about the rectum and anus*, such as fistula, ulcer, or stricture, by inducing local congestion and irritation, may excite the disease; so also, *uterine affections* and various *diseases of the genito-urinary organs* may give rise to this affection.

The most direct exciting cause of piles is certainly a *retardation to the return of the portal blood*. Habitual constipation; the accumulation of hardened feculent masses in the large intestine; obstruction to the proper action of the liver, and consequent congestion of that organ; the pressure of abdominal tumours, or of the gravid uterus, are all active exciting causes, interfering as they do with the proper return of the blood from the hæmorrhoidal veins. In some cases, even the existence of an obstacle to the circulation in the systemic veins may occasion this disease: thus it will arise from the pressure of an aneurismal tumour on some of the large venous trunks within the chest.

**Structure.**—A pile, whether external or internal, consists essentially in the first instance of a varicose condition of a portion of the hæmorrhoidal plexus, or rather, of the small veins of the submucous tissue that pour their contents into this; this varicose condition, becoming prominently developed at certain points, gives rise to small knots or tumours. A pile in this state is quite soft and compressible, and can readily be emptied by pressure; and when cut into, it will be found to be composed of one or more spaces filled with blood, and surrounded by areolar tissue. These spaces are formed by

the sacculated and dilated veins that enter into the composition of the tumour. After the piles have existed for some little time, or after they have once become inflamed, the tissues that enter into their composition undergo modifications that induce corresponding alterations in the character of the tumour. The coats of the veins become thickened ; their cell-like dilatations may be filled with coagulated blood ; the investing areolar tissue is thickened ; and, on being cut into, the pile is seen to be composed of a spongy kind of tissue containing much blood. External piles, when examined after removal, often resemble in structure a mass of hypertrophied cutaneous and subcutaneous tissue, in which a number of small vessels of uniform character ramify, but without any appearance of cyst-like spaces. Internal piles, on the contrary, contain more of the venous, and less of the areolar, element. They are also commonly furnished with a small central artery, which is apt to bleed freely, or even dangerously, if the tumour be cut across ; hence, provided they are not clogged with coagulated blood, they may readily be injected from the inferior mesenteric artery.

In studying the structure of hæmorrhoids, it is of importance to observe that they occur in two different forms : one in which there are distinct tumours, within or external to the anus, and another in which there is merely a varicose condition of the veins of this region, without distinct intumescence.

In those cases in which there is merely a general varicose state of the veins of the submucous areolar tissue of the anus, without any distinct tumour, it will be found that the smaller branches of the hæmorrhoidal plexus, and the small twigs that enter these from the submucous areolar tissue, have undergone varicose dilatation, being apparently greatly increased in number as well as in size. The mucous membrane is of a deep mulberry or port-wine colour, and becomes everted after each motion. There is usually some mucous secretion about the anus, rendering the part moist ; and the patient complains at times of weight and of bearing down, with pains either in the part itself, in the sacro-lumbar region, or in the thighs. The motions, more especially if hard, are streaked with blood, and more or less of this fluid drops in a rapid manner after the passage of the fæces. There is seldom much blood lost ; but at times there is an exacerbation of all these symptoms, and the hæmorrhage, as will be mentioned more particularly hereafter, may become very abundant. This condition of the mucous membrane may precede, and is frequently found to accompany, the true pile, whether external or internal, and may be looked upon as constituting the first stage of this disease. If this state of things be allowed to continue unrelieved, the tendency to congestion increases ; more and more of the mucous membrane is everted and protruded after defæcation ; the submucous areolar tissue becomes relaxed, and the case is apt to become one of partial prolapsus recti.

**External Hæmorrhoids** are those which are situated below the verge of the anus, and which are invested by cutaneous, or, at most, by muco-cutaneous tissue. Before appearing as defined tumours, they usually constitute longitudinal folds that surround the anal aperture, or radiate from it as from a centre ; and, their tegumentary covering consisting of the thin skin of the part, they resemble folds of this tissue rather than of mucous membrane. In colour they vary from that of the natural structures to a pink or purplish hue. Their size varies, according to the state of congestion ; and hence the same

tumour may at one time be soft, flaccid, and loose, apparently nothing more than a fold of integument, and at another may become tense and tumid.

**Symptoms.**—When of small size and recent formation, external piles do not in general give rise to much distress, but merely to some local heat, pricking, and itching, with a sense of fulness after defæcation; but when of large size, and inflamed or irritated, they may occasion very acute suffering. There is not only deeply-seated, dull, aching and throbbing pain in the pile itself, but this shoots up the side of the rectum, through the perinæum, and into the nates, and is much increased when the patient stands or walks. After a few days these symptoms subside; suppuration either taking place in the pile, or the blood contained in it coagulating. The parts are, however, left in a thickened and indurated state, and do not readily resume their former soft and flaccid condition, inflammatory exudation taking place into the areolar tissue, and the contained blood coagulating, so that the tumour can no longer be emptied by pressure, but assumes the form of a broad, rounded, and indurated mass.

**Internal Piles.**—When the pile is situated altogether within the verge of the anus, it is called “internal;” of these there are two principal varieties, the *Longitudinal* and the *Globular*.

The **Longitudinal**, or, as it is sometimes called, the **Fleshy** pile, is generally met with about an inch up the rectum. It is spongy, elastic, firm, or tough, of a dark-reddish or dusky-brown tint, tapering upwards from a broad base. It seldom bleeds or varies much in size; between the piles are found small valves, or folds of mucous membrane, forming pouches, with their concavities looking upwards. These are apt to become distended and pressed downwards by the fæces, especially if the motions be hard and the bowels have been constipated, thus giving rise to a tendency to prolapsus.

When the hæmorrhoid assumes a **Globular** form, it constitutes the ordinary bleeding pile. It may be situated on a broad base; or, as not unfrequently happens, its point of attachment to the mucous membrane becomes elongated, and it assumes a pedunculated shape, hanging downwards into the cavity of the rectum. It is of a dark-bluish colour, and numerous small vessels of a brighter hue than the body of the pile may be seen ramifying in the mucous membrane investing it. Its surface is at first smooth and shining, and may continue so throughout, being covered with a thin and delicate prolongation of the lining membrane of the gut. Not unfrequently, however, superficial ulceration takes place, and then it has a granulated strawberry-like appearance.

**Symptoms.**—Internal piles are usually attended with a sensation of heat, itching, pricking, or smarting about the anus, and a feeling as if there were a foreign body within the gut. After defæcation these sensations are increased, and are often accompanied by a bearing down sensation, as if the bowel were not emptied of its contents, that is peculiarly distressing and sickening. This is occasioned by the piles, or the relaxed mucous membrane, being protruded during the expulsion of the fæces, and not returning sufficiently quickly, being grasped by the sphincter ani and constricted by it. This feeling of discomfort and bearing down is much increased, if the patient stand or walk much after having had a stool, or if he be constipated. If this state of things be not properly attended to, the symptoms increase; the bearing-down sensation amounts to true tenesmus, and the act of defæcation becomes so painful that the patient defers it as long as possible, and then when it does take place, in consequence of the accumulation of the excreta and their hardness,

the suffering is much increased. External piles now usually make their appearance, if they have not existed before ; the mucous membrane of the rectum becomes prolapsed, and an increased secretion of thin mucus takes place from the anus, moistening the part and soiling the patient's linen. Irritation in the neighbouring organs is frequently set up ; occasionally to so great an extent as to mask the original complaint, the patient referring his principal pain and discomfort to these sympathetic disturbances. There is often a dull aching fixed pain at the lower part of the lumbar spine, and more frequently opposite the sacrum or the sacro-iliac articulation on either side ; this is sometimes very severe, perhaps runs down the thigh, or round the groin ; irritability of the testicles may come on, or irritation about the neck of the bladder, causing frequent desire to micturate, and increasing the patient's sufferings by the straining that takes place. The general health now suffers ; the patient may become emaciated, and the countenance often presents a peculiarly anxious and careworn look.

The symptom, however, that first of all and most prominently fixes the patient's attention is **Hæmorrhage**. This varies greatly in quantity ; at first there may merely be a few drops falling after the passage of a motion, or the cylinder of fæces may be stained on one side by a streak or spots of blood, or the bleeding may amount to several ounces, or even pints.

The hæmorrhage is connected with, and in the great majority of cases dependent upon, the existence of distinct hæmorrhoidal tumours. Occasionally, however, it appears to occur when there is no distinct separate tumour projecting above the surface of the membrane ; but in these cases there is general swelling and congestion of the mucous membrane of the lower part of the rectum, from which the blood exudes in drops, or it may even spurt in a distinct jet from the open mouth of a blood-vessel. The bleeding is frequently preceded by an exacerbation of those symptoms that commonly accompany piles, such as a sensation of fulness, weight, and tension about the parts. But the symptoms that precede its occurrence are often much more imperfectly marked than is usually stated, and are frequently absent altogether.

The discharge of blood may be periodical, especially in women, occurring every month, or at intervals of two, three, or six months ; and it may be remittent or intermittent. In these cases, it usually continues from three to six days, increasing up to the third or fourth day, and then lessening.

When moderate in quantity and short in duration, it is often a source of relief to the patient ; but if a very large quantity be lost at one time, or if it continue for a long period, it causes great debility ; more harm is usually done to the patient by its long continuance than by its excessive quantity at any one time. The patient may become much weakened and anæmic ; nervous headaches, pallor, palpitations, and syncope may result. In some cases the hæmorrhage is of service in preventing disease of more important parts ; it has especially been looked upon as a safeguard from apoplexy, particularly when it occurs as a consequence of cirrhosis of the liver, or in corpulent persons who habitually live too highly. But as a rule the continued loss of blood from piles is undoubtedly injurious.

Hæmorrhage from piles is sometimes vicarious with, and at other times arrests, the menstrual flow. In a case which I attended with Garrod, the patient had suffered from the hæmorrhoidal flux and piles from the age of puberty. She menstruated for the first time when thirty-seven years old ; up

to that period the hæmorrhage had occurred abundantly at monthly intervals. After the late establishment of the menstrual function, the piles continued to bleed, but less regularly, and she became anæmic and emaciated to the last degree. When she was forty-four years of age, I saw her for the first time; the piles, which were very large and vascular, were ligatured, and she made a perfect recovery.

The colour of the blood is most generally florid, as if it came from the small arteries or capillaries of the part rather than from the veins. It would appear that, in consequence of the over-distended and varicose condition of the veins, the onward flow through the arteries and capillaries leading to them is obstructed; and that, in consequence of the accumulated pressure on those vessels, their parietes give way, allowing the florid blood to escape.

Very commonly the internal piles, when brought down, present a somewhat granular surface, in consequence of ulceration having taken place, and the whole surface will be seen to exude blood in drops. In other instances, the blood appears to come from a cavity in one side of the hæmorrhoid, as if rupture had occurred from over-distension at that part.

The hæmorrhage may be accompanied by a thin mucous discharge from the rectum; this would appear to be nothing more than excessive secretion from the mucous membrane, in consequence of the irritation set up by the piles; it is seldom in sufficient quantity to produce much annoyance, or to be of much moment to the patient.

**Complications.**—Piles are not uncommonly complicated with other diseases of the rectum, such as fissure, fistula, or prolapsus. When connected with fissure, the hæmorrhoid often, as Syme remarked, assumes a peculiar appearance, presenting itself as a small red body, like a pea in size, firm, and seated at the base of the fissure, which it often conceals; to a practised eye, however, the presence of a pile of this peculiar colour and shape is sufficient to indicate the existence of a fissure.

In that form of fistula in which the aperture is near the anus, one or more external piles of small size are often found situated at the orifice of the fistula; and prolapsus rarely, if ever, is met with in adults, without the simultaneous occurrence of piles.

**Terminations.**—Hæmorrhoidal tumours may terminate by Subsidence, Coagulation, Suppuration, or Sphacelus.

Complete **subsidence** of a pile can take place only when the disease is of recent occurrence. When of long standing, and after it has been exposed to successive attacks of turgescence and inflammation, an external pile never subsides completely; and the areolar tissue and the muco-cutaneous structures, becoming hypertrophied, form elongated pendulous flaps around the margin of the anus.

**Coagulation** of the contents of the pile is the result of inflammation. When it takes place, the tumour, after more or less acute inflammation, becomes hard, incompressible, permanent in size, and of a purplish or plum colour. The coagulum thus formed may excite suppuration, or may be absorbed, the hypertrophied tissues forming one of the usual anal folds if the pile be external. In some rare instances, the coagula may calcify and form phleboliths.

Coagulation takes place more frequently in external than in internal piles, owing to their greater liability to inflammation, their exposed situation leading

them to be bruised or otherwise injured. When it occurs in internal piles, it most commonly affects those that are of a columnar or longitudinal shape, and least frequently the globular variety.

**Suppuration** is not an uncommon termination, if acute inflammation have been set up in internal piles, more especially in those that have previously been coagulated. When the abscess is discharged, small coagula escape with its contents, the cavity granulates, and becomes obliterated, and the pile is cured. The pus in other cases may burrow in the submucous tissue, and, by bursting externally, give rise to a fistula in ano.

**Sphacelus.**—In some cases, when there is much elongation of the mucous membrane from which the pile springs, prolapsus of that membrane and of the piles may take place; and, this being grasped by the contraction of the sphincter, the same effect may be produced as if a ligature were applied. The tumour becomes much swollen, hard, livid, and tense; there are much constitutional disturbance and restlessness; but after a few days the part that is constricted sloughs and drops off, and all the symptoms are relieved.

**Diagnosis.**—The diagnosis must be regarded from two points of view:—1st, as concerns the *Hæmorrhoidal Tumours*; and 2dly, with reference to the *Hæmorrhoidal Flux*.

1. **Hæmorrhoidal Tumours** must be diagnosed from prolapsus recti, polypus of the rectum, epithelioma of the anus, and condylomata about the anus. From partial prolapsus the diagnosis is not always easy; indeed, the two conditions are so generally associated, that it is of little moment to attempt it. In complete prolapsus examination will suffice to distinguish the membranous wall of the intestine, forming a smooth, rounded, and somewhat lobulated annular protuberance, from the isolated tumours of piles. In polypus the history of the case, the pedunculated and solitary character of the tumour, its large size, and comparatively slight tendency to hæmorrhage, will enable the Surgeon to make the diagnosis. **Epithelioma** is easily recognized by its hardness and by its deep infiltration of surrounding parts. In any case of doubt, a digital examination of the rectum will make its nature evident. From **condylomata** the diagnosis is easy: the soft, flat, and wart-like character of these growths, their history, and their occurrence at other points, as the perinæum, scrotum, vulva, and buttocks, will enable the Surgeon to distinguish them without any difficulty.

2. The **Hæmorrhoidal Flux** must be distinguished from other **intestinal hæmorrhages**.—This may be done by attention to the character of the blood, which will generally indicate its source. When it comes from piles it is liquid, of a more or less florid colour; not unfrequently it is quite bright, staining or coating the feces rather than being mixed up with them. When, on the contrary, the blood is poured out at some higher point in the intestinal canal than the usual seat of hæmorrhoids, it is of a dark tarry character, mixed up with liquid feces either in a diffused form or in small black coagula, and no fresh or bright blood will be visible. Digital exploration of the rectum in cases of piles, and the presence of symptoms indicating the existence of mischief at a higher part of the intestine than the anus in cases of melæna, will also serve to point to the source of the blood.

**Treatment.**—In conducting the treatment of a case of piles, that Surgeon will succeed best who looks upon the disease not as a local affection, merely requiring manual interference, but as a symptom, or rather an effect, of remote

visceral obstruction and disease, the removal of which may alone be sufficient to effect the cure, without the necessity of any local interference ; or, should it be thought necessary to have recourse to operation, this must be made secondary to the removal of those conditions that have primarily occasioned the congestion and dilatation of the hæmorrhoidal vessels. The treatment of piles, therefore, must be considered, 1st, as regards the Removal of these Constitutional Conditions or Visceral Obstructions that occasion the disease, together with any Local Applications that may be considered necessary ; and 2ndly, with reference to the Operative Procedures that may be required for the removal of the affection.

1. The **Constitutional Management** of piles necessarily varies considerably according to the condition of the patient in whom they occur, and the visceral obstruction to which they may be referable. Thus, when they occur in debilitated persons most benefit will be derived from a mild tonic and nutritious plan, at the same time that the bowels are kept regular by some of the aperients that will immediately be mentioned. A small cold water injection after each motion is of the greatest possible service in these cases. In the great majority of instances, however, more particularly when occurring about the middle period of life, piles are connected with a plethoric state of the system, and congestion of the abdominal viscera. In these circumstances, careful attention must be given to the diet, the use of stimulants being prohibited, and the quantity of animal food lessened. When piles arise from the pressure of a gravid uterus or other abdominal tumour, little can be done, except, by local palliatives and mild aperients, to moderate the inconvenience attending them.

In all cases of piles, but more particularly in those arising from hepatic obstruction, mild aperients are of essential service ; by removing feculent accumulations, and establishing a free secretion from the intestinal surface they tend materially to prevent congestion of the portal system. At the same time, drastic purgatives of all kinds should carefully be avoided. The most useful aperients are the electuaries of senna, sulphur, and castor-oil ; one or other of which should be taken regularly twice or thrice a week at bed-time, in as small a quantity as will suffice to keep the bowels free. In many cases, the confection of senna may advantageously be given in combination with precipitated sulphur and the bitartrate of potash, equal parts of each of these being made into a mass with twice their quantity of the confection and a little syrup ; of this electuary a dessert-spoonful may be taken every night or every second night. In many cases the laxative mineral waters, such as Friedrichshall, Hunyadi Janos, or *Æsculap*, taken on rising in the morning, will be found of great use. *Cascara sagrada* is often useful ; 20 to 60 drops of the tincture or liquid extract should be given at night, or a corresponding dose in capsules or tabloids. If there be a relaxed condition of the rectum and anus conjoined with the piles, as not unfrequently happens in old as well as in young people, the administration of an electuary composed of equal parts of the confections of senna and of black pepper, or of cubebs, will be found very useful. When the liver is much obstructed, the treatment should be specially directed to the relief of this organ ; with this view, a course of Plummer's pill, followed by taraxacum, and, in relaxed constitutions, the mineral acids, will be found especially serviceable, at the same time that the bowels are kept free by gentle aperients.

Tincture of hamamelis is said materially to relieve, and, in fact, to cure bleeding internal piles. It may be administered by the mouth and by enema simultaneously. The habitual use of clysters, consisting either of soap and water or thin gruel, will be found advantageous in many cases of piles, though in some they appear to irritate, and rather to increase the disease. In the general management of piles, it need scarcely be observed that any habits which favour the disease should be sedulously avoided.

The **Local Treatment** of piles is of considerable importance. The parts should be regularly sponged with cold water, morning and evening. If there be much relaxation, and the piles be internal, benefit may result from the employment of some astringent injection, such as a very weak solution of the sulphate of iron, or of the tincture of the sesquichloride—a grain of the first or ten drops of the second, to an ounce of water; of this about two ounces may be injected every night and left in the rectum. The application of an astringent ointment, such as the unguentum gallæ co., extract of hamamelis, or the employment of the anodyne and astringent suppository already recommended for fissure of the anus, will be very beneficial.

If an external pile become inflamed, it should be painted with equal parts of extract of belladonna and glycerine, hot fomentations applied, a very spare diet enjoined, and the bowels opened by mild saline aperients. If a coagulum form in the inflamed pile, the tumour should be laid open with a lancet, and its contents squeezed out. If an abscess form, it must be punctured in the usual way, and the part afterwards fomented or dressed with boric lint soaked in warm boric lotion. Should strangulation of internal piles take place, the protruded swelling must be returned by gentle steady pressure, and the part afterwards well fomented.

2. **Operation.**—The means above indicated are usually sufficient in ordinary cases of piles; but very frequently operative interference is required. This is most commonly called for on account of hæmorrhage or the prolapse of the piles during defæcation. No operation should be undertaken whilst the piles are in an inflamed state, lest unhealthy inflammation be set up in the part. It is also well to get the patient's health into as good a state as possible before the operation; as a rule no operation is justifiable if the patient is suffering from cirrhosis of the liver. Whatever method be adopted, care should be taken that the bowels have been well opened by a purgative, and the rectum cleared out by an enema of warm water.

Of the various methods adopted for the removal of piles, excision is alone applicable to external piles, whilst in the case of the internal variety the choice will usually lie between strangulation by ligature, destruction by the clamp and cautery, and complete removal of the affected part of the mucous membrane. Among other methods which have from time to time been advocated by different Surgeons may be mentioned: crushing the pile with screw-forceps or a specially constructed clamp, the application of nitric acid and other caustics, the injection with carbolic acid, and electrolysis. Although all these plans have been employed with success in the treatment of internal piles they offer no advantages over the methods before mentioned, and are not extensively used at the present day.

**Excision of External Piles.**—The removal of external piles is readily effected. The tumour should be seized with a catch-forceps, and snipped off with a pair of scissors, curved upon the flat. At the same time any pendulous

flaps of skin in their vicinity should be excised, lest they become irritated, and constitute the basis of a fresh pile. In doing this the scissors must be made to cut in lines radiating from the anus, and too much skin must not be removed lest a strictured anus result. After the excision of external piles the hæmorrhage may readily be arrested by the application of dry iodoform wool, or a pad of lint and T-bandage; should any small artery bleed, it may be twisted or tied. The hæmorrhage attendant on this little operation is sometimes rather profuse. The small wound which results may often conveniently be closed by one or two fine silk sutures.

It may be laid down as a rule that no internal pile should ever be simply excised in the manner above described. The hæmorrhage which results is so profuse and difficult to arrest, that patients have actually lost their lives from loss of blood, even in the hands of most distinguished Surgeons.

The **Application of the Ligature** is the treatment which is most commonly employed for the removal of internal piles. The operation is thus performed: The patient, having had his bowels cleared out by a dose of castor-oil on the day preceding that fixed for the operation, should have an abundant enema of warm water administered about an hour before the Surgeon arrives; he should then be directed to sit for half an hour on a bidet, or over a pan containing hot water, bearing down at the same time, so as to cause the piles to protrude. When all is ready, he should be laid on a table on his left side, with the nates well projecting. The Surgeon commences by steadily stretching the sphincter with his two thumbs. This aids the prolapse of the piles, and is said to diminish the subsequent pain. The piles are then separately seized with ring-forceps (Fig. 828), three or four pairs of which should be at hand. Each pile is then ligatured around its base with a stout silk ligature, which should be tied as tightly as possible, so that the pile may at once be effectually strangled. Before applying the ligature the base of the

Fig. 828.—Ring Forceps.

pile should be snipped through with curved scissors where the mucous membrane joins the skin, thus leaving a deep groove for the reception of the ligature, which then constricts only the substance and mucous surface of the hæmorrhoid.

When all the tumours requiring ligature have been tied, the superficial part of each strangulated pile may be cut off with scissors, and the stump carefully touched with chloride of zinc lotion (gr. 40 to 3j), care being taken to avoid the surrounding mucous membrane. Iodoform in crystal may then be well rubbed into the raw surface. The ends of the ligatures must next be cut off close, and the strangulated mass pushed back into the bowel. If there be any external piles, these must now be cut off; for, unless this be done, they become irritated and swollen, and constitute a source of much distress. A morphia suppository is administered and the patient must now return to bed, and should keep the recumbent posture until the ligatures separate, which usually happens from the sixth to the eighth day, when an ulcerated surface will be left, which, however, speedily contracts and closes. In some cases this process may be facilitated by the application of the nitrate of silver through a speculum ani. On the sixth or seventh day after the operation the bowels may be opened with a dose of castor-oil; until then they should be kept from acting

by proper diet and small doses of opium. The pain which necessarily attends the passage of the first motion may be lessened by the use of a cocaine suppository and a small oil enema.

In the *after-treatment* of the case, care must be taken to prevent the recurrence of those causes that gave rise to the affection in the first instance. After piles have been tied, more particularly if they be seated towards the anterior part of the rectum, great irritation is frequently set up about the neck of the bladder, so that the patient experiences difficulty in passing his urine, and sometimes suffers from complete retention; a full dose of hyoscyamus and nitrous ether will sometimes relieve this, but if it fails, a catheter must be passed. In some cases, where the external piles are very large and vascular, and the patient debilitated, the ordinary rule of cutting them off may advantageously be deviated from, and a combination of the treatment by excision and ligature adopted. In such cases an incision may be made through the integuments merely, and then the piles tied in the course of the groove thus formed. By these means the pain and constitutional disturbance consequent on the inclusion of a portion of the integument in the ligature are avoided, at the same time that the risk of hæmorrhage is not incurred.

The treatment of piles by ligature is not altogether free from danger in

Fig. 829.—Smith's Clamp.

persons of broken constitution. I have more than once known death from pyæmia result in these cases. The application of chloride of zinc and iodoform as above described is all we can do to lessen this danger.

**Cautery.**—Piles may be removed with but little fear of hæmorrhage by the method introduced by H. Smith. The preparation of the patient and the preliminary dilatation of the sphincter are conducted in the same way as in the operation with the ligature. The pile is drawn down with spring-forceps and seized in a clamp (Fig. 829), which is tightened by means of a screw in the handles. The projecting part of the pile is burnt off with the blunt point of Paquelin's cautery at a dull-red heat. The clamp is then very slowly relaxed, and should any bleeding occur as it becomes loose, it is again tightened, and the cautery applied once more. The charred tissue held by the clamp may be touched with chloride of zinc (gr. 40 to 3j), and dusted with iodoform. The operation is usually followed by less pain than the ligature, and gives equally satisfactory results. The use of the cautery is especially applicable to those cases in which the piles are granular and but little pedunculated, and perhaps associated with a considerable tendency to prolapse of the mucous membrane.

**Excision of affected Mucous Membrane.**—In 1876 Whitehead of Manchester revived the abandoned operation of excision with so many modifications as to make it altogether a new proceeding. He contends that internal piles are never to be regarded as distinct localised tumours, amenable

to individual treatment, but are component parts of a diseased condition of the entire plexus of veins of the lower end of the rectum, and that to effect a permanent cure the whole of the affected mucous membrane with the diseased veins should be removed. He was led to this conclusion partly by observing the frequency of relapses after operations by the ligature or caustics. He maintains that by his method of operating, the objections to the old method of excision are done away with, as all bleeding vessels are secured during the operation, and no raw surface is left in the bowel to heal. The operation is thus performed: The patient is placed in the lithotomy position, and the sphincter is then thoroughly paralysed by digital stretching, so that the hæmorrhoids may prolapse without impediment. By the use of scissors and dissecting forceps the mucous membrane is divided at its junction with the skin round the entire circumference of the bowel, every irregularity of the skin being carefully followed, encroaching rather on the mucous membrane than on the skin. By a process of rapid dissection with a blunt instrument, such as the closed scissors, aided by successive snips where necessary, the mucous membrane and attached hæmorrhoids are separated from the sub-mucous bed on which they rested and are pulled bodily down, the hæmorrhoids being brought below the margin of the skin. During this part of the operation it is very important to keep close to the mucous membrane. The bleeding is free but is easily controlled, each vessel being seized in forceps and twisted as it is cut. The raw surface may then be carefully cleaned and dusted lightly with iodoform. The next step in the operation is to divide the mucous membrane transversely above the piles. This must be done gradually, commencing below and doing the anterior part last, and after each cut with the scissors the divided part of the mucous membrane must be attached by silk stitches to the corresponding part of the cut edge of the skin of the anus. If the whole circumference of the gut were divided at once the mucous membrane would retract, and great difficulty might be found in bringing it down again. When the complete ring of mucous membrane has been attached to the skin of the anus, a suppository of two grains of extract of belladonna is introduced, the area of the wound is again dusted with iodoform, and a piece of oiled lint applied externally with a bandage. In highly neurotic patients Whitehead keeps a bag of ice in close proximity with the rectum for the first few days. He opens the bowels by a dose of castor-oil on the fourth day, and allows the patient to sit up on the same day. Healing almost invariably takes place by first intention, and is complete by the tenth day, the patient returning to work in two weeks. Retention of urine is an occasional complication, as in all other operations in this region. Whitehead had in 1887 performed this operation in 300 cases without a single failure or a single serious complication of any kind. He knew of no case of relapse, and none of strictured anus.

**Dangers attending Operations for Piles.**—The operation for the removal of piles may be attended by three sources of danger. After excision, and even the application of the ligature, erysipelas may develop. If the objectionable practice of transfixing the pile by the needle be followed, and it be tied in two separate parts, a hæmorrhoidal vein may thus be opened, and its sides held apart by the action of the ligatures, and thus a tendency to direct pyæmic infection may be induced; and lastly, I have seen a kind of erysipelous colitis follow the operation, leading to profuse muco-purulent discharge

and high fever. I have also in one case seen pelvic cellulitis set up. But all these various secondary affections are happily of rare occurrence.

#### PROLAPSUS RECTI.

1. **Partial Prolapse**, or, as it has been called, "prolapsus ani," consists in a protrusion of the mucous membrane of the rectum through the anal orifice; the submucous tissue being also, in the majority of instances, much thickened and elongated. It occurs almost exclusively in adults.

*Causes.*—In weakly persons generally there is a natural tendency to prolapse, as the result of an increase of the slight protrusion of the mucous membrane which usually takes place during defæcation, especially if there be irritation of the intestinal mucous membrane, as in dysentery, chronic diarrhoea, &c. So, again, the habitual constipation, often occurring in persons of a relaxed habit of body, apparently proceeding from want of power in the rectum to expel its contents, and requiring constant straining at stool, predisposes to this affection. It is especially common in those who labour under stricture, stone, or any other disease about the urinary organs that requires a considerable effort to be made in expelling the contents of the bladder. In persons whose constitution has been relaxed by a long residence in India, this disease also frequently occurs. In other cases, and indeed most usually, the prolapse is associated with piles, the weight and dragging of the hæmorrhoids drawing down the mucous membrane. This is especially apt to happen when there is a general hæmorrhoidal tendency about the anus. In fact, the causes of prolapse may be summed up thus: 1. Simple relaxation of tissue, such as is met with in weakly persons; 2. Sympathetic irritation, as in chronic tenesmus, stone in the bladder, &c.; 3. A hæmorrhoidal or polypoid condition of the mucous membrane of the rectum.

Fig. 830.—Partial Prolapse of Rectum.

*Diagnosis.*—Partial prolapse consists in the protrusion of a ring of mucous membrane of a red or purplish colour, and having a somewhat turgid look, rather lobulated in shape, and varying in size from half a walnut to a small orange (Fig. 830). The mucous membrane forming this ring will be found to be continuous with that investing the sphincter, and this constitutes the mark of distinction between prolapse, and a projecting intussusception or a polypoid growth. In prolapse there is, when the protrusion is down, a dragging and smarting sensation, often attended with a good deal of spasm about the neck of the bladder. In chronic cases, the anal aperture is permanently relaxed. The folds of skin in its neighbourhood are relaxed and elongated, radiating from it as from a centre; they are commonly bluish, soft, somewhat swollen, and pendulous, and often the seat of a good deal of irritation. The protrusion at first occurs only after defæcation, and then readily goes back of itself, or is reduced by steady pressure upon it; after a time,

however, it will come down at other periods: thus it may protrude during riding, walking, or even standing, and is returned with much difficulty.

Strangulation of the prolapse may occasionally occur, if it be allowed to protrude for a considerable length of time without a proper attempt being made to push it back. It then becomes swollen and livid, with great pain and tenesmus, discharges fetid pus, and may eventually fall into a sloughy state, and thus separating, undergo a spontaneous cure.

*Treatment.*—The treatment of prolapse is palliative and curative. The *Palliative Treatment* consists in the first place in reducing the tumour when protruded. This, in ordinary circumstances, the patient does for himself; but, if it become congested, it requires the help of the Surgeon to put it back. This may occasionally be readily done by making the patient lie on his side or lean over the back of a chair; and then greasing the mass with some oil, seizing it with a soft towel, and gradually compressing it, working it back. It may be kept up by wearing a belt with a pad and elastic support. Olive-shaped pewter pessaries are occasionally employed, with the view of preventing the protrusion; but I have never seen them do any good, the sphincter being usually too relaxed to keep them up, and their pressure appearing to excite irritation. The regulation of the bowels is as important in prolapse as in piles. It is usually best done by the administration of those laxatives that have been recommended for the latter disease. It is a good plan to get the patient to have his daily motion at bed-time instead of at the usual hour in the morning.

*Curative Treatment.*—The relaxation of the mucous membrane of the rectum that essentially constitutes partial prolapse may often be obviated by astringent injections or suppositories. The best injection is that of the sulphate of iron, in the strength of from one to three grains in an ounce of water, thrown up in small quantities sufficient for the bowel to retain. At the same time the action of the bowels must be regulated by means of an electuary taken in the morning or at night.

In those causes in which the prolapse is hæmorrhoidal or polypoid, the protrusion being dragged down by the weight and strain of the pile or polypus, the same treatment must be adopted as has been recommended for the latter disease; and usually, after the ligature and removal of the pile or polypus, the prolapse will be cured. In slight cases of prolapse, in which the disease appears rather to be owing to the relaxation of the sphincter and of the tissues external to it, the muco-cutaneous integument hanging in loose folds around the anus, considerable benefit will commonly result from snipping off these pendulous flaps of skin with curved-edged scissors in a direction radiating from the anus; the cut surface that is left cicatrizes, and by its contraction braces up the part, and thus prevents its further protrusion.

When the prolapse is considerable, and the ordinary palliative treatment after a proper trial fails in effecting a cure, it will be necessary to remove the protruded mucous membrane by operation. This may be done by the application of the ligature, or by the clamp and caustery. Whitehead's operation is well suited to these cases.

Should the prolapse become strangulated, it would be necessary to try to reduce it through the sphincter by taxis; if this cannot be accomplished, free incisions may be made into it; if it be not reduced, it will slough away, and thus undergo permanent cure.

2. **Complete Prolapse or Procidentia of the Rectum** differs from the partial form in that all the coats of the bowel protrude from the anus, and not merely the mucous membrane. It is the condition which is almost invariably met with in children, and is comparatively rare and seldom extensive in adults.

The prolapse presents a smooth red surface, and projects usually for some distance from the anus. As much as six or seven inches have been known to be extruded. It has before been pointed out that intussusception commencing at the ileo-cæcal valve may reach the anus and actually project from it. In this condition the valve itself forms the apex of the protrusion. If the intussusception occur in the rectum it may still more readily project from the anus. These conditions are easily distinguished from prolapse of the rectum, for in the latter condition the mucous membrane covering the protruded gut is continuous with the skin at the margin of the anus, while in an intussusception the finger can be passed into the bowel by the side of the projecting mass. Complete prolapse of the rectum is seldom much swollen, and very rarely becomes strangulated.

The *causes* of complete prolapse of the rectum in children are numerous. It is common in connexion with dysenteric diarrhoea, especially in weakly children. The irritation of worms is one of the most frequent causes. Polypus of the rectum is an occasional cause, and is easily recognized by the protrusion of the tumour with the bowel. Stone in the bladder is most frequently accompanied in children by some protrusion of the bowel during the straining to pass water. On the other hand, an extensive prolapse may cause irritation of the bladder in a male child, and thus simulate stone.

In adults complete prolapse may occur as a persistence of the condition occurring in childhood, but more often it begins late in life, probably as the result of a general loss of tone in the part.

*Treatment.*—The large majority of cases of complete prolapse in children are cured if the cause be removed. Worms, diarrhoea, polypus of the rectum, phimosis, and stone in the bladder, if present, should receive appropriate treatment. The prolapsed bowel should in all cases be well bathed with cold water, and then reduced by gentle pressure with some oiled rag. A pad supported by a T-bandage will often aid in preventing the descent of the bowel; or the buttocks may be drawn together with a broad strip of strapping. In obstinate cases the child should be kept in the recumbent position, and the bowels allowed to act whilst it lies on the side. In many cases a course of tonics, especially iron and cod-liver oil, is beneficial.

Very rarely the administration of an anæsthetic is required before the prolapse can be reduced. Still more rarely strangulation and sloughing occur, in which case small doses of opium must be administered to relieve pain and arrest any action of the bowels, whilst the prolapse is protected and kept clean.

It is only in exceptional cases that any operative treatment is called for, and in adopting such measures it is very necessary that the Surgeon bear in mind the possibility of the peritoneum having descended, and even of small intestine being present in the pouch of peritoneum in front of the bowel.

Superficial cauterization has been employed with success, the blunt point of Paquelin's cautery being drawn in several longitudinal lines across the mucous membrane. Another method consists in excising small wedge-shaped strips from the anal margin, each strip including part of the mucous membrane.

As extreme measures which are only justifiable in very exceptional cases, especially in adults, may be mentioned excision of the prolapse, and fixation of the prolapsed bowel by abdominal section. If excision be practised it must be remembered that the peritoneum will probably be opened, and that small intestine may have prolapsed into the peritoneal pouch. The operation consists in dividing the outer and inner tubes of the prolapse in small segments at a time, and bringing together the serous coat, and the muscular and mucous coats with two separate rows of sutures. Fixation of the rectum by abdominal section has been successfully carried out by Caddy, of Calcutta, in a man aged thirty-two. An incision was made very similar to that used in inguinal colotomy, and the rectum being drawn up to the full extent, it was attached to the muscles and peritoneum of the abdominal wall by means of two silk sutures passing through the meso-rectum.

**Protrusion of an Ovarian Cyst from the Anus** occurred in a unique case recorded by Stocks of Salford. The cyst, which was the size of a cocoon, was removed by incision through the coats of the bowel, which were forced out before the tumour; and after the wound had healed, the gut was returned.

## DISEASES OF THE GENITO-URINARY ORGANS.

## CHAPTER LXV.

## SECONDARY DISEASES OF THE URINARY ORGANS ARISING FROM SURGICAL CAUSES. PYÆMIA AND SEPTICÆMIA IN URINARY DISEASES.

THE great majority of cases of stone in the bladder, stricture of the urethra, cystitis secondary to paralysis, retention from enlarged prostate, tumours of the bladder, and, in short, of every disease tending to hinder the escape of urine from the bladder, or to induce chronic inflammation of that organ, terminate, if not relieved, by giving rise to fatal disease of the kidneys. This fact alone is sufficient to make the study of the secondary affections of the kidney of the greatest importance to the Surgeon ; and the obscurity which surrounds their diagnosis, and the general futility of treatment intended for their relief, render the subject worthy of the fullest investigation.

**Morbid Conditions of the Bladder.**—If we examine a case in which death has occurred from one of the above-named diseases, we find that the mucous membrane of the bladder shows signs of both recent and old inflammation. The *recent inflammation* is indicated by the swollen and softened condition of the mucous membrane, the intense purple colour of the summits of the rugæ, and possibly by patches of ulceration, the ulcers often being covered by a thick slough closely resembling a diphtheritic membrane. The *old inflammation* is indicated by patches of dark slate-grey pigmentation in the mucous membrane, which have resulted from repeated attacks of intense congestion, in which red blood-corpuscles have become extravasated, and, after breaking up and becoming absorbed, have left their pigment behind them. The muscular wall of the bladder is found to be *hypertrophied*, or not, according to circumstances. If, in order to expel the urine, it have been called upon to make a greatly increased pressure on its contents, the hypertrophy will be very marked. If the obstruction to the flow of urine have been of a valvular nature, as is often the case in enlarged prostate, then *dilatation* of the bladder will greatly exceed the hypertrophy of the muscular walls. It may, therefore, always be supposed, when great hypertrophy with contraction of the bladder is found, that increased difficulty existed in expelling the urine, but that the increased power of the bladder proved equal to the occasion. When dilatation is found combined with hypertrophy, we must conclude that increased power was required to expel the urine, but that the increase of muscular tissue was not quite sufficient, and that the bladder suffered frequently from over-distension. When dilatation alone is found with scarcely

any hypertrophy, we know either that the bladder has been paralysed or atonic, or that the obstruction to the exit of urine was valvular in nature, so that increased force applied to the contents of the bladder could only shut the valve more closely; and over-distension, with such an amount of stretching of the neck as to render the valve incompetent, was the only means by which urine could be passed without artificial aid. This last condition is peculiar to prostatic disease, and some cases of tumour of the bladder. In all cases of great hypertrophy, the bundles of muscular fibres form ridges on the surface, giving rise to the condition known as *fasciculation*. In many cases in which great pressure has frequently existed in the bladder, either from the forcible contraction of its hypertrophied walls on the contained urine, or from simple over-distension from retention arising from a valvular obstruction in the prostate, the mucous membrane is pushed between the bundles of muscular fibres, so forming pouches called *sacculi*. These sacculi occur most frequently in the posterior part of the bladder, and, in most cases, their walls are composed merely of mucous membrane and peritoneum. Sometimes, however, a layer of muscular fibres is also found in them. These sacculi form pouches in which putrid urine accumulates and frequently gives rise to inflammation of the mucous membrane, sometimes ending in ulceration, and possibly perforation of the bladder. Much more often it gives rise to attacks of local peritonitis, and portions of intestine may thus become adherent to the bladder.

The *causes* which give rise to an increased demand for force in expulsion of the urine, and consequently to hypertrophy of the bladder, are various. The most common is perhaps obstruction in the urethra from stricture. In some cases it may arise from an irregular enlargement of the prostate in which the obstruction is not valvular in character. Villous growths and other tumours of the bladder may call for increased force, from partially obstructing the orifice of the urethra. Chronic cystitis, from the alteration it produces in the character of the urine, always causes more or less hypertrophy. Stone in the bladder causes obstruction to the flow of urine, partly mechanically, and partly by the chronic cystitis to which it usually gives rise. The thick ropy mucus of chronic cystitis undoubtedly offers very considerable obstruction to the flow of urine. All these causes, therefore, may give rise to more or less hypertrophy. There is no evidence that mere frequency of action plays any important part in the production of hypertrophy. In the few recorded cases in which there was great frequency of micturition with healthy urine in cases of calculous or tuberculous pyelitis, no mention is made of any marked hypertrophy.

There is every reason to believe that hypertrophy of the bladder plays a very important part in the production of kidney disease. In no case, as the result of obstruction to the exit of urine from the bladder, do we find the valves of the ureters incompetent. In the simple dilatation from valvular obstruction in the prostate, they are closed more firmly than natural. No regurgitation takes place, but of course the pressure in the ureters and kidneys will be increased, while the bladder is over-distended. In hypertrophy of the walls, we find also a certain amount of obstruction to the entrance of urine into the bladder, as the ureter has to pass obliquely through the thickened wall, and is doubtless often pressed on by thickened bands of fibres. The swelling of the mucous membrane at the orifice of the ureter in an inflamed

bladder probably adds to this obstruction. Here then, although there may be no over-distension of the bladder, there is increased pressure in the ureters and kidneys, the force of secretion remaining unaltered while obstruction to the onward flow is offered by the narrowed orifices of the ureters. The degree of obstruction offered by a hypertrophied bladder varies much, as it is not uncommon to find considerable thickening of the wall of the bladder without any marked signs of pressure in the ureters or kidneys. In cases of villous tumour of the bladder, one ureter and kidney only may be found to be affected, and it will then be seen that the growth implicates the orifice of that ureter. In others, both sides may be equally affected, and both orifices healthy, but it will then be found that the growth has obstructed the neck of the bladder, and that the signs of pressure in the ureters and kidneys are due to hypertrophy or over-distension of the bladder.

#### **Diseased Conditions of the Ureters and Pelvis of the Kidney.—**

In such cases as we have been considering, three chief forms are met with : 1. The results of simple over-distension without acute inflammation ; 2. Acute inflammation without signs of over-distension ; 3. A combination of the two. Simple chronic over-distension leads to dilatation of the ureter and pelvis of the kidney, with some thickening of their walls. The thickening is in part due to hypertrophy of the muscular coat of the ureter, and in part to fibroid overgrowth of the submucous tissue. The mucous membrane is of an opaque white colour, and free from pigmentation or ulceration. At the same time that the ureter becomes dilated, it is often increased somewhat in length, and is more or less tortuous, and not unfrequently irregular pouch-like dilatations occur. The dilatation is sometimes so great that the ureter resembles a piece of small intestine. In inflammation of the ureter and of the pelvis of the kidney, we find the mucous membrane swollen and softened, of an intense red colour, and frequently showing slate-grey patches, resulting from previous attacks, as in the bladder. Ulceration is not uncommon, and often the ulcers are coated with a tenacious slough like a diphtheritic membrane. The urine contained in such a ureter and pelvis is often ammoniacal and abominably fetid, and mixed with much pus and mucus. This is a consequence of extension of decomposition from the urine in the bladder to that in the ureter ; the severity and acuteness of the inflammation in the ureter being due to the irritation of this foul and decomposing urine. But it by no means follows, because the urine in the bladder is decomposing, that the same condition extends up the ureter. In the great majority of cases, the extension of decomposition to the pelvis occurs late in the disease, and acts as the final cause of death, by exciting acute inflammation in the kidney. This extension does not take place on account of any incompetence of the valves or regurgitation of urine, as, on testing the valves in such cases they will be found to be competent. It probably creeps through the orifice of the ureter, by means of the tenacious mucus secreted from the pelvis and ureter, irritated by over-distension. This adheres to the mucous surface and forms a stagnant layer in which decomposition may extend upwards. If after washing out a bladder with an antiseptic fluid, the first urine that enters from the ureters and flows from the catheter be ammoniacal, the condition of the patient is always serious, as the decomposition has spread from the bladder to the pelvis of the kidney, where no local means can reach it.

**Morbid Conditions of the Kidney.**—The conditions found in the kidney

itself vary considerably. They may be divided as follows: 1. Changes resulting from pressure by obstruction to the entrance of urine into the bladder; 2. Acute interstitial inflammation; 3. Acute interstitial inflammation with scattered abscesses; 4. The results of former acute or subacute attacks from which the patient has recovered.

**1. The Results of Pressure.**—A case once occurred at University College Hospital, which afforded an opportunity of examining the uncomplicated effects of pressure with great advantage. The ureters had been pressed upon by two enormous sacculi, which projected from the bladder immediately behind the trigone. The bladder was much dilated and hypertrophied, but the cause of this was uncertain. There were no signs of old or recent cystitis, and no instrument had been passed during life. In this case both ureters were greatly dilated, and the pelvis on each side was expanded so as to contain many ounces of fluid. The kidneys were somewhat increased in size, and before being opened felt like great thick-walled bags of fluid giving all over a distinct sense of fluctuation. On being cut open, each presented the following appearance. The capsule was tough and opaque, and separated with difficulty from the kidney substance, slightly tearing it in so doing, and leaving the surface coarse and irregular. The surface was uniformly pale, and whitish in colour. No trace of the pyramids was to be seen, but where each should have been was a deep hollow lined with a smooth membrane continuous with that lining the pelvis of the kidney. The cortex was of about normal thickness, but in some parts thinner than natural; it was somewhat tough in consistence, and presented a uniform opaque whitish tint. The whole kidney was thus converted into a great sacculated bag, composed on one side of the dilated and thickened pelvis, and on the other of the expanded cortex. There were no signs of past or present acute inflammation. On microscopic examination of a section of the cortex, the chief change noticeable was an abundant small round-celled infiltration of the intertubular tissue of the kidney. Every tubule was separated from its neighbours by rapidly growing young connective tissue, crowded with small round cells, and this, by pressing on the vessels, had given rise to the pale colour above noted. The new growth was most abundant round the Malpighian bodies, the capsules of which were greatly thickened; so much so, that in many the vessels had been strangled and obliterated. The amount of change was not uniform, the new growth being more abundant in some parts than in others. The tubules themselves showed no great signs of change. They were slightly dilated in some parts, and the epithelium looked as if flattened by pressure, but in other respects it was perfectly healthy. This case shows that uncomplicated tension from partial obstruction of the ureter gives rise to a gradual absorption of the pyramids, and to a condition of interstitial inflammation of the kidney, probably varying in severity with the degree and acuteness of the obstruction. In more extreme cases than that above described, the atrophy of the cortex becomes much more advanced, till nothing may be left but a layer of kidney substance no thicker than a shilling. It is interesting to note, that in the case above described the secretion of urine was abundant, its specific gravity was 1009, and it was free from albumen and casts. It is also evident that, if such a kidney as this were exposed to any additional source of irritation, more acute inflammation incompatible with life would readily be set up.

**2. Acute Diffuse Interstitial Inflammation.**—In this condition the

kidney is soft and swollen. The capsule is opaque, and small vessels are seen ramifying in it. It separates easily, but tears the kidney substance in so doing. The surface of the kidney is coarse and irregular. The colour of the surface is mottled, the greater part being usually of a pale yellowish tint intermixed with purple patches. Sometimes the mottling is very fine, almost granular. The venous stars always seen on the surface of the kidney are injected, and show out prominently. On section, the cortex is found to be abnormally soft, and to present the same mottled colour as the surface. Sometimes the part of the cortex corresponding to one pyramid may present a more uniformly pale appearance than that belonging to another. Small yellowish spots, looking like minute collections of pus, may be present, which are, however, on section found to be solid, though very soft. The pyramids are usually intensely injected, and contrast strongly with the paler cortex. Pale streaks can often be seen running parallel to the straight tubules. These are most frequent in those cases in which the pelvis is filled with putrid urine. The pelvis is found in some cases free from any signs of acute inflammation, though more frequently it is much affected and filled with foul urine and mucus. The appearances here described are often conjoined with the signs of pressure mentioned above, varying from mere flattening to complete destruction of the pyramids. The microscope shows that this condition is a mere exaggeration of that found as the result of simple pressure. The change is chiefly and primarily interstitial, but the small-cell growth is so abundant as in many parts to press upon and even destroy the tubules, areas being found in which nothing but crowds of small round cells can be seen. These, when large, form the small yellowish spots visible to the naked eye. It requires only an increased intensity of the inflammation and a softening of these spots to convert them into minute abscesses. As in the form of interstitial nephritis first mentioned, the cell-infiltration is most marked round the Malpighian bodies. The change is rarely uniform throughout the kidney. It varies in degree usually in every field of the microscope, and parts may be found apparently almost healthy. The epithelium throughout the kidney is usually swollen and granular, and readily washes out in preparing the specimen, but it does not choke the tubules as in acute catarrhal nephritis. In very acute cases, small round cells, similar to those outside the tubules, are seen in the lumen of the tube surrounded by epithelium. These have probably found their way in from the outside, and, if washed on by the secretion from above, would appear as pus-cells in the urine. The vessels are often seen to be gorged with blood, and occasionally minute hæmorrhages are present. It is not always easy to distinguish this form of disease by the unaided eye, as, from the pallor caused by the pressure on the vessels from the small-cell infiltration, it closely resembles the fatty kidney or some cases of catarrhal nephritis. The microscope alone can decide the question with certainty. Even in such a kidney the secretion of urine may be moderately abundant. In a case at University College Hospital, the patient excreted over 300 grains of urea on the last day of his life.

3. **Acute Interstitial Nephritis with Scattered Abscesses.**—[Suppuration of the kidney—suppurative nephritis : when accompanied by pyelitis—pyelo-nephritis (Rayer).] This is usually found in conjunction with that form of acute pyelitis in which the pelvis of the kidney is filled with putrid urine, pus, and mucus, but is by no means constantly so. In one case which was observed at University College Hospital, both kidneys were equally riddled

with abscesses, but in one the pelvis was acutely inflamed and filled with foul urine, while in the other it was free from disease, and the urine it contained was acid, and without unpleasant smell. The kidney is generally swollen and enlarged. The fat surrounding it is usually abnormally adherent to the capsule. The capsule is thick and opaque, and marked by ramiform vessels, showing clearly on the surface. It separates easily, but in so doing tears the kidney substance. The surface of the kidney presents a more or less mottled appearance. The chief tint is the same as in the diffuse form just described, and is, in fact, due to the existence of the same condition; but scattered here and there, usually in groups, are bright yellow spots, surrounded by a dark red areola, and varying in size from a pin's head to a split pea (Fig. 833). On cutting into these yellow spots, each is found to contain a drop of pus. These minute abscesses are usually grouped in areas corresponding to that part of the cortex which belongs to a single pyramid. If now a section be made of the kidney, the points of suppuration will not be found to be limited to the surface. Often they are continued down towards a pyramid, and are con-

Fig. 831.—Acute Interstitial Nephritis: Scattered Abscesses. Margin of Abscess to the right. Malpighian body in the middle. Comparatively healthy tubules with intertubular cell-infiltration, to the left.

nected with a yellow streak running parallel to the straight tubules as far as the papilla, or, if that have been partly destroyed by pressure, as far as the point at which the tubules open into the pelvis. This condition is not invariable, as sometimes the abscesses are perfectly isolated, and show no connexion whatever with the pyramidal portion of the kidney. Occasionally one or more of the abscesses may burst beneath the capsule, separating it from the kidney, and, giving rise to further suppuration, may include the whole organ in a large collection of pus. This form of kidney, which is perhaps that most frequently met with in the *post-mortem* room, is often conjoined with the signs of pressure, absorption of the pyramids, and dilatation of the pelvis. The microscope shows that in this form the appearances are essentially the same as in the last; the chief change being the accumulation of crowds of small round cells in the intertubular substance, the degree of cell-infiltration varying in almost every field of the microscope. At the point at which an abscess is forming, or at the margin of one already formed, the crowds of small round cells are seen to press upon the tubules, separating them widely, and squeezing their walls together (Fig. 831). Then the wall becomes indistinct; next only a few epithelium-cells can be recognized in the crowd of leucocytes; lastly, nothing but leucocytes can be seen, and a little nearer the centre the

intercellular substance becomes fluid, the cells float free, and pus is thus formed. The red areola is not found to be due to extravasation, although hæmorrhages may exist scattered through such a kidney. The yellow streaks in the pyramids are found to be due to a similar condition of intertubular cell-infiltration. Sometimes clots may be seen in the vessels of the pyramids. These are probably secondary to the inflammation of the parts surrounding the vessels. As in the former variety, small round cells may be found in the tubules as well as outside them. The epithelium is usually much swollen, and sometimes desquamating and choking the tubules (Fig. 832), but this is only in those areas in which the interstitial inflammation is most advanced. In others it may appear almost healthy. In the pyramidal portion of the kidney many of the large tubes are found to have lost their epithelium by desquamation. This form of kidney merges into the diffuse variety, the solid yellowish spots before mentioned representing points which, had the patient lived

Fig. 832.—Acute Interstitial Nephritis: Condition of Epithelium.

Fig. 833.—A. Group of Abscesses on Surface of Kidney. B. Vertical Section of the same.

longer, might have softened into abscesses. Klebs, many years ago, described the presence of microscopic organisms in the suppurating kidney, but the means of observation were at that time so imperfect that considerable doubt existed as to the correctness of the statement, more especially as he described a micrococcus subsequently developing a branching mycelium—a form of growth, the existence of which was, to say the least, improbable. Later observations by Koch, with improved methods of staining, have clearly demonstrated the fact that, in every case of disseminated suppuration of the kidney, colonies of micrococci similar to those found in putrid urine are scattered throughout the gland, distending and obstructing the urinary tubules. The abscesses of the kidney thus arising in acute suppurative nephritis must not be confounded with those seen in pyæmia. These are usually larger, and more distinctly wedge-shaped, and are sometimes surrounded by a zone of hæmorrhage. They are always in the cortex, and the pyramids show no signs of disease. Pyelitis is absent, but, as before stated, it may be wanting, or feebly marked in cases of genuine interstitial nephritis, secondary to affections of the bladder. Koch has, moreover, pointed out an important microscopic distinction. Micrococci are found in the pyæmic kidney as well as in the pyelo-nephritic kidney; but in

the former they are in the vessels, especially in the Malpighian loops, while in the latter they are in the tubules. Microscopic examination of a pyæmic kidney further shows an absence of the general diffused inflammation characteristic of the ordinary septic kidney.

**4. Effects of Former Attacks from which the Patient has Recovered.**—It is possible that the kidney may undergo extensive intertubular change, and yet, if the cause be removed, the inflammatory growth may be completely absorbed, and the organ regain its normal condition. More commonly, however, the new growth undergoes a development into fibrous tissue, a change corresponding exactly to that which occurs in the cicatrization of a granulating sore, and accompanied by a similar process of contraction. Thus we get an increase in the intertubular connective tissue, and at the same time a contraction and induration of the whole organ, so much so that it is sometimes reduced to less than a quarter of its normal bulk. If the pyramidal portion have undergone absorption, this is never repaired, but, as its function seems merely that of a duct, its loss is of no great moment. In a kidney of this kind we find the fat adherent to the capsule, and the capsule to the gland-tissue. It strips off with difficulty, and is thick and opaque. The surface of the kidney is irregular, granular, or perhaps even puckered by cicatrices. Scattered over the surface in most cases are numerous small cysts. These are supposed to be due to the strangulation of the tubules by the fibrous growth. The colour is usually dark and somewhat red, with numerous small dilated veins showing on the surface. On section, the cortex will be found to be greatly thinned, being sometimes not thicker than a shilling. The pyramids, unless absorbed from previous pressure, are but little altered. The whole organ is of a leathery toughness which is quite peculiar. The pelvis may be pigmented from previous inflammation. The microscope shows a great increase of the intertubular tissue which is of a dense fibroid character. The tubules vary in size; some are strangulated and compressed, others are dilated above the strangulation. Many of the Malpighian corpuscles are obliterated, leaving merely capsules containing the remains of the obliterated vessels. The capsules of all the Malpighian bodies are greatly thickened. The epithelium may be flattened by pressure, or normal. The small arteries usually show some hypertrophy of their muscular coats. Such a kidney as this may undergo a second attack of acute inflammation, and we then find a combination of the form of the contracted kidney with the colour and softness, and possibly the scattered abscesses, of the acute variety. It will be seen from the above description that this form of kidney differs in no way to the naked eye from the ordinary granular contracted, or gouty kidney. We do not, however, find the general changes associated with that disease. In a case at University College Hospital, in which this condition was well marked as the result of stricture of the urethra, there was no hypertrophy of the heart, and no change could be recognized in the walls of the small vessels in other parts.

**Causes of Interstitial Inflammation.**—The following may be stated as the causes which in varying degree take part in the production of interstitial inflammation of the kidney: 1. Tension; 2. Reflex irritation of the kidney; 3. The presence of septic matter in the pelvis and the invasion of the kidney by septic organisms. Each of these acting singly may induce serious disease, or perhaps even cause death; but we seldom see such cases. More often two causes at least are in operation.

1. **Tension.**—It has been shown before how this is induced by any obstruction to the free entrance of urine into the bladder. Every practical Surgeon is acquainted with the fact that tension is one of the most powerful irritants to which the living tissues can be exposed. In the liver, Wickham Legg and others have shown that ligature of the bile-duct causes interstitial hepatitis. In the kidney, no recorded case is to be found of suppuration occurring as the result of simple tension; but in all cases in which evidence of tension exists—that is to say, dilated ureter or pelvis of the kidney, or some source of sudden obstruction, as a more or less impacted calculus—subacute interstitial inflammation will be found. It seems almost as if the new cell-growth were a conservative change intended to strengthen the tubules to resist the increased pressure. However this may be, a kidney in this condition is in a state in which a little further irritation from any cause may hurry it on to fatal and acute inflammation.

2. **Reflex Irritation of the Kidney.**—Mechanical injuries to the neck of the bladder or posterior part of the urethra, and probably diseases of these parts in which constantly recurring irritation is present, re-act upon the kidney through the influence of the nervous system. It is needless here to attempt any explanation of the exact manner in which this takes place, as it would be merely a matter of speculation; but a few facts may be given as proof of the assertion. It is well known that cases are on record, in which death has occurred from suppression of urine following the simple introduction of a catheter, the *post-mortem* examination showing a condition of intense congestion of the kidney. Again, patients with stone in the bladder occasionally die from acute inflammation of the kidney, often accompanied by suppuration, after the operation of lithotripsy. Cases of this kind have occurred in which the cystitis was not increased by the operation, in which the decomposition of urine remained unchanged, and no altered circumstance existed, except the mechanical injury of the passage of the instrument, to account for the sudden supervention of acute nephritis. In these cases signs of chronic disease, which has been rendered acute by the additional irritation, are always present. Lastly, a few cases have been observed at University College Hospital after operations for stricture, with the view of ascertaining if any change could be found in the urine as the direct result of the operation. In three cases of Holt's dilatation, the urine was found to be free from blood, or to contain no more than could be accounted for by the operation, during the first hour or hour and a half after the operation, and then to become gradually more and more bloody for another hour or hour and a half, and after that to become gradually free from blood. In one case there was almost total suppression for the first hour and a half, followed by very bloody urine. In one case of internal urethrotomy, during the first hour the urine flowed away in great quantities, and was almost free from blood. For the next six hours it was passed in moderate quantity, and was very darkly tinged with blood. In all four cases, there was reason to believe that the blood came from the kidney. It occurred after the hæmorrhage from the wound would have ceased; it was uniformly mixed with the urine, and free from clots. These cases are of course insufficient in number for any conclusions to be drawn from them; but, as far as they go, they tend to show that, in all cases of operation on the urethra, there is a miniature representation of that intense congestion of the kidney which is found in cases of death from suppression of urine after simple

catheterism. Possibly in some cases the dilatation of the vessels is preceded by a contraction of longer or shorter duration, giving rise to the suppression noted above. In a healthy kidney such an attack of acute hyperæmia soon passes off and does no harm ; but, supposing the kidney to be already diseased, the subacute condition may readily become acute and terminate fatally. Repeated attacks of such hyperæmia, which probably result from the irritation of a stone, or passing urine through a bad stricture, would in all probability alone be sufficient to lead to a chronic interstitial change in the kidney. It is a matter of observation that fatal affections of the kidney scarcely ever result from operations performed on the penile portion of the urethra.

**3. The presence of Septic Matter in the Pelvis of the Kidney.**—This plays the most important part in producing the final acute condition which so often kills the patient. In the first place, the mere presence of so irritating a substance as ammoniacal urine in the pelvis of a kidney already diseased would certainly intensify the existing inflammation. It seems probable, however, that in many cases the septic matter thus pent up at some degree of pressure (for the thick mixture of mucus, pus, and urine cannot pass the valves of the ureter, already somewhat obstructed by the swollen mucous membrane and perhaps by a hypertrophied or distended bladder, so readily as healthy urine) becomes absorbed by the lymphatics of the kidney, and thus gives rise to a diffuse intertubular inflammation rapidly running on to suppuration. This would account for the pale streaks seen running in many cases parallel to the straight tubules in the pyramids, and expanding in the cortex. The presence of the micrococci in the tubules may also be taken as evidence that the decomposition of the urine may extend far into the kidney substance from the pelvis. Probably this condition alone is sufficient to account for many cases of acute suppurative nephritis, but it must be remembered that suppuration of the kidney does occur, occasionally, in cases in which the urine in the pelvis is free from decomposition. George Johnson suggests that the scattered abscesses may occasionally be due to rupture of the tubules and local extravasations of urine, and Goodhart has suggested the possible connexion between erysipelas and suppuration of the kidney.

The most important observations on this point are, however, those published by J. Lindsay Steven. He confirmed the statement of Ludwig that the superficial lymphatics of the kidney are continuous with those of the ureter, and these again with the lymphatics of the bladder. By forcibly injecting the ureter the coloured fluid can be made to pass into the lymphatic vessels on the surface of the kidney, and to a certain extent into the intertubular tissue of the cortex. It is easy to understand, therefore, how micro-organisms and their products can find their way from a diseased pelvis or ureter to the cortical surface of the kidney without passing up the urinary tubules, and also that in ulceration of the mucous membrane from septic cystitis a similar extension may take place from the bladder to the cortex of the kidney without the mucous membrane being seriously implicated. This explains those cases in which multiple abscesses are found in the cortex of the kidney without foul urine being present in the ureter and pelvis. Steven confirmed his views by demonstrating the micrococci in a case of septic cystitis with suppurating kidney, in the superficial lymphatics of the bladder, ureter, and in the capsule and cortex of the kidney.

**Symptoms of Kidney Disease in Surgical Affections of the Genito-**

**Urinary Organs.**—*Simple dilatation of the kidney*, although a condition seriously endangering the success of any operation on the urinary organs, gives rise to remarkably few symptoms; and it is surprising to what an extent the structure of the kidney may be damaged by chronic interstitial nephritis arising from this cause without interfering in any noticeable degree with the patient's health. It gives rise to no œdema, no marked anemia, and no alteration in the function of the skin. The most characteristic feature is probably an increase in the quantity of urine, with a diminution in the specific gravity. In a case lately in University College Hospital, the patient passed five pints of urine daily with a specific gravity of 1003 or 1004. In all cases in which it is desirable to ascertain the condition of the kidneys, the urine should be collected for the whole day, and the specific gravity taken. If the quantity be large and the specific gravity low, chronic interstitial nephritis may be suspected. The quantity of albumen is always small, and it may be absent altogether. At most, only a few hyaline casts can be found, and often no renal epithelium. The excretion of urea is usually in sufficient amount, as the quantity of urine makes up for the low specific gravity. If the primary disease give rise to much pus and mucus, or to a little blood, the difficulties of diagnosis are greatly increased, and reliance must then be placed solely on the quantity and specific gravity, and even these may prove deceptive. It is rarely possible to gain much information by feeling the kidney. There is no tenderness, and it is seldom sufficiently enlarged for the Surgeon to form any conclusion as to its condition.

*Subacute interstitial nephritis* gives rise to more evident symptoms. The patient is weak and languid, and slowly but steadily emaciates. He loses his appetite and has occasional attacks of nausea, though rarely actual vomiting. His tongue is furred and has a tendency to become dry, and occasionally there is thirst. There is no tenderness over the kidney. There may occasionally be a slight feeling of chilliness, seldom actual rigors. The temperature will be found to be slightly elevated, especially at night; and for this reason, in any doubtful case, it is essential to obtain the evening temperature, as in the morning it may fall to normal. It seldom rises above 101° F. The urine is abundant and usually of low specific gravity, but by no means always so. It is seldom possible to find casts or to judge of the amount of albumen, as this form of disease usually accompanies bladder affections, which fill the urine with pus or mucus, as chronic cystitis, stone, and stricture. At most, only a few renal epithelium cells and possibly a hyaline cast or two could be found. This condition may last for weeks or even months, the patient gradually becoming weaker and weaker, until he is carried off by some intercurrent disease, or dies of pure exhaustion. More commonly, however, an acute attack supervenes on the subacute, either spontaneously or as the result of some surgical interference, and, rapidly ending in suppuration of the kidney, terminates fatally. On the other hand, the symptoms often gradually subside, the temperature becomes normal, and the patient gains strength. The improvement usually coincides with some diminution of the local irritation at the primary seat of disease, such as results from rest in bed in a case of stone, or from the cleansing of a foul bladder. As the symptoms are somewhat indefinite, it is often difficult to say how much is due to renal mischief and how much to the primary affection: but wherever we find a dry tongue, a persistent nocturnal elevation of temperature, loss of appetite, general weakness and

emaciation, we ought to make every attempt to get rid of these symptoms before undertaking any serious surgical procedure, such as the treatment of stricture, lithotomy, or lithotrity, the irritation of which might start the smouldering inflammation into activity.

*Acute interstitial and suppurative nephritis* gives rise to much more manifest symptoms, often supervening on those just described. The attack, which is often induced by some surgical procedure, although it may commence spontaneously, begins with a severe rigor, followed by profuse sweating. The temperature may rise to 105° F. or 106° F. After the rigor it falls, but remains somewhat above normal. The rigors and sweating may be repeated more than once. The tongue rapidly becomes dry, red, and fissured, looking like a piece of broiled ham, and sordes accumulate on the teeth. There is complete loss of appetite, with rapid emaciation; nausea is almost a constant symptom, and actual vomiting is common. Diarrhœa may occur. The patient soon sinks into a heavy drowsy state, often with contracted pupils, so that the condition may closely resemble that of opium poisoning. He can be roused and answers rationally if spoken to, and in most cases complains of little pain or discomfort. The temperature now usually falls, sometimes below normal, and the skin feels cold and clammy. In this form there is usually some tenderness on pressing firmly in the region of the kidneys. As the case progresses, muttering delirium sets in, followed by more complete insensibility, but it rarely reaches a condition of absolute coma. Convulsions are extremely rare. There is no œdema at any time. The urine varies much. It usually becomes more or less bloody, and in rare cases it is suppressed; much more frequently a considerable quantity is passed up to the time of death. It is usually in such a state from decomposition and the presence of pus, blood, and mucus, as to render accurate chemical and microscopical investigation impossible. Pus-cells are constantly present, but whether they come from the kidney or the bladder in any particular case cannot be ascertained, unless they are found, as in rare cases they are, in the form of pus-casts. In some anomalous cases, diarrhœa forms a very prominent symptom. In one case that occurred in University College Hospital, the stools exactly resembled those of typhoid fever, and the *post-mortem* examination, in addition to suppuration of the kidney, showed ulceration of the lower part of the small intestine.

The duration of an acute attack as above described, when terminating fatally, varies from a few days to a couple of weeks. In favourable cases, even after very marked symptoms, such as rigors, dry tongue, vomiting, and diarrhœa, the patient may slowly recover. The immediate cause of death seems to be poisoning by absorption of the septic matter from the kidney rather than uremia. Certainly the mode of death differs greatly from that of acute Bright's disease, the profound coma and convulsions being very rarely present.

The **Diagnosis** has to be made from pyæmia, peritonitis, typhoid fever, and ague. From *pyæmia* the diagnosis is somewhat difficult, the most important points being the vomiting, the absence of secondary abscesses, the drowy state into which the patient soon falls, and the fact that the temperature often remains below normal for days before death. The vomiting and extreme illness may resemble the low, diffuse, painless form of *peritonitis* sometimes seen in affections of the bladder, but the vomiting has not the pumping character of that in peritonitis, and the elevation of temperature for the first few days

is unlike that form of peritonitis in which the temperature is persistently low. Suppurating kidney can resemble *typhoid fever* only in rare cases, and the absence of spots, together with the temperature will usually serve to distinguish them. In the case above mentioned, the temperature was below normal for three weeks before death. From *ague*, the disease is diagnosed by the absence of the complete intermission after the sweating stage; but it must always be remembered that patients who have suffered from *ague* are singularly liable to attacks of fever after any operation on the urinary organs.

**Urethral Fever or Uræmic Fever.**—This term has been somewhat loosely used to signify a rigor followed by sweating, and more or less prolonged elevation of temperature, consequent on some operation on the urinary organs, or possibly arising spontaneously. It will be seen at once that this definition includes acute interstitial nephritis, as above described, and also pyæmia. When a patient has been said to have died of "urethral fever," one of these two conditions has invariably been found, although no Surgeon would intentionally include pyæmia under urethral fever. It is probable that the real nature of the affection is, at least in the great majority of cases, a disturbance of the circulation in the kidney, or some interference with its function, due to reflex irritation from the passage of the instrument, as before described in speaking of the sources of irritation to the kidney. That it is not due to absorption of urine from a wound in the urinary passages, is evident from the fact that rigors are rare after lithotomy, and are not common in extravasation of urine, and that wounds of the urethra anterior to the scrotum scarcely ever give rise to them. This view of the renal origin of "urethral fever" is supported by Malherbe, in his treatise on Uræmic Fever, as he has called it. It is difficult to obtain direct proof, but further knowledge might be gained by carefully examining hour by hour the quantity and quality of the urine secreted after any urethral or vesical operation, and at the same time accurately observing the changes in temperature, even when a rigor does not occur. Malherbe states that the temperature rises in almost every case; and in one of the four cases of stricture before mentioned the temperature rose to 100·3° F. three hours after the operation, when the urine became bloody. It fell to 99·2° F. when the blood disappeared; but three hours afterwards a little more blood showed itself, and the temperature rose to 100·3° F.

Sir Andrew Clark suggested the quaint name of "**catheter fever**," for those cases in which, shortly after the commencement of the habitual use of a catheter, obscure febrile symptoms set in gradually, terminating frequently in death. The symptoms most commonly develop about a week after habitual catheterism has been commenced, and almost invariably in those cases in which it is rendered necessary by enlargement of the prostate or atony of the bladder with partial retention of urine. With the ordinary symptoms of febrile disturbance there is a diminution of the specific gravity of the urine and in the amount of solids excreted by the kidney. There are at the same time but moderate symptoms of cystitis. The symptoms may gradually pass off, or the patient may die exhausted at the end of three or four weeks. At the *post-mortem* examination it is said that the kidneys are found perfectly healthy, and no definite organic change is present to account for death. Clark was inclined to attribute the fever to repeated disturbance of the nervous system by the passage of the instrument. Further investigations concerning this subject are needed, and it remains to be seen how many cases will be left to

be included under the name of "catheter fever" after the elimination of chronic septicæmia and pyæmia, and all cases of chronic or subacute interstitial inflammation aggravated by the reflex irritation of the passage of instruments.

The **Prognosis** in acute affections of the kidney, secondary to bladder disease, is always grave; but even the most unpromising cases may recover. Vomiting, delirium, partial insensibility, and a very dry tongue, are all bad signs. A marked diminution of the quantity, and much blood in the urine, are unfavourable symptoms.

**Treatment.**—Prevention is of course first to be aimed at. No patient should therefore be submitted to an operation on the urinary organs, except in cases of necessity, without a careful examination of the whole day's urine as to specific gravity, the presence and quantity of albumen, and the microscopic appearances. If possible, the temperature should be observed night and morning for two or three days. If any suspicion arise as to the condition of the kidneys, that operation should be selected, when practicable, which gives rise to least irritation. Soft instruments should be employed instead of metal, and a sufficient interval allowed between their use. Above all, any treatment calculated to cause cystitis, or to give rise to decomposition of the urine, should be avoided. As there can be no doubt that the causes of decomposition are often introduced into the bladder by catheters or other instruments, these should be kept scrupulously clean and be washed before and after use in carbolic lotion (1 in 40); they should be greased with carbolic acid and oil (1 to 10). If decomposition already exist in the urine, it should if possible be arrested by washing out the bladder with some antiseptic, for which purpose quinine and diluted sulphuric acid, in the proportion of gr. ij. and m. ij. to an ounce of water will be found very efficacious; or, better still, 10 grains of iodoform to 4 ounces of water, and  $\zss.$  of mucilage. If the cause of the renal mischief be stricture of the urethra or stone, some operation must of course be undertaken; but if the temperature be elevated, or there be other signs of renal disease, it should be delayed until an attempt has been made by rest and other remedies to bring the kidneys into a healthy state. If after a few days no improvement be seen, and it seem probable that the disease is kept up by the presence of the stone or stricture, further delay is useless; and, choosing the least severe and irritating procedure, the Surgeon must operate at once.

The treatment of well-marked interstitial nephritis is extremely unsatisfactory. If there be any tenderness in the loins, dry cupping may be of service. The bowels should be well acted on by purgatives, and the skin by hot-air baths, to relieve the kidneys as much as possible. Heroic operations undertaken during acute nephritis in the hope of removing the cause, are almost always, if not invariably, fatal. Quinine and opium have been recommended for the prevention of the rigors that frequently follow catheterism or other operations on the urinary organs. Opium is probably of service, but must be given with great caution if any symptoms of uræmic poisoning exist; but quinine has not, according to most who have tried it, proved of any use. A pure milk diet will usually be found the best in all cases if the patient can take it; stimulation must be regulated on general principles.

**Pyæmia and Septicæmia in Diseases of the Urinary Organs.**—These conditions are not uncommonly the cause of death after operations

on the urinary passages. Their general symptoms and pathology have already been fully described; but a few words on the peculiarities they manifest when secondary to affections of the urinary organs may not be out of place here.

Pyæmia may assume the ordinary rapid course of embolic pyæmia, with secondary abscesses in the viscera; but this is not of very frequent occurrence. Should it occur, softening thrombi will usually be found in the prostatic plexus or in the vesical branches of the internal iliac vein. More commonly visceral abscesses are wanting, the secondary seats of suppuration being most frequently the joints and subcutaneous tissue. In such cases the prognosis, though bad, is not hopeless, as the disease may assume a chronic form, and the patient may recover after long suffering, possibly, with one or more joints stiffened.

Septicæmia may appear under the forms of septic poisoning and septic infection. Poisoning from the absorption of the chemical products of putrefaction is probably the immediate cause of death in many of those cases in which the bladder, ureters, and pelves of the kidneys are filled with foul decomposing urine and mucus. The symptoms present nothing peculiar. Septic infection may be assumed to be the cause of death in those cases in which there is febrile disturbance of varying severity, preceded or not by a rigor, and ending in death from exhaustion in a period of from a few days to a fortnight or three weeks, and in which at the *post-mortem* examination a definite source of infection can be found, without the presence of such an accumulation of putrid matter in the urinary tract as to render mere septic poisoning probable, and without evident fatal disease of the kidney. Such cases are not uncommonly met with, especially after operations on the urethra, and less frequently after those affecting the bladder. In one case in University College Hospital the source of infection was a slight injury from the point of a catheter to a prominent ridge of a fasciculated bladder. In these cases the wound is found to be covered with an adherent grey layer, closely resembling the false membrane of diphtheria. A section carried through this, and the parts beneath, shows that the membranous layer is composed of a coagulated fibrinous exudation, everywhere crowded with micrococci. The submucous tissue and the parts beyond, show the ordinary appearances of inflammation, and in many cases the micrococci can be recognized invading the affected tissues. In some cases further investigation shows the nearest lymphatic glands to be swollen, and micrococci may be found forming colonies in their substance. Under these circumstances there is strong reason to believe that the diseased spot has been the source of the mischief, and that some infective material has found admission from it, and by infecting the whole system has been the cause of death. The relation of these cases to the chronic form of pyæmia is very close; possibly, the two conditions are identical, the presence or absence of secondary abscesses being merely an accidental variation. The chief peculiarity of the condition is that, although there seems good evidence of a general infective process, it tends to run a somewhat chronic course, sometimes lasting for weeks before terminating fatally, and, probably, in many cases ending in recovery.

## CHAPTER LXVI.

## DISEASES OF THE KIDNEY.

UNTIL within recent years, although some doubtful cases of removal of renal calculi by operation had been recorded, but few affections of the kidney were considered within the reach of surgical interference. Renal abscesses, when distinctly pointing in the loin were opened, and calculi had in exceptional cases been discharged from the opening then made; but until Simon of Heidelberg, in 1869, successfully removed the kidney, no definite operations were systematically undertaken on that organ.

At the present time the following distinct operations are performed on the kidney:—1. Aspiration. 2. Nephrotomy, or incision of the kidney. 3. Nephro-lithotomy, or removal of a stone from an otherwise healthy kidney. 4. Nephrectomy, or complete removal of the kidney. 5. Nephrorrhaphy, or fixing a movable kidney in the loin.

The various morbid conditions of the kidney for which operative interference is required are fully described in works on Medicine. A brief description only will be given of them here, having reference especially to such points as concern the diagnosis of the diseases and influence the Surgeon in his decision regarding the advisability of undertaking operations for their relief.

## STONE IN THE KIDNEY.

Deposits of uric acid and oxalate of lime frequently take place in the kidney. In the great majority of cases the calculous matter passes down into the bladder, either in fine particles, when it is commonly spoken of as *gravel*, or in larger masses, when it is termed a *renal calculus*. In many cases, however, the stone remains in the kidney, and may occasion various changes in the organ. Sometimes the calculus occupies one of the calyces and may lie firmly encapsuled in the kidney substance, which in every other respect appears perfectly normal. In other cases a large branched calculus occupying the pelvis and calyces is firmly embraced by the remains of the kidney substance, which is atrophied and indurated as the result of chronic inflammation. A common effect of the lodgment of a calculus in the kidney, especially if it be movable in the pelvis, is the production of **Calculous pyelitis**, with a gradually increasing formation of pus which escapes by the ureter. Before long, the ureter, partly obstructed by the stone, becomes insufficient to drain away the secretion of the kidney, or the pus which is constantly discharged by the inflamed pelvis, and **Hydronephrosis** (p. 1017), or **Pyonephrosis** (p. 1017), is the result. The kidney gradually becomes enlarged, and the swelling assumes the ordinary form of a renal tumour, subsequently to be described. The pelvis becomes dilated, the calyces enlarged, the pyramids destroyed, and at last the kidney may be reduced to a multilocular sac, the walls of which are composed of the thinned cortex surrounded by the thickened

capsule and the indurated perinephritic fat (Fig. 834). Fluctuation is often distinctly perceptible. If the disease be allowed to progress unrestrained by treatment, the dilated pelvis or the thickened cortex may give way, and a **Perinephritic Abscess** form. The pus then gradually points towards the surface in the loin, but before doing so it may extend widely, from the iliac fossa to below the ribs. In other cases rupture into the colon may take place.

**Symptoms.**—The passage of a calculus along the ureter, if it be of sufficient size to offer resistance, is accompanied by the symptoms of **Renal Colic**. There is intense paroxysmal pain which shoots from the loin downwards to the groin, and usually into the spermatic cord and testicle of the same side. In many cases it radiates into the inner side of the upper part of the thigh of the same side. There is retraction of the testicle and sometimes much nausea or actual vomiting, and faintness with profuse sweating. During the attack there is irritability of the bladder, and blood is often present in the urine. Sudden relief is experienced as the stone enters the bladder. The stone may be passed by the urethra often with considerable pain and irritation. The symptoms due to the presence of a calculus in the kidney vary greatly, and stones of considerable size, which were altogether unsuspected during life, are sometimes found *post mortem*. In cases of renal calculus unaccompanied by suppuration the two most important symptoms are pain and hæmaturia. The pain is usually referred to the loin, but occasionally it radiates downwards in the line of the ureter or to the testicle, and in some cases repeated attacks of renal colic result from the entry of the calculus into the upper end of the ureter. The pain may extend to the thigh and may even be referred to the leg or to the sole of the foot. The pain is sickening in character and variable in intensity. It is in most cases distinctly aggravated by movement. In some cases walking gives most uneasiness, apparently from the movement of the muscles upon which the kidney lies. In other cases walking causes but little pain, while jolting of any kind causes intense suffering. In other cases any kind of movement is almost unbearable. In very rare instances the pain has been referred to the kidney of the opposite side. There may be acute tenderness on pressure over the affected kidney; but in this stage of the disease no enlargement is to be recognized. Frequency of micturition may or may not be present. In some cases it forms one of the most prominent symptoms, so much so that the case may be mistaken for one of disease of the bladder. The urine almost always contains a trace of blood to be recognized by the microscope, and occasional attacks of profuse hæmaturia are common, most frequently brought on by violent movement. In the early stages pus is absent,

Fig. 834.—Kidney removed for Calculous Pyelitis.  
The figures point to six separate calculi.

pus is absent, and the disease may progress to suppuration without being detected. In some cases the disease is discovered only at autopsy. In the early stages of the disease the kidney is not enlarged, and the only signs are pain and hæmaturia. In the later stages the kidney becomes enlarged, and the pain is more severe. The disease is more common in the male than in the female, and is more common in the right than in the left kidney. It is more common in the middle-aged than in the young, and is more common in those who have been exposed to cold and dampness. The disease is more common in those who have been exposed to long and arduous journeys, and in those who have been exposed to excessive exertion. The disease is more common in those who have been exposed to excessive drinking, and in those who have been exposed to excessive smoking. The disease is more common in those who have been exposed to excessive sexual indulgence, and in those who have been exposed to excessive masturbation. The disease is more common in those who have been exposed to excessive exposure to the sun, and in those who have been exposed to excessive exposure to the cold. The disease is more common in those who have been exposed to excessive exposure to the heat, and in those who have been exposed to excessive exposure to the cold. The disease is more common in those who have been exposed to excessive exposure to the sun, and in those who have been exposed to excessive exposure to the cold. The disease is more common in those who have been exposed to excessive exposure to the heat, and in those who have been exposed to excessive exposure to the cold.

or only a few corpuscles can be found. Cubical cells are said to occur similar to those forming the superficial layers of the epithelium lining the pelvis of the kidney, but these are not sufficiently definite for any conclusion to be drawn from them, as similar cells may be derived from other parts of the urinary tract.

When calculous pyelitis results, the same symptoms as above described persist, but the pain is more constant, though often less acute. There may be great frequency of micturition. The urine, which remains acid, contains a gradually increasing amount of pus, reaching sometimes to many ounces daily. If the several quantities of urine passed during the day be collected, it may be found that the pus is variable in quantity, and may even disappear for a few hours, or even days, its reappearance being accompanied by some relief of the pains in the loin. Intermittent pus in acid urine may be regarded, as Rayer pointed out, as undoubted evidence of pyelitis affecting one kidney only. The symptoms of calculous hydronephrosis and pyonephrosis will be considered later.

**Diagnosis.**—It is impossible to enter in detail into a consideration of the many different conditions which may simulate, or be simulated by the symptoms of renal calculus. That the subject is one of much importance to the Surgeon is best shown by the fact, which will again be referred to, that in a considerable number of cases operation has been undertaken for the removal of a suspected renal calculus which has been found not to exist.

Certain *abnormal conditions of the urine*, especially a high degree of acidity with an excess of uric acid or the presence of crystals of oxalate of lime, may occasion symptoms closely resembling those of renal calculus; for this reason, before undertaking an operation for the removal of a suspected renal calculus, it is generally wise to submit the patient to a course of medical treatment. Among *other affections of the kidney* which may occasion symptoms resembling those of stone are certain tumours, tuberculous disease, movable kidney, interstitial nephritis, neuralgia, and in rare instances, the effects of an injury. Most of these conditions will be considered subsequently. West and Bowlby have published cases of granular kidney in which hæmaturia was a marked symptom; the most important features of these cases are the low specific gravity of the urine and the general condition of the arterial system. Simple neuralgia of the kidney is the only explanation forthcoming of some cases of renal pain in which operation exposes an apparently healthy organ. In connexion with injury it must be remembered that a stone may in this way be displaced, and so for the first time give rise to symptoms, but apart from this, Morris suggests that a neuralgic condition may be set up by the scarring in or around the kidney due to a laceration. Many *affections of other abdominal viscera* may simulate the symptoms of renal calculus; among these may be mentioned gall-stones, ulcer of the stomach or duodenum, and typhlitis. On the other hand it must be remembered, as Godlee has shown, that repeated attacks of intestinal colic, accompanied by nausea, may be the most marked symptom of stone in the kidney. The pain of *spinal caries* may resemble that of renal calculus, and Wright of Manchester has recorded a case in which testicular pain, increased frequency of micturition and nausea were probably caused by the pressure of a small abscess upon the kidney itself. Lastly, it has already been mentioned that irritability of the bladder may be so marked a symptom that the case may be mistaken for one of *vesical disease*, especially calculus.

**Treatment.**—During the descent of a renal calculus, which always occupies many hours, and perhaps some days, the patient should have full doses of opium, drink bland diluents freely, be put into a warm hip-bath, and have hot fomentations or mustard poultices applied to the loin; the bowels should also be thoroughly emptied by enemata. Should the pain be very intense the administration of chloroform may be necessary, and whilst the patient is under the influence of the anæsthetic the abdomen may be thoroughly manipulated along the course of the ureter. It is well to bear in mind that a train of symptoms somewhat similar to that induced by the descent of the calculus may be excited by some forms of irritation or flatulent distension of the cæcum and descending colon, which will require appropriate treatment.

Should the stone fail to descend, and give rise to the train of symptoms just described, medical treatment may be of much use. An attempt may be made to dissolve the stone by the administration of doses of potash or lithia sufficient to keep the urine persistently alkaline. At the same time the diet must be strictly regulated on the principles laid down in the Chapter on Urinary Calculi. The patient must use distilled water only for drinking purposes. By this treatment the stone appears in some cases to have been dissolved sufficiently to allow of its passage by the ureter. If the patient's circumstances allow of it, several months' rest in the recumbent position may be tried, as under this treatment the calculus may become encysted and fixed in one calyx, and cease to cause trouble. If these means fail, the question arises of performing the operation to which the term "nephro-lithotomy" has been applied by H. Morris, who was the first to undertake it. This operation, which consists in the removal of a stone from an otherwise healthy kidney, must be clearly distinguished from simple incision of the kidney or "nephrotomy," undertaken in the later stages when the kidney is distended with pus or urine. It must not be assumed, however, that every case of renal calculus is one suitable for operation. The conditions justifying surgical interference are the following:—

1. The disease must have lasted sufficiently long to make it certain that there is no hope of natural cure by spontaneous expulsion.
2. The inconvenience caused must be such that it seriously interferes with the patient's enjoyment of life.
3. Medical treatment must have been fairly tried and have failed.
4. The patient must not be passing gravel habitually, as it is evident that under these conditions a fresh stone would probably form in the injured kidney, and lodge there after the operation.
5. The symptoms must be distinctly unilateral.
6. The patient must be otherwise in good health, not too old, and especially not too fat.
7. Lastly, if in spite of treatment the symptoms of pyelitis come on, especially a steadily increasing amount of pus in the urine, the operation may be undertaken in the hope of saving the kidney and of preventing the occurrence of pyonephrosis, provided that other conditions are favourable.

**Nephro-lithotomy** was first performed by Henry Morris in 1880. Three incisions have been recommended for exposing the kidney in the loin: a vertical incision immediately external to the edge of the quadratus lumborum; a long oblique; and a transverse, or nearly transverse, incision. Of these the last is preferable, as being accompanied by less hæmorrhage, and more fully exposing the kidney. It is best made slightly obliquely, commencing immediately below the free extremity of the last rib, and passing backwards to the edge of the erector spinæ. It must not be made parallel to the rib, but

slightly less obliquely, so that its posterior end is from three-quarters of an inch to an inch below the rib. This is necessary to avoid the risk of wounding the pleura, which often extends below the last rib posteriorly for from half to three-quarters of an inch. This incision may be enlarged forwards if necessary, care being taken to avoid wounding the peritoneum; but should more room be required for any purpose, it is best obtained by cutting from the first incision downwards towards the crest of the ilium, parallel to the outer border of the quadratus lumborum. The position of the patient and the early stages of the operation are the same as those of colotomy, except that the incision is placed higher up; for the anatomy of the parts cut through the reader is referred to the description of that operation (p. 921). The fat about the kidney being reached, the wound must be held forcibly open by copper spatulæ, while an assistant pushes the kidney towards the wound by pressing on the abdomen. The fat is then torn through with fingers or forceps, keeping to the back part of the wound close to the quadratus. If the fat is much indurated by chronic perinephritis, considerable difficulty may be found in exposing the capsule of the kidney, but in a case suitable for nephro-lithotomy, in which the kidney is healthy, no difficulty is found in so doing. The sense of resistance offered by the solid mass of the kidney will serve as a guide to the direction in which it is to be sought. This part of the operation is accompanied by little or no bleeding. The kidney, being exposed fully, should now be methodically punctured with a smooth round needle. A common darning-needle held in a pair of torsion-forceps answers the purpose admirably. A piece of carbolized silk may be passed through the eye and tied round the forceps to prevent the needle from accidentally slipping out. If, after a methodical examination carried out over the whole kidney, nothing is felt, the forefingers may be passed before and behind it, and the kidney pressed between them and the pelvis and upper end of the ureter examined.

Supposing a stone has not been detected by these methods, the Surgeon should proceed to incise the kidney, in order that he may explore its interior. A narrow scalpel is passed through the kidney substance at its convex border in the direction of the pelvis, and this puncture is sufficiently dilated with sinus or polypus-forceps to allow the introduction of the finger. The incision is usually followed by a profuse gush of blood, which is at first very alarming, but the pressure of a sponge for a few minutes arrests it. The pelvis is now carefully explored with the finger, and with a small bladder-sound which is passed into the different calyces and into the upper end of the ureter. Before proceeding to puncture or incise the kidney, Morris turns the organ out on to the surface of the loin, and is thus able to examine it thoroughly by sight as well as by touch.

The stone is removed through the incision by which it was detected, or if the stone was found with the needle, by passing a scalpel down to it before the needle is removed. The finger is inserted, and the stone may perhaps be hooked out by it; but if this cannot be done, a pair of forceps must be applied, guided by the finger. It is better in all cases to cut through the cortex, and not to try to open the pelvis. Wounds of the kidney substance heal readily, but those of the pelvis are apt to leave a fistula. The stone having been removed and all bleeding arrested by temporary pressure on the kidney with a sponge, the external wound may be closed by sutures, leaving an opening at its middle for a drainage-tube, which should reach the kidney

out not enter it. The urine will probably flow from the wound for some days or weeks, but in several of the recorded cases rapid healing has taken place. One of the most extraordinary is that recorded by Bennett May, in which he removed a stone weighing one ounce, and of extremely irregular form, the wound completely healing in five weeks. The dressing should be strictly antiseptic, and while the urine is escaping, it must be changed twice a day.

It has already been said that the profuse hæmorrhage which as a rule follows incision of the kidney, usually quickly ceases with pressure. In some instances, however, it has been found necessary to plug the wound with strips of gauze, or to pass a ligature deeply through the kidney substance, as suggested by Arbuthnot Lane, and thus close the part of the wound containing the bleeding vessel. Nephrectomy is a last resource. Godlee has recorded a case in which the hæmorrhage which occurred during the extraction of a large calculus, and had been arrested by plugging, recurred and proved fatal about an hour after the operation.

No better proof can be given of the difficulties attending the diagnosis of renal calculus than a consideration of the large number of cases in which the kidney has been explored for stone unsuccessfully by operators skilled in this department of Surgery. Morris has recorded no fewer than 28 cases occurring in his own practice. He classifies the conditions actually present as follows : Tuberculous pyonephritis in 2 cases ; abscess of the kidney in 5 cases ; effects of former perinephritis due to injury in 4 cases ; movable kidney in 2 cases ; abscess of prostate in 1 case ; calculus in lower end of ureter in 2 cases ; effects of former passage of a calculus in 2 cases ; disease in neighbouring organs, such as cæcum and stomach, in 2 cases ; spinal disease with perinephritic suppuration in 1 case ; undetected renal calculus in 2 cases ; no sufficient cause detected in 2 cases. Of the whole series of 28 cases there was disease in the kidney or around it in 21 ; complete recovery followed operation in 14 cases.

When the presence of a renal calculus has led to the production of hydro-nephrosis or pyonephrosis, medical treatment is useless, and early surgical interference gives the only chance of cure. The treatment consists in nephrotomy—simple incision of a kidney distended with pus or urine. The removal of a stone under these circumstances is, as Morris points out, a very different operation from nephro-lithotomy, and should certainly be distinguished by another name, otherwise great confusion must arise in our statistical records. **Nephrotomy** is performed through an incision in the same position as that employed in nephro-lithotomy, but it need not be so extensive, as no exploration of the surface of the kidney is required.

The surface of the enlarged kidney being exposed, it must be punctured with a broad-bladed scalpel, and the finger inserted at the puncture before the fluid escapes. In this way the dilated calyces are easily examined, and should a stone be present it may be removed. After the operation a large drainage-tube is inserted, reaching well into the pelvis of the kidney ; this must gradually be shortened as the cavity closes. **Nephrectomy**, or excision of the kidney, has frequently been performed with success for calculous pyonephrosis, most commonly for the cure of a fistula resulting from nephrotomy and drainage. Indeed, these simpler means so frequently fail that some Surgeons are of opinion that it is, as a rule, advisable to resort at once to nephrectomy

in cases of calculous pyonephrosis if the other conditions are favourable. The operation is described at page 1020.

**Examination of the Kidney by Abdominal Section** has been advocated by Knowsley Thornton, as applicable to the majority of cases of calculus, or other diseases of the kidney, on the following grounds: First, that by abdominal exploration we can ascertain certainly whether there is another kidney, and if it is healthy; secondly, the presence of a calculus, and its exact situation can be more accurately determined by manipulation from the peritoneal cavity than from a lumbar incision; thirdly, if it be determined to remove a stone by lumbar nephrotomy, the operation is facilitated by steadying and manipulating the kidney from within the abdomen; fourthly, if the stone happen to be lodged in the ureter, this condition can be recognized and dealt with from the abdominal incision. Lastly, he maintains that the abdominal incision in no way adds to the danger of the operation. In Thornton's own hands the combined operation has given excellent results in several cases, but most Surgeons prefer reserving it for exceptional cases. In all cases in which there is but little enlargement, both sides of the kidney can be examined from the lumbar wound, and probably a stone is not more likely to be missed when searched for in this way than when the kidney is handled from the abdomen.

**Complete Suppression of Urine** may result from the simultaneous obstruction of both ureters by calculi. It has also been known to occur after excision of one kidney from obstruction of the ureter of the remaining organ; and, in a remarkable case recorded by Godlee, complete suppression, which ended fatally, was due to obstruction by a calculus of the right ureter, with suppuration in and around the kidney, the left ureter being free and the kidney in a condition of chronic interstitial nephritis.

The symptoms of this so-called "obstructive suppression" differ in many respects, as William Roberts and others have pointed out, from those which occur in "non-obstructive suppression" due to Bright's disease and other causes, including the reflex disturbances following the passage of instruments along the urethra (Chap. LXXI.) The duration of life is usually nine to eleven days, and for about a week no serious symptoms supervene. During the last two or three days of life the most important symptoms are muscular twitchings and gradually increasing weakness; the pupils are contracted; the mind remains clear to the last, and convulsions and coma are rare; the appetite is lost and the tongue dry, but there may be no vomiting; there is often profuse sweating. Death is preceded by increasing drowsiness, and sometimes by slight delirium. Frequently a small quantity of pale urine, of low specific gravity, is passed at irregular intervals. The successful treatment of cases of obstructive suppression by operation may justly be regarded as a triumph of renal surgery.

Ralfe and Godlee have recorded the case of a woman, aged twenty-six, in whom suppression of urine followed several attacks of bilateral renal colic. Operation was undertaken after the suppression had persisted for fifty-three hours. The urethra was first dilated and the orifices of the ureters explored for stone, with a negative result. The left kidney was then exposed in the loin, and a stone removed from the ureter about two inches below the kidney. The secretion of the kidney was re-established, but the attacks of colic on the right side recurred. A month later the right kidney and ureter were explored, but only some gravel and mucus were found in the pelvis. Eleven days after-

wards a weak antiseptic solution stained with ink was injected into the drainage-tube which entered the kidney, and was found to pass along the ureter into the bladder. On the following day a small stone, presumably dislodged from the ureter by the injection, was passed *per urethram*. The patient made a perfect recovery. If no stone is detected in the pelvis of the kidney or ureter a fine cesophageal bougie may be passed downwards along the ureter in the hope of displacing a calculus which may be blocking it at a lower level. In an altogether doubtful case the suggestion of Knowsley Thornton must be taken into consideration : viz. to open the abdomen by Langenbuch's incision on the side on which the blocked ureter seems most likely to be found, and thus to explore both ureters and kidneys before proceeding to the lumbar operation.

Clement Lucas and Meyer of New York have successfully operated for the relief of obstructive suppression due to blockage of the ureter of the remaining kidney after nephrectomy. In Lucas's case nephrectomy has been performed for calculous disease. Three months later suppression occurred, and after five days' medical treatment had failed to give relief, the remaining kidney was explored from the loin, and a stone, which had acted as a ball-valve to the upper end of the ureter, removed from the pelvis. The wound healed completely, and the patient was in good health five years after the operation.

A **Calculus in the Ureter** is most commonly arrested at one of the three following positions: at a distance of about two inches below the kidney; at the brim of the pelvis; and at the vesical orifice. At the first and last of these positions the ureter is narrowed, and opposite the pelvic brim it presents a sharp curve. In several cases a stone lodged in the uppermost of these positions has been removed through the lumbar incision by which the kidney had been previously explored with a negative result. Calculi arrested at or above the vesical orifice of the ureter have been detected by vaginal or rectal examination, and have been removed by dilatation of the female urethra, by suprapubic cystotomy, or by an incision in the roof of the vagina, as successfully practised by Emmet, Cabot, and Cotterell. The diagnosis of a stone lodged in the ureter at or about the brim of the pelvis will usually depend upon the association of the ordinary symptoms of calculus with localized pain and tenderness on abdominal palpation. Twynam and Arbuthnot Lane have confirmed the diagnosis in two cases by abdominal section. In Twynam's case the pain was referred to the left side, but the stone was found in the right ureter; the abdominal wound was closed, and three weeks later the stone was removed extraperitoneally through an incision in the right iliac region similar to that employed for ligature of the common iliac artery. A similar operation has since been performed by Cotterell. In stripping up the peritoneum from the iliac fossa it must be remembered that the ureter adheres closely to the serous membrane. The use of sutures in the ureter seems to be unnecessary. In Lane's case the stone was removed transperitoneally through the exploratory incision which had been made at the outer edge of the rectus, and the incision in the ureter was closed with sutures.

#### MOVABLE KIDNEY.

Two distinct anatomical varieties of abnormal mobility of the kidney are met with : first, the *movable kidney*, properly so called, in which the kidney moves behind the peritoneum; and secondly, the *floating kidney*, the

mobility of which depends upon the presence of a more or less perfect mesonephron. Clinically the two varieties are usually indistinguishable, although the existence of a very wide range of mobility in all directions is suggestive of the floating variety. True floating kidney is rare, and probably always congenital. Movable kidney is very much more common in females than males, and the right kidney is more often affected than the left. Among the causes which are supposed to act in the production of the affection are a relaxed condition of the abdominal walls following pregnancy, rapid absorption of the perinephritic fat due to general wasting, and falls or other injuries.

**Symptoms.**—An extremely movable kidney may be discovered accidentally on abdominal examination, and be altogether unproductive of discomfort. The most common symptom is a heavy dragging pain in the loins, which is liable to exacerbations, and may be attended with nausea. The affection is not uncommon in neurotic subjects; it may be attended with gastric disturbances, and the pain is apt to be increased at the menstrual periods. Intermittent hydronephrosis is an occasional complication, and is doubtless due to twists and kinks of the ureter; the periodical disappearance of the swelling will be observed to be followed by an increased flow of urine. Hæmaturia and albuminuria have also been known to occur, apparently from transient disturbances of the circulation in the kidney. Abnormal mobility of the kidney may be associated with disease of the organ, such as calculus—a fact which must be borne in mind when prominent renal symptoms are present.

The **Diagnosis** of movable kidney is usually easy. Among the many conditions with which it has been confounded are ovarian cysts, tumours of the mesentery and omentum, and distended gall-bladder. The latter affection has not unfrequently been mistaken for movable kidney, and it is an interesting fact that the two conditions may be present together, each being possibly the result, as Morris suggests, of tight lacing.

**Treatment.**—In some cases all the symptoms due to a movable kidney are relieved by the use of a padded elastic belt, which should always be tried before other means are suggested. Operation is justified if the pain is extreme or if there are evidences of obstruction of the ureter or renal vessels. Nephrectomy has repeatedly been performed for this condition, but it is a severe measure in a disease attended with so little danger to life, and should be reserved for the exceptional cases in which the kidney is extensively diseased, or in which the operation described below has failed and the symptoms are extremely severe. Newman of Glasgow has collected 30 cases of nephrectomy for movable kidney of which 9 died. In 17 cases the excised kidney was normal. A simpler method of treatment, which consists in suturing the kidney or the perinephritic tissue to the parietes, was first adopted by Hahn of Berlin in 1881. This operation, which is known as "*nephrorrhaphy*," has since frequently been performed with considerable success.

**Nephrorrhaphy.**—The kidney is exposed by the lumbar incision described at p. 1022.

The method of fixing the kidney originally adopted consisted in suturing the perinephritic areolar tissue to the divided muscles of the abdominal wall, but a more certain result is obtained by passing two or three sutures through the kidney substance itself. Silkworm gut, silk, or kangaroo tendon

may be employed. Morris uses three sutures, which penetrate half an inch into the kidney substance, and are passed through the transversalis fascia and muscles. Some Surgeons recommend that the fibrous capsule should be reflected from that part of the surface of the kidney which will lie in contact with the abdominal wall. The incision is closed with sutures, drained, and dressed in the usual way. Keen has collected 134 cases of nephrorrhaphy with 4 deaths. In not a few instances the operation has failed to relieve the symptoms completely, although it has succeeded in fixing the kidney.

## TUBERCULOUS KIDNEY.

The pathology and symptoms of this disease are fully described in works on medicine. It will be sufficient to allude here merely to those points that have a bearing on surgery.

Tuberculous disease of the kidney is indeed of considerable interest to the Surgeon, not only because he may be called upon to perform nephrotomy or nephrectomy for this condition, but because in a considerable proportion of cases the early symptoms are referred by the patient to the lower urinary tract, and may closely simulate stone and various other vesical affections. Tubercle of the kidney may form merely a part of general tuberculosis, but in these cases the infection occurs late in the disease, and gives rise to no symptoms. Primary tuberculosis of the kidney may commence in that organ, and be limited to it for some time, or it may be merely a part of general tuberculous disease of the genito-urinary tract. When the disease begins in the kidney, it commences by the formation of a caseating centre in the cortex, or at the base of a pyramid. This softens and gradually extends until, by the destruction of the pyramid corresponding to the affected part, it reaches the pelvis, and the products of the process mixed with pus are discharged with the urine. Several such centres in various stages of softening and disintegration are usually met with in the same kidney. The mucous membrane of the pelvis then becomes affected, and the disease extends to the bladder. In some cases the disease follows the reverse course, commencing in the prostate or bladder, and extending upwards to the kidney. It frequently happens in the later stages that the ureter becomes obliterated. The disease then follows one of two courses: either the chronic suppuration continues and the remains of the kidney become distended into a huge abscess, which may finally point in the loin or burst into the gut, or the fluid parts of the pus may be absorbed and the residue form a thick putty-like mass, which may remain unchanged for months or years. The former condition must necessarily occur if any secreting substance remains undestroyed in the kidney.

The **Post-mortem Appearances** of a kidney in the advanced stages are the following:—The whole kidney is greatly enlarged, often to five or six times its natural size. The perinephritic fat is densely indurated by chronic inflammation, and intimately blended with the capsule; the capsule is thickened, but separates with moderate ease from the cortex; the cortex, if any remains, is thin and tough; the pyramids have disappeared, the pelvis and calyces are dilated, and the whole cavity is filled with a thick creamy or putty-like mass having a sour offensive smell. In less advanced cases only one or two pyramids with the corresponding part of the cortex may be affected. Two important facts with regard to this affection are: First, that in a large proportion of cases

both kidneys are implicated, though the disease is always more advanced in one than in the other ; and, secondly, that if it is at all advanced, the morbid condition extends a greater or less distance down the ureter.

The **Symptoms** may, in the early stage, be referred chiefly to the bladder : there may be great irritation and an almost constant desire to pass water, with scalding pain during the act. There is at the same time pain in the loin, usually dull and aching, and not radiating to the testicle or groin. It may be increased by movement, especially of the neighbouring muscles. When both kidneys are seriously affected, constant vomiting may form a marked feature of the case. The urine contains pus, often in considerable amount and intermittent, and the bacillus tuberculosis has been recognized in it, and the diagnosis thus established. Blood may occur, but is seldom abundant, and often completely wanting. If both kidneys are affected, the quantity of urine gradually diminishes, and the amount of solids excreted becomes less. As the disease advances, the enlarged kidney becomes clearly perceptible, presenting the ordinary signs of a renal tumour. A chronic abscess gradually forms in the loin in many cases ; general tuberculous infection takes place, and the patient dies of exhaustion.

The **Diagnosis** is often extremely difficult. It has already been mentioned that the irritability of the bladder may be so great as to be suggestive of vesical disease. The distinction between calculous and tuberculous disease may be attended with insuperable difficulties. The following points may serve to effect the diagnosis :—1. Hæmaturia is often absent in tuberculous disease, and when present is uninfluenced by rest and exercise. 2. Pus is present early, is often abundant, and more constant in amount than when due to calculous pyelitis. 3. Caseous matter may be present in the urine, and may contain the bacillus tuberculosis. 4. The frequency of micturition is, as a rule, more marked than in stone, and not relieved by rest. 5. The pain in tubercle is generally more persistent and localized than in stone, and less influenced by movement. 6. Evidence of tubercle may be present elsewhere, especially in the testes, prostate, or vesiculæ seminales. 7. Nocturnal elevation of temperature is suggestive of tubercle ; and 8. Progressive emaciation may occur, but not uncommonly the general condition of a patient with primary tuberculous disease of the kidney is good.

In the later stages the diagnosis of tuberculous pyonephrosis from calculous pyonephrosis may be attended with equal difficulty.

The **Treatment** is a matter of considerable doubt. When abscess forms, early nephrotomy and drainage give great relief, and certainly prolong life : but should nephrectomy ever be performed for this disease ? In the early stages, before the kidney is much enlarged, the diagnosis is so uncertain, even after examination by an exploratory incision, that it could scarcely ever be justifiable to remove the organ. On the other hand, Knowsley Thornton believes that in the early stages of primary renal tuberculosis incision and drainage may be followed by a cure. In the later stages, if both kidneys are affected, as happens in about 35 per cent. of all cases, nephrectomy would evidently be useless and probably fatal. The difficulty of ascertaining the condition of the opposite kidney is so great that, as a general rule, it seems inadvisable to interfere with these cases except by nephrotomy. At least it may be said that the cases in which excision of a tuberculous kidney is justifiable are comparatively few in number. (See Nephrectomy, p. 1021.)

## HYDRONEPHROSIS AND PYONEPHROSIS.

**Hydronephrosis** consists in the distension of the kidney with its secretion, more or less altered in character. The early stages have already been described as the result of increased urinary tension (p. 1006, *et seq.*); only in exceptional cases does the dilatation continue to increase till a large tumour is formed. The essential element in the causation of advanced hydronephrosis is an incomplete obstruction of the ureter; when the obstruction is complete, atrophy of the kidney occurs before much dilatation has taken place. Hydronephrosis may be due to congenital malformations of the ureter, and may be present at birth. The most frequent cause of the affection is pressure on the ureter by malignant disease in the pelvis, especially carcinoma of the uterus, whilst from a surgical point of view the most interesting cause is impaction of a calculus in the ureter. Hydronephrosis as an occasional result of movable kidney has been mentioned at p. 1014, and the traumatic form has been considered in Vol. I., p. 874. The symptoms are those of a renal tumour, fluctuating distinctly, and accompanied by little pain and no hæmaturia. Whatever the cause may be the tumour is apt to vary in size, and occasional complete disappearance of the swelling may be accompanied by an abundant flow of urine of low specific gravity. The diagnosis may be confirmed by aspiration and examination of the fluid withdrawn, which will be found to contain urea and uric acid.

*Treatment.*—Aspiration has occasionally been followed by a cure, but usually only after it has been several times repeated. The spot selected for aspiration must vary with the case, but care should be taken to avoid any risk of puncturing either the colon or the peritoneum. In all enlargements of the kidney these are carried forwards. If, therefore, the normal line of the colon—that is to say, a line drawn vertically upwards from midway between the anterior and posterior superior iliac spines—be taken, the needle is certain to pass behind the gut if there be any distinct enlargement of the kidney. If any part of the tumour be particularly prominent this may be punctured, but if it be in front of the line just mentioned a careful search for the colon by palpation and percussion should be made. Aspiration, if carefully performed with a clean instrument, is perfectly free from danger.

If aspiration fails, nephrotomy with drainage should be performed, but is frequently followed by an incurable renal fistula. Nephrectomy by the abdominal incision has been practised successfully, but probably the best treatment is antiseptic drainage and subsequent lumbar nephrectomy.

**Pyonephrosis** may result from suppuration occurring in a kidney already distended in any of the ways above mentioned. It most commonly occurs as a late stage of calculous or tuberculous pyelitis. Pyonephrosis is an occasional sequel of gonorrhœa. In a case of this kind in University College Hospital the patient was completely cured by two aspirations, nearly a pint of pus being removed on each occasion. He died some years afterwards, and the kidney was found reduced to a mere shrivelled mass of fibrous tissue.

*Treatment.*—Aspiration is of service rather as a means of diagnosis than of treatment, but has occasionally been followed by cure. Nephrotomy with drainage should be tried, and if this fails, lumbar nephrectomy may be practised in suitable cases. In opening a pyonephrosis of doubtful cause a careful search must be made for calculi in the dilated kidney and in the upper end of the ureter.

## TUMOURS OF THE KIDNEY.

**Cysts** are not uncommon in the kidney, but they seldom reach such a size as to call for surgical interference. *Simple cysts*, quite distinct from the small cysts so common in granular kidneys, are occasionally met with, and may reach a considerable size. In the affection known as *cystic kidney* the whole organ may be converted into little more than a mass of cysts, varying in size from a pea to an orange. The kidney may thus form an enormous tumour, filling a great part of the abdomen and extending down to the pelvis. The disease is not uncommonly bilateral, but one kidney is usually more affected than the other. These tumours seem to cause but little trouble beyond that arising from their size, and are often discovered only on the *post-mortem* table. *Hydatid cysts* are occasionally met with, and may be recognized by the character of the fluid drawn off by the aspirator.

The *Treatment* of simple cysts of large size and of hydatids should consist in aspiration, followed if necessary by antiseptic drainage. Cystic degeneration of the kidney is scarcely amenable to surgical treatment; tapping is useless, and nephrectomy can rarely be justifiable as the affection is so often bilateral.

**Adenomata** of small size are occasionally met with in the kidney, but they very rarely reach such dimensions as to be recognizable during life. Newman has collected three cases in which nephrectomy was performed for adenoma of the kidney by Czerny, Schönborn, and Weir.

**Papillomata** occasionally occur in the pelvis of the kidney, and may occasion more or less profuse hæmaturia. T. Jones, of Manchester, has recorded a case of this nature, in which free hæmaturia and pain in the right loin of eighteen months' duration were the chief symptoms. The kidney was incised, and a villous growth as large as the end of the thumb was removed from the pelvis with the finger and a Volkmann's spoon. Seven months later the kidney was excised on account of return of the hæmaturia; the lower part of the pelvis contained a papilloma as large as a pigeon's egg. Knowsley Thornton has recorded a case in which he excised a kidney for hydronephrosis resulting from obstruction of the upper end of the ureter by a papilloma covered by a calculous deposit.

**Sarcoma** of the kidney is met with in infancy and in adult life; in the former case the tumour may be congenital. Sarcoma occurring in young children is usually of very rapid growth, and proves fatal by secondary deposits in the lungs or elsewhere, or by the mechanical effects of the tumour. Hæmaturia is rare. Bland Sutton finds that in half the cases both kidneys are affected. The tumour has a mixed structure, being composed of round and spindle cells mixed with spaces lined with epithelium; some of the long spindle cells may exhibit transverse striation, and are regarded by some pathologists as muscle fibres.

In adults sarcoma of the kidney usually runs a less rapid course than in infants, and is attended with hæmaturia. It eventually proves fatal by exhaustion or as the result of secondary deposits.

Certain tumours of the adrenal capsule may closely resemble sarcoma of the kidney. In two cases of this nature, in which nephrectomy was performed by Thornton, there was a complete absence of hæmaturia and other urinary symptoms. The tumours consisted of spheroidal cells arranged in small

columns, and closely resembled the normal structure of the zona fasciculata of the adrenal. Similar tumours imbedded in the substance of the kidney, and probably taking origin from accessory adrenals, have also been observed.

The *treatment* of sarcoma of the kidney is necessarily limited to nephrectomy, which has been done both by the lumbar and the abdominal incisions. If the tumour exceed a moderate size the latter is the only possible method. The immediate mortality is great and the prospect of permanent cure very small. This is especially the case when the disease occurs in early life. Thus of 21 cases collected by Bland Sutton, 12 of the children died from the operation, and the other 9 were all dead before the end of a year. It must be considered doubtful whether the results so far obtained in children justify a repetition of the operation. In adults also the operation is attended with a high mortality, and rapid recurrence usually follows in cases which recover from the operation.

**Carcinoma** is not common as a primary affection of the kidney. It is usually of the encephaloid variety, and grows rapidly.

The disease occurs after middle life. The amount of pain varies, and the most important symptom is free hæmaturia, which is not uncommonly present before a tumour can be detected. In the absence of hæmaturia we are never justified in making a diagnosis of renal cancer. Nephrectomy is only justifiable when the disease is recognised early, and holds out very little hope of cure.

The **Diagnosis of Renal Tumours** is usually not accompanied by any great difficulty. In examination of a kidney, the patient must be placed on his back, with the knees drawn up and the shoulders supported. The Surgeon then places one hand in the flank with the tips of the fingers immediately outside the mass of the erector spinæ just below the last rib, and pushes firmly forwards, while with the other hand placed flat upon the abdomen outside the edge of the rectus, he presses backwards. The kidney is thus grasped between the two hands, and in this way a healthy kidney can usually be distinctly felt, and in the case of a diseased organ its size and form can be readily judged of. It is more difficult to estimate the degree of mobility in this way, as the parts to which the kidney adheres in this region are themselves movable. A tuberculous or calculous kidney which is really adherent to a mass of indurated fat can often be moved forwards and backwards for some inches. If the tumour be large, the hand must next be passed below its border to ascertain by the absence of a pedicle passing into the pelvis that it is not ovarian. When the tumour is of such size that this cannot be done, errors are very likely to occur, and numerous cases are on record in which the most accomplished Surgeons have been deceived, the nature of the case being ascertained only after opening the abdomen. The anterior border of the tumour must next be examined; all renal tumours are rounded in form, and lobulation is common. The movement during respiration must not be too much relied upon; renal tumours move less than those of the liver, but are not as a rule fixed. The outline of the tumour must next be ascertained by percussion: it will be found that all renal tumours form an angle with the costal margin, which is less than a right angle. The reverse is the case with splenic tumours, and some of those of the liver. The flank will be found to be persistently dull in any position in which the patient may be placed. The most characteristic sign is the presence of the colon crossing the tumour.

This may sometimes be recognized by manipulation, and after watching the case for a few days and examining repeatedly so as to hit upon a time when the colon contains flatus, a line of resonance will often be found passing across the dull mass of the tumour. A retroperitoneal sarcoma close to the kidney may not only closely resemble a renal tumour, but may be indistinguishable from it. In these cases the presence of a rapidly-growing soft tumour in the renal region without hæmaturia would lead to a suspicion that it did not implicate the kidney.

The presence of a renal tumour having been made out, it remains to determine its nature. When fluctuation is distinctly present it is probably either hydronephrosis, pyonephrosis, or a cystic kidney. A very soft sarcoma may, however, yield a sense of elasticity or even of fluctuation. The diagnosis is best effected by aspiration, during which the nature of the disease may be still further cleared up by the needle impinging on a calculus.

If it be pyonephrosis, the pus has usually a peculiar sickly smell, especially if it be tuberculous. In calculous pyelitis it is sometimes offensive from decomposition which has spread up from the bladder. This is far less common in tuberculous pyelitis. All renal abscesses may acquire a faecal smell when they approach very near to the colon.

The lobulated form and great size of the cystic kidney and the absence of hæmaturia would probably serve to indicate its nature. Profuse hæmaturia following the examination is suggestive of malignant disease. In some cases of large accumulations of calculi, grating has been felt during manipulation. The above, taken in connexion with the symptoms already described, will usually enable the Surgeon to determine the nature of a renal tumour with sufficient accuracy.

#### NEPHRECTOMY.

By **Nephrectomy** is meant the complete extirpation of the kidney, an operation which a few years since would have been considered as unsound in physiological principle as impracticable to surgical art. Before proceeding to the removal of the kidney, it was necessary to ascertain that a person could not only live, but that the health might be maintained, after the removal of so important an organ. That this is possible has been proved by the result of injury, by pathological research, and by physiological experiment. There are cases on record in which, in consequence of a deep stab or cut in the loin, one kidney has been wounded and forced out of the wound, whence it has been removed after ligature of its pedicle, the patient making a good recovery. Then, again, it has long been known to pathologists that a person may live with one kidney practically useless, either blocked by calculus, destroyed by suppuration, or converted into a mere sac in hydronephrosis. Simon, of Heidelberg, proved by numerous experiments on dogs that one kidney might be extirpated without danger, and that the animal enjoyed perfect health afterwards.

The ground having thus been cleared, Gustav Simon was encouraged to undertake the operation for the extirpation of one kidney. This he did in 1869, in the case of a woman who, having had the ureter cut across in the operation of ovariectomy, was left with a urinary fistula otherwise incurable. The kidney, which was healthy, was removed by a lumbar incision. The

patient made a good recovery. Seven years after the operation she was in perfect health. Since that time the operation has become an established one in surgery, and has frequently been performed.

The conditions in which nephrectomy may be undertaken have already been described. They may briefly be enumerated as follows :—

1. For calculous disease : As a primary measure, if the stone be very large or multiple, and the kidney disorganized ; if there be destructive suppuration ; or, very rarely, if severe hæmorrhage during the operation prove uncontrollable in any other way ; as a secondary operation for the cure of a fistula after nephrotomy.
2. For tuberculous disease : In rare instances in which the kidney is extensively disorganized, or for the cure of a fistula after nephrotomy ; if the patient's general condition be favourable, and there be reason to believe that the opposite kidney is healthy.
3. For pyonephrosis and hydronephrosis : Occasionally as a primary operation, but more often subsequently to nephrotomy.
4. For movable kidney : In rare instances in which nephrorrhaphy has failed, and the symptoms are very severe.
5. For tumours of the kidney : Under the conditions already considered.
6. For injuries of the kidney or ureter : In cases of prolapse of kidney through a wound of the loin, for rupture of kidney attended with hæmorrhage dangerous to life or followed by suppuration, or in cases of penetrating wound causing uncontrollable hæmorrhage or followed by fistula ; in cases of rupture of the ureter in which nephrotomy is followed by fistula, and for fistulous communications between the ureter and the uterus or vagina, due to injury during labour and during operations.

In all cases, before undertaking nephrectomy, the condition of the other kidney must, if possible, be ascertained. In one recorded case the kidney excised was the only one the patient possessed, and more than once in spite of all precautions the only working kidney has been removed. In one case in University College Hospital nephrotomy was performed and some pus let out by a free incision. The wound healed and the patient was well for three months. The symptoms then returning, nephrectomy was performed, and the patient died on the sixth day of complete suppression of urine. The other kidney was found to be completely destroyed by old tuberculous disease. This shows that we must not assume that the other kidney is sound because the patient has passed safely through nephrotomy.

The quantity of urine and the amount of urea must be examined for several days. A marked deficiency in the quantity of urine excreted, or in the solids eliminated by the kidneys, is a grave sign. The sound kidney must be examined by manipulation for enlargement or tenderness. Severe vomiting should always lead to a grave suspicion of double disease.

Various methods have been suggested for observing the character of the urine entering the bladder from each ureter. The cystoscope can hardly prove of much service in this connexion, as it merely shows the appearance and not the quality of the urine (p. 1110). Catheterization of the ureters in the female was first suggested by Simon as a means of obtaining separately the secretion of the two kidneys. It has been successfully employed, but is difficult and uncertain. In two cases of tuberculous disease of the kidney Newman catheterized the ureters ; in one the urine from the opposite kidney was practically normal and nephrectomy was successfully performed ; in the other both samples of urine contained pus and tubercle bacilli, and the proposed operation was abandoned. Various methods of compressing one ureter and collecting

the urine from the other have been devised, but have not proved of much practical value. Lewers has found it easy in the female to collect the urine from each ureter by dilating the urethra and introducing one piece of a Bryant's rectal speculum into the bladder. The speculum is held so that it covers one ureter, whilst the urine from the other collects in its hollow. Lastly, it is urged as one of the great advantages of nephrectomy by an abdominal incision that it allows the condition of the other kidney to be ascertained; but even this only serves to show whether or not marked structural changes are present, and can give no indication of its secretory power.

**Lumbar Nephrectomy.**—If the lumbar method be adopted the transverse incision, with the vertical extension carried from it to the crest of the ilium, is the best, as giving most room. The early steps of the operation are the same as in nephro-lithotomy. When the capsule is reached this must be opened in cases of calculous or tuberculous pyelitis; in other cases it should be preserved uninjured if possible. The kidney is then carefully enucleated with the fingers of one hand till it remains attached merely by its pedicle. In doing this care must be taken to keep close to the gland lest the peritoneum or colon be torn. The kidney may now be drawn forwards in the wound, and if the ureter can be isolated, this should be done and a double ligature passed round it. It may then be divided between the ligatures, its end being touched as it is cut with a solution of chloride of zinc lest septic matter pass from it into the wound. In cases of pyonephrosis it is usually impossible to separate the ureter from the rest of the pedicle. A strong carbolized silk ligature is now passed through the pedicle, and it is tied in two pieces. If this be done carefully with a blunt aneurism-needle there is no fear of puncturing the renal vein. The pedicle at this stage must not be dragged on too forcibly, first, for fear of tearing it, and secondly, lest on the right side the ligature be applied too close to the vena cava. The pedicle having been securely tied, the kidney is cut off with a pair of scissors, not too close to the ligature. All bleeding having been arrested, the ligatures are cut short and the wound is closed, a large drainage-tube being inserted and the case treated as an ordinary wound in any other part of the body by some form of antiseptic dressing. The chief dangers during the operation are hæmorrhage from the substance of the kidney in the case of a tumour, wound of the peritoneum, and wound of the colon in cases of pyonephrosis. These are avoided by keeping outside the capsule in the former case, and inside in the latter. The shock of the operation is great, and often directly fatal.

**Abdominal Nephrectomy** is performed with all the precautions already laid down as being necessary in abdominal operations (p. 819). The incision now adopted in all cases is that recommended by Langenbuch, in the *linea semilunaris*. It should commence, according to Thornton, just below the ribs, a narrow hand's breadth from the middle line, and be carried downwards for about four inches. As soon as the abdomen is opened the hand is introduced and the condition of the opposite kidney and ureter investigated.

The intestines being held aside with a flat sponge, the peritoneum external to the colon is carefully divided, all bleeding being immediately arrested by forcipressure forceps. The pedicle of the kidney is then exposed, and the vessels ligatured, either separately or in the same way as in the lumbar operations. The enucleation of the tumour can then be completed, and finally the ureter is divided between two ligatures, care being taken that while so doing none of

its contents pass into the abdominal cavity. The divided ends must immediately be disinfected with chloride of zinc (40 gr. to 3j). Thornton recommends that the cut end of the ureter be at once drawn outside the abdomen, and subsequently fixed into the wound.

All bleeding points having been ligatured a large sponge is placed in the cavity whilst the sutures are introduced in the abdominal incision. Thornton finds that drainage is unnecessary if the wound is dry, and has not been fouled by the contents of the kidney. Otherwise a tube should be inserted, and in some cases it may be advisable to introduce a second tube through an aperture in the loin, as recommended by Barwell.

The chief advantages of Langenbuch's incision over one in the middle line are that it exposes the pedicle more directly, that it enables the intestines to be readily held on one side during the operation, and that, as the kidney is reached through the outer layer of the meso-colon, there is less hæmorrhage and less interference with the vascular supply of the colon than when the inner layer is divided.

In the after-treatment of nephrectomy the patient must be covered up as warmly as possible to promote the action of the skin. Vomiting is almost always a troublesome symptom; it must be relieved by ice. Thornton finds that oxalate of cerium in fifteen-grain doses frequently repeated is sometimes useful. Opium must be avoided, as the opposite kidney often becomes congested and somewhat disturbed in its functions for a few days.

By most Surgeons the lumbar method is preferred whenever practicable, the abdominal operation being reserved for the removal of large tumours. In a large proportion of cases nephrectomy is performed for the relief of a fistula resulting from nephrotomy and drainage, and under these circumstances only the lumbar operation is available. The increased risk which results from opening the peritoneum must as a general rule be considered to outweigh the advantages derived from an examination of the opposite kidney.

The **Results of Nephrectomy** were at first very discouraging, for out of the first 12 cases in which the operation was done but 2 recovered. But increased experience in the operation, a more just appreciation of its difficulties, and, above all, the great advances in abdominal surgery generally, have during recent years turned the balance in favour of the operation, so that the recoveries now largely exceed the deaths.

Newman has collected 324 cases, of which 201 recovered and 123 died, or 35·2 per cent. The lumbar incision was adopted in 177 cases, with 54 deaths, or 30·5 per cent.; while of 138 operated on by the abdominal incision 66 died, or 47·8 per cent. The influence which the nature of the disease for which the operation was performed has upon the mortality is shown by the following details. The operation was performed for movable kidney in 30 cases with a mortality of 30·0 per cent.; for hydronephrosis in 30 cases—40 per cent.; for cystic disease in 16 cases—7·5 per cent.; for suppurative disease without calculus in 54 cases—33·3 per cent.; for suppurative disease with calculus in 61 cases—36 per cent.; for tuberculous disease in 33 cases—36·6 per cent.; for traumatic lesions in 27 cases—33 per cent.; for benign tumours in 12 cases—25 per cent.; for carcinoma in 25 cases—56 per cent.; for sarcoma in 36 cases—53·0 per cent. Of the total deaths almost exactly a third were due to shock or collapse, the mortality from this cause after the abdominal operation being 14·5 per cent., and after the lumbar, 12 per cent. The ~~rest~~

most frequent causes of death were peritonitis, septic poisoning, and suppression of urine. The mortality from these causes after abdominal nephrectomy was 13, 1·5, and 6·5 per cent. respectively ; and after lumbar nephrectomy, 1·1, 4·0, and 4·0 respectively.

Knowsley Thornton has performed nephrectomy 49 times ; in all but one the kidney was removed through an abdominal incision, and in the large majority this was made at the outer border of the rectus. The total number of deaths was 10, but if two of these, which occurred from causes not directly connected with the operation, be subtracted, we have 47 cases with 8 deaths, or a mortality of 17 per cent.

Of 23 cases of nephrectomy reported by Henry Morris in 1893, 7 died. Of 5 cases of solid tumour 2 died within twenty-four hours of the operation ; Langenbuch's method was adopted in 3 cases and the lumbar in 2. Of 6 cases of hydronephrosis all recovered from the operation ; 1 died a month later of uræmia, and the *post-mortem* examination revealed advanced hydronephrosis of the opposite kidney. Of 7 cases of calculous disease, 2 died ; one death occurred four days after the operation as the result of disorganization of the other kidney by calculous pyelitis and tuberculous disease of the lungs ; in the other case, in which a stone was impacted in the ureter, the cause of death was not explained. Of 5 cases of tuberculous disease, 3 died from defective secretion of the other kidney. Morris has since abandoned nephrectomy in the treatment of tuberculous disease unless the kidney be found absolutely destroyed. If we leave out of consideration the 5 tuberculous cases we have a total of 18 with 4 deaths ; but if the case in which the other kidney was disorganized and the lungs tuberculous be also omitted there remain 17 cases with 3 deaths, or a mortality of 17·3 per cent.

## CHAPTER LXVII.

## URINARY CALCULUS AND LITHOTOMY.

## URINARY DEPOSITS AND CALCULI.

THE urine is liable to deposit various solid matters, which when impalpable are termed **Sediments**; when in fine gritty particles, **Gravel**; and when forming a larger concrete mass, **Calculus** or **Stone**. These deposits may be the result of constitutional abnormality, and the conditions giving rise to them are then sometimes termed a **Diathesis**. Much importance was formerly ascribed to these so-called diatheses, as it was believed that there was some definite constitutional condition corresponding to each form of urinary deposit; but this view can no longer be maintained.

**Uric Acid Deposits.**—These occur in two forms: as free uric acid and as urates. Free uric acid, in the form of crystals, is never met with in healthy urine. When it forms a deposit it appears as small red grains which may be compared in general appearance to cayenne pepper. Under the microscope it

Fig. 835.—Uric Acid.

Fig. 836.—Urate of Ammonium and Amorphous Urates.

is found to be crystalline. The form of the crystals varies considerably; most commonly they appear as smooth, transparent, rhomboidal plates, mixed with which may be diamond-shaped, prismatic, or needle-shaped crystals. Occasionally they are barrel-shaped (Fig. 835). As a rule they are darkly stained with urinary pigment, and present a reddish colour, but the tint varies greatly in different cases. The crystals are readily soluble in dilute solutions of potash or soda.

Urates form the common pale yellow or reddish-yellow deposit which is so frequently observed to form as urine cools after being passed. This deposit is amorphous, and has no very definite chemical composition, consisting of uric acid, combined with sodium, potassium, and ammonium in varying proportions.

with traces of calcium and magnesium. The depth of colour is proportional to the amount of pigment in the urine.

Urate of ammonium (Fig. 836), in the form of spiked globular masses, is occasionally met with alone or mixed with amorphous urates. The amorphous urates are readily recognized clinically by their completely dissolving when the urine is warmed. Free uric acid and urates are not uncommonly found together.

Uric acid is one of the products formed in the elimination of nitrogenous material from the body. Under normal circumstances by a process of oxidation it becomes converted into urea and carbonic acid, the former being eliminated with the urine and the latter by the lungs. Such uric acid as remains unoxidised is excreted in the form of urates in such quantity as is, under normal conditions, readily soluble in the urine. The presence of an excess of uric acid is therefore due to imperfect oxidation. The deficiency of oxygen may be absolute, as when the patient is confined to close ill-ventilated rooms, and takes insufficient exercise in the open air, or when he suffers from some disease interfering with respiration, as phthisis or emphysema, or when, from the deficiency of red corpuscles, the blood is not in a state to take up the necessary quantity. In all these conditions copious deposits of urates are habitually met with. In other cases the supply of oxygen is normal in amount, but the refuse products to be oxidised are excessive. This may arise from an excessive supply of nitrogenous food, or, in fact, of food of any kind, for there seems reason to believe that the carbo-hydrates, starch, sugar, &c., and alcohol, exert a sort of preference claim on the oxygen, and if supplied in excessive quantities leave an insufficient amount for the perfect oxidation of the refuse nitrogenous substances arising from the natural waste of the body. These deposits are therefore commonly met with in individuals of a robust habit of body and florid appearance who have lived too well. Copious deposits of urates occur also in all febrile conditions which are invariably associated with an increased waste of the tissues of the body. Violent and prolonged muscular exertion may produce the same effect.

William Roberts has, however, shown that an unnatural tendency to the precipitation of uric acid in the urine is not necessarily due to its presence in excessive amount. Among the other conditions of the urine which favour the deposit of uric acid are, according to Roberts, high acidity, poverty in salines, and low pigmentation. Without considering the chemical aspect of this important subject, it is worthy of notice that Roberts suggests that the poverty in the salines of the urine by favouring the formation of free uric acid from the amorphous urates may serve to explain the greater frequency of stone among the children of the poor as compared with the children of the rich, and its special frequency among the natives of India. In both instances the diet is unusually deficient in mineral salts.

Excess of uric acid in the blood, as was clearly demonstrated by Garrod, is an essential feature of gout. In this disease deposits of uric acid, either as urates or as pure uric acid, are always met with in the urine; and the gouty deposits in joints and other structures are composed of urate of sodium.

Uric acid is frequently met with in unhealthy children of the poor and less commonly among the children of the rich, who are allowed more animal food than they can readily digest.

The mere deposit of the normal quantity of urates on the cooling of the urine, concentrated by excessive sweating, may be regarded as a natural condition.

**Uric Acid Calculi.**—The calculi containing uric acid are of two kinds : pure uric acid and the urate of ammonium. Uric acid in the form of urate concretions forms the most common variety of gravel. When a uric acid calculus is formed it is usually of regular form, oval, somewhat pressed and flattened, smooth, or slightly nodular on the surface, and of a brown or fawn colour. On section it is seen to be laminated, and to present various fissures of light brown or fawn tint. Fissures are occasionally met with in its structure, the origin of which it is difficult to explain, and in rare cases the calculus has been known to break up spontaneously into small fragments. The urate of ammonium calculus is of very rare occurrence ; it is met with chiefly in children, is composed of concentric rings, has a fine earthy appearance, and is clay-coloured. The uric acid calculus may be distinguished from the urate of ammonium by heating a fragment in solution with tartaric potash : both dissolve, but the latter evolves ammonia in the process of solution.

**The treatment of uric acid deposits** must be directed to the removal of the prime causes of this condition, viz., assimilation, defective oxygenation, and the ingestion of so large a quantity of nitrogenous food. All these may be remedied by attention to ordinary hygienic measures ; the patient must live sparingly, should avoid fermented liquors, richly red and effervescent wines, and abstain from pastry, &c. He should take plenty of outdoor exercise, keep the skin in healthy action by warm dry air or vapour bathing, and the use of horsehair gloves. The bowels also must be carefully acted upon by means of saline and other aperients, with occasional alterative use of blue pill ; to which, if the constitution be gouty, some colchicum may advantageously be added. Preferable to all medicines, perhaps, are the natural aperient saline waters of Pullna, Friedrichshall, or Carlsbad, taken in small quantities. The patient may also be directed to drink some of the natural mineral waters, as those of Vichy, Vals, or Fachingen. The Vichy waters, containing a large quantity of carbonate of sodium, with free carbonic acid gas, are extremely serviceable. If they cannot be procured, a very good substitute drink consists of a scruple of bicarbonate of potassium and five grains of citric acid dissolved in a tumbler of cold or tepid water, to which about five drops of citric acid or a tablespoonful of lemon juice may be added ; this may be taken early in the morning or in the middle of the day. The preparations of lithia are of essential service in removing uric acid gravel or in acting on the urine of urates. They may be given alone, or in combination with the citrate or carbonate of potassium. Piperazine, a powerful solvent of uric acid, may be given in five-grain doses three times a day ; or aerated mineral water containing 5 grains to the tumblerful may be used.

**Deposits of Oxalate of Lime.**—Oxalate of lime appears in two forms, as dumb-bells (Fig. 838), and as hemp-seeds. The crystals are colourless or nearly colourless. The dumb-bells sometimes become agglomerated into small rounded masses, forming the so-called hemp-seed calculi. The origin of oxalate of lime in the urine is a somewhat doubtful point. Oxalic acid is not present in the urine, and is supposed to be derived from uric acid by imperfect oxidation. It has been ascribed also to the imperfect oxidation of uric acid hydrates taken as food. Certain articles of diet, as sorrel and

Fig. 837.—Uric Acid Calculus.

rhubarb, which contain oxalates in considerable quantities, will cause their presence in the urine. It was formerly supposed to be associated with marked symptoms indicating the so-called oxalic diathesis, the patient being pale, hypochondriacal, dyspeptic, and suffering from acidity of the stomach, disturbed sleep, and loss of sexual power. Roberts, however, states that oxaluria is accompanied by no constant train of symptoms, and asserts that the presence of oxalates furnishes no definite indication for treatment. Urine containing

Fig. 838.—Crystals of Oxalate of Lime.

Fig. 839.—Very rough Oxalate of Lime Calculus.

oxalates is usually pale, abundant, and acid, and may cause some sensation of heat and pain in its passage along the urethra. It forms no definite deposit, but is usually associated with a slight excess of mucus. The crystals adhere to the side of the glass in lines corresponding to any irregularity in the glass, or to marks left by the cloth used in wiping it out. There is strong reason to

believe that in many cases the oxalic acid is produced during the early stages of decomposition after the urine has been passed.

**Oxalate of Lime Calculus.**—The oxalate of lime or mulberry calculus is usually of a dark brown or even black colour, rough, tuberculated, and sometimes almost spiculated on the surface (Fig. 839). It is very heavy and hard. It seldom reaches a great size, as the irritation it causes calls attention to it early. Oxalic calculi of small size are not unfrequently passed as gravel.

**Treatment.**—When the patient habitually passes oxalates, and especially if they appear as gravel, he must be put upon a

light and nourishing diet, especially fish, as recommended by Bird, and he should be cautioned to avoid sweets and all fermented liquors, with the exception of a moderate quantity of weak spirits and water. Tonics, particularly the mineral acids, iron, zinc, and quinine, may be given, and the residence should, if possible, be changed for a time to a warm climate. Distilled water only must be used for drinking purposes. When calculus is formed, there is, owing to its roughness, usually a good deal of pain in the region of the bladder, requiring the free administration of opiates.

Fig. 840.—Crystals of Ammonio-Magnesian Phosphate.

**Phosphatic Deposits.**—The sediments and calculi containing phosphates occur in three distinct forms : 1. Triple or Ammonio-Magnesian Phosphate ; 2. Phosphate of Lime ; and 3. Mixed Phosphates, consisting of a mixture of the preceding varieties.

1. The **Triple or Ammonio-Magnesian** phosphate is met with in all specimens of urine that are decomposing. It has no pathological significance, and is not associated with any special constitutional condition. It forms the chief part of the white crust which is deposited on all instruments tied into the bladder for any length of time, and on all stones which have given rise to severe cystitis.

2. The **Amorphous Phosphate of Lime** is deposited whenever the urine becomes alkaline, whether from the administration of alkaline drugs, from the presence of alkaline mucus in large quantities secreted from an inflamed bladder, or from the formation of carbonate of ammonium from decomposition. It very rarely forms a concretion alone. Excess of phosphates is met with in some forms of disease of the nervous system, but unless the urine be at the same time alkaline it does not form a deposit. Amorphous phosphates are very frequently passed a few hours after a meal, during the so-called "alkaline tide" in the urine, especially about eleven or twelve o'clock after a heavy late breakfast. This occurs more readily if the actual amount of phosphates be in excess. The causes of this condition are not very clear, but the alkalinity can easily be shown in many cases to be due to the presence of alkaline carbonates, the urine effervescing vigorously on the addition of any acid. It is frequently associated with late hours and overwork. The patient is often much alarmed by the appearance of the phosphates, as they usually come at the end of micturition, forming a white cloud in the stream, which he may mistake for seminal fluid. If the phosphates are very abundant, they often hang about in the urethra, and may cause severe smarting or burning pain after micturition. The condition is easily detected by examining the urine. The white heavy deposit looking almost like pus disappears immediately on the addition of a little acid.

3. **Mixed phosphates** are usually met with in all cases of disease of the bladder with ammoniacal urine, as in the cystitis following an injury to the spine, or in advanced cases of prostatic disease.

**Phosphatic Calculi.**—Pure phosphatic calculi are very rare, if we exclude those soft concretions that form in a foul bladder. They are commonly composed of mixed phosphates in varying proportions. If the proportion is about two parts of the ammonio-magnesian to one part of the phosphate of lime, it fuses readily into a bead before the blow-pipe, and hence has been called the fusible calculus. This calculus is friable, laminated, and has a chalky or earthy look. The ammonio-magnesian calculus is less common. It may be beautifully crystalline in structure. The phosphate of lime calculus is still more rare, as the amorphous phosphates seem to show but little tendency to agglomerate into a concretion. The few that have been met with are laminated, and harder than the other phosphatic stones.

The **Treatment of the deposit of phosphates** is in most cases purely local, decomposition of the urine being prevented, and the bladder kept clean by those means that will be described in the chapter on cystitis. The passage of amorphous phosphates may be treated by avoidance of overwork and late hours, and by exercise in the open air, a few days of which treatment will

usually cause a complete disappearance of the symptoms. Tonics, especially nitric acid or nitro-hydrochloric acid and tincture of nux vomica, are often of use.

**Cystine** is rarely met with in the urine. It differs from all other ingredients in containing a large quantity—about 26 per cent.—of sulphur. It is very rarely seen as a sediment in the urine; but when it occurs in this form it presents the microscopic characters seen in Fig. 841, being composed of hexagonal plates. The causes which lead to its formation are uncertain, but the tendency to it is often hereditary. Calculi containing cystine are occasionally met with. Golding Bird states that in Guy's Hospital museum there are eleven; and in the museum of University College are some good specimens. Thompson has removed a cystine calculus weighing  $2\frac{1}{4}$  ounces. Cystine in calculus has a peculiar yellowish colour, becoming green after exposure to the air, and a waxy look, quite peculiar to itself. Friction

Fig. 841.—Crystals of Cystine.

applied to its cut surface causes it to emit a smell like that of garlic.

**Xanthine, or Xanthic Oxide**, was first noticed by Marcet, and has since been observed by Langier, Langenbeck, and others. It is of extremely rare occurrence, and has been found in only four recorded instances in the form of calculous concretions. These have generally been of small size, with the exception of the one removed by Langenbeck, which weighed 388 grains. For a detailed account of the chemical characters and constituents of this substance, as well as of the other materials of which calculi are formed, I must refer to the works of G. Bird, Beale, and Ralfe.

**Carbonate of Lime** has occasionally been met with as an amorphous powder in alkaline or very faintly acid urine. Bird states that he detected carbonate of lime as forming a distinct stratum in some phosphatic calculi; and Thudichum has examined prostatic concretions consisting almost entirely of this substance—the urinary origin of which, however, he doubts. Vesical calculi composed of carbonate of lime are certainly very rarely met with.

**Chemical Examination of Calculi.**—For a complete account of the chemical examination of urinary calculi I must refer the reader to works on medical chemistry by C. H. Ralfe and others. The following rough tests may, however, be employed for the three chief varieties, the other forms being so rare that they may practically be excluded from consideration: Place a small fragment on a piece of platinum foil, and hold it in the flame of a spirit lamp. If it burns completely away, or at most leaves a scarcely appreciable residue, it is probably uric acid or urate of ammonium. If it blackens and then leaves a white residue of the same size as the original fragment, it is either oxalate or phosphate. Then place three very small fragments on three glass slides, and add by means of a glass rod a drop of dilute liquor potassæ to one, of acetic acid to another, and of dilute hydrochloric acid to the third. If it dissolves in the liquor potassæ it is either uric acid or urate of ammonium; if it dissolves in acetic acid and hydrochloric it is phosphate; if it dissolves in hydrochloric acid and not in acetic it is oxalate of lime. If it dissolves in

liquor potassæ, put a glass slip cover over it and then run in beneath a drop of acetic or hydrochloric acid ; as the acid meets the alkaline fluid a white cloud will appear ; examine this under the microscope and it will be found to be composed of diamond-shaped crystals of uric acid. As a confirmatory test for oxalate of lime, the white residue left after heating on the platinum foil may be placed on a glass slide and a drop of acid added, when it will be seen to dissolve with effervescence, oxalic acid having been broken up by the heat, and carbonate of lime remaining.

## STONE IN THE BLADDER.

**Structure of Calculi.**—Calculi, though sometimes composed throughout of the same deposit, are frequently made up of layers or strata, differing in chemical composition from one another, and these usually go by the name of *alternating calculi* (Fig. 842). Most frequently the nucleus consists of uric acid ; next in order of frequency comes the oxalate of lime ; and then the concretion of a phosphatic character throughout. It is very seldom

Fig. 842.—Section of an Alternating Calculus.

Fig. 843.—Section of Oxalate of Lime Calculus encrusted with Phosphates.

that the nucleus is absent ; but concretions have occasionally been met with in which none could be detected, or in which it was even replaced by a cavity. The nucleus is usually as nearly as possible in the centre of the calculus, and is generally nearly regular in shape ; occasionally, however, it is branched or curiously radiated ; and then the concretion generally affects a corresponding outline. Calculi containing two or three nuclei have sometimes been found, consisting probably of an equal number of concretions agglomerated together. A foreign body occasionally takes the place of a nucleus.

The body of a calculus having the uric acid nucleus is generally composed of the same substance possibly mixed with some urates ; but not unfrequently these are encrusted with deposit of phosphates. In other instances the body may be wholly composed of some of the earthy phosphates, which more rarely alternate with the oxalate of lime or the triple phosphates.

An oxalate of lime nucleus usually has a body of the same constitution ; but in some cases it is encrusted with phosphates or urates (Fig. 843). When the interior is phosphatic, the concretion is always of the same constitution.

The alterations in the composition of a calculus are due to varying conditions of the general health, and consequently of the character and constituents of the urine, and of the state of the lining membrane of the bladder. The uric acid and oxalate of lime nuclei and layers are undoubtedly due to

constitutional causes. The phosphatic laminæ, whether interposed between the uric acid or encrusting the calculus, are dependent on vesical irritation and decomposition of the urine, consequent on the presence in the bladder of the uric acid or oxalate of lime nucleus which has previously been formed.

**Origin.**—Calculi may be formed either in the kidneys or in the bladder. Those that contain nuclei of the urates or oxalates are probably renal in their origin; whilst those that have a phosphatic nucleus are usually vesical, renal nuclei of this composition being rarely met with.

All renal calculi, all those vesical calculi that have a renal origin, and some of those even that appear to be formed primarily in the bladder, have a constitutional source; they arise from a morbid state of the urine, which in its turn probably depends upon mal-assimilation, the particular form of which determines the chemical composition of the stone. Those calculi that are formed by deposit from the urine upon and around some foreign body, as a pin or straw accidentally introduced into the bladder, and some soft phosphatic concretions that appear to be the result of an unhealthy state of its mucous membrane, may be looked upon as being local in their origin.

The symptoms arising from a stone in the kidney and during its passage to the bladder have already been described (p. 1007). Though a vesical

Fig. 844. — Uric Acid Calculi matted together.

Fig. 845.—Calculi with Facets.

calculus often owes its origin to the descent of a stone from the kidney, yet frequently there is no evidence of its coming from such a source, but every appearance of its being deposited in the bladder; a nucleus being originally formed in the viscus by the aggregation of some sabulous matters, upon which fresh deposits take place, until a true calculus is formed. In some instances, vesical calculi have been found deposited upon and encrusting foreign bodies, accidentally introduced into the bladder, such as a piece of straw, a pin, bit of bougie, fragment of bone, &c.

**Number.**—The number of calculi in the bladder varies considerably: most commonly only one is encountered; but in about one-fifth or one-sixth of the cases operated upon several will be found; from two to six or eight are by no means uncommonly met with. Occasionally, several dozens have been detected; and there are instances on record in which even some hundreds of distinct and separate calculi have been found in one bladder. The most remarkable case of this kind is one in which Physick removed from a Judge in the United States upwards of a thousand calculi, varying in size from a partridge-shot to a bean, and each marked with a black spot. Several calculi may become matted together in one large concretion, as in the annexed representation of a calculus (Fig. 844) which I removed from a child four years old; it was formed of eleven distinct uric acid calculi soldered together in

this way ; besides which, three others were loose in the bladder. When two or more calculi occur they are often uniform in shape, size, and weight, one being the exact counterpart of the other. This symmetry is remarkable when the calculi are very numerous, dozens of small stones of exactly the same size, shape, and weight, being met with. One large calculus is very rarely, if ever, found associated with numerous small ones.

When there are several calculi in the bladder, the friction of one against another usually causes the opposing surfaces to become smooth, thus constituting "facets" (Fig. 845). In some cases, however, when the calculi are numerous, there are no signs of attrition. This is probably owing to the bladder being atonic, always containing urine, and thus not compressing and grinding the calculi against one another. In a patient of mine who had fifteen calculi in his bladder, all the stones were round, about the size and shape of marbles, without any facets. In other cases, again, there may be more facets on one calculus than companion calculi in the bladder. A second stone may occasion two or even three facets on the first, having rolled first to one and then to the other side of it.

**Spontaneous Fracture of a Calculus** will sometimes occur within the bladder. This has been met with only in uric acid calculi, and may happen to a stone that is single, or to one among many. Civiale suggested that the fracture might be due to the pressure of a hypertrophied bladder, and others have supposed that it might be caused by concussion of one stone against another, but neither of these theories has any evidence to support it. In the museum of University College is a calculus removed as it were in the act of disintegrating. Apparently by a process of shrinking of the older parts of the stone, fissures have formed concentrically round the nucleus, and the zones thus formed are divided transversely by other fissures. The urine has soaked into these and deposited a small quantity of soft white phosphatic matter, showing that the shrinking and fissuring had occurred before removal. The stone shows great tendency to break up into segments, and has in part done so. Where spontaneous fracture occurs great irritability of the bladder is set up. In some cases the fragments become agglomerated together by the deposit of a quantity of phosphatic matter upon and around them. In other cases, the different fragments may each form the nucleus of a fresh calculus, so that the bladder may afterwards contain numerous concretions.

**Physical Characters.**—The **Size** of calculi varies from that of a hempseed or pin's head to a concretion of immense magnitude. One of the largest with which I am acquainted is a calculus removed by the suprapubic operation by Uytterhoeven of Brussels ; it is pyriform, and measures  $19\frac{1}{2}$  inches in its longest circumference, and  $12\frac{1}{2}$  inches round at its broadest part, being  $6\frac{1}{2}$  inches long and about 4 wide. In the celebrated case of Sir W. Ogilvie, Cline attempted, but failed, to extract a calculus measuring 16 inches round one axis and 14 round the other. These enormous concretions are happily seldom met with at the present day ; the usual size of stones removed by operation being from about one to two inches in the longest diameter, somewhat narrow, and perhaps flattened.

The **Weight** of calculi varies from a few grains to several ounces ; the commonest weight is from three drachms to about one ounce, reaching occasionally from three to six ounces ; from this they may range upwards until several pounds are reached. Thus, in Cline's case the stone weighed

44 ounces. Deschamps saw one of 51 ounces, and Morand one weighing 6 lbs. : none of these admitted of removal. Thompson has successfully removed one weighing 14 ounces, and W. Rivington one weighing 23, which had to be broken up in the bladder ; whilst Milton of Cairo extracted a stone weighing nearly  $34\frac{1}{2}$  ounces by abdominal section, the patient dying two and a half months afterwards of renal disease. The largest calculi are usually composed chiefly of phosphates. Large and heavy calculi are certainly less frequently met with now than formerly, owing to operations for stone being simpler and less dreaded since the introduction of anæsthetics, and hence practised in an earlier stage of the disease.

The **Hardness** of calculi varies considerably : the oxalate of lime is the hardest ; the uric acid comes next, and is often very hard, though brittle ; the phosphatic calculi are always comparatively soft.

The **Shape** of calculi presents great variety ; most commonly, however, they have an ovoid figure. Concretions of uric acid and urate of ammonium are generally pretty regularly ovoidal, smooth, and disc-like. Those com-

Fig. 846.—Exterior of Bladder, containing an Encysted Calculus at *a* ; *b*, Ureter.

Fig. 847.—Interior of the same Bladder, showing small Orifice leading into Cyst at *a* ; *b*, Ureter.

posed of oxalate of lime are usually somewhat globular or square-shaped, and generally rough, nodulated, or spiculated upon the surface. The phosphatic calculi present often the most irregular outline ; most commonly, it is true, they are ovoid or globular, but are not unfrequently branched, as if moulded to the interior of a sacculated bladder, constricted, or of an hour-glass shape. The cystine calculi are generally tolerably oval and regular in outline.

**Position.**—Most frequently calculi lie loose in the bladder ; but occasionally they may be fixed, either by being encysted, and then lying in one of the sacculi that have already been described within the walls of the bladder (Figs. 846 and 847) ; or by being impacted in one of the ureters ; or, in other cases by being partly included in villous or malignant growths.

**Causes.**—Whenever a foreign body of any kind, as a piece of broken catheter, &c., is introduced into the bladder, it will form the nucleus of a calculus, speedily becoming encrusted by calculeous phosphatic matter. But the causes of calculi occurring spontaneously are very obscure. There can be little doubt, it is true, that the different forms of concretion are connected with the various general and local conditions that have already been described :

and we may look upon the formation of a calculus as an indication of the existence, in a greater degree of intensity than usual, of the causes which ordinarily give rise to sediments or gravel; but why, in particular cases, aggregation into a calculous mass takes place it is impossible to say.

**Age** exercises considerable influence upon the production of calculi. Stone may occur in the bladder at all periods of life, and may even, according to Stahl, be congenital. The greatest number of cases apparently occur during the first two decennial periods: thus, the statistics collected by Thompson from the chief hospitals of this country show that one-third of the entire number of cases occurred before seven years of age, and one-half before the thirteenth year is completed. Coulson collected 2,972 recorded cases of lithotomy from various sources: of these, 1,466 occurred under the age of ten, 731 from eleven to twenty, 205 from twenty-one to thirty, 264 from thirty-one to fifty, and 306 from fifty-one upwards. These statistics refer entirely to hospital practice. The later statistics published by Thompson, derived from his own practice, public and private, show somewhat different results. Thus of 949 male cases 16 were under sixteen years of age, 13 occurred between sixteen and twenty-four, 111 between twenty-five and fifty, 621 between fifty and seventy, and 188 above seventy. This apparent discrepancy arises from two causes. First, the more extensive statistics are derived from cases operated on chiefly before the days of anæsthetics, when numerous adults died unrelieved rather than face the horrors of lithotomy; whereas children had little choice in the matter. Diagnosis also was not so perfect at that time, and many small stones in old people escaped detection. Secondly, Thompson's own statistics are chiefly derived from private practice, and it is well known that the children of the rich very rarely suffer from stone. Thus of 100 hospital cases in Thompson's list, 13 were below sixteen, whilst of 849 private cases only three were below that age. The cause of this is not very certain, but some attribute it to insufficiency of milk in the diet.

**Sex** influences materially the occurrence of stone, which is far more frequent in the male than in the female, in the proportion of about twenty to one of cases requiring operation. This, however, does not represent the exact ratio; as, owing to the shortness and large size of the urethra in females, many small calculi are voided by them that would be retained in the male. In Thompson's series of 964 cases only 15 were females.

**Locality.**—It would appear that *in some parts of the world* calculus is a far more common disease than in others. It is generally more frequently met with in cold than in warm climates. The negro race is remarkably exempt from this affection. It is a singular fact that in some parts of the same country calculous disorders are of far more frequent occurrence than in others. Thus it is well known that the inhabitants of the east coast of England and Scotland are peculiarly liable to these disorders; and that in Norfolk stone occurs with especial frequency, the mortality from calculus being much higher there in proportion to the population than in any other county of England (Cadge). In America, also, it would appear that the inhabitants of certain States are peculiarly liable to this affection; and I understand that in some districts of Germany the disease may be said to be almost unknown, whilst in others it is of common occurrence. The relative frequency of the kinds of calculus also varies in different countries. H. V. Carter, who analysed and described upwards of a hundred specimens contained in the museum of

the Grant Medical College at Bombay, shows that the percentage of calculi with a uric acid or urate of ammonium nucleus is, in India, 56·30, in England, 71·79; while that of calculi with a nucleus of oxalate of lime is in India, 38·65, in England, 16·87. The calculi composed purely of oxalate of lime also greatly exceed in number those which consist entirely of uric acid or urate of ammonium. Peculiarity of race, of constitution, and of diet, with exposure to prevalent dry and cold winds, have all been assigned as reasons for these differences; but probably not on very sufficient grounds.

The **Symptoms** of stone in the bladder vary according as the calculus is free or encysted. Their intensity will depend on the size and shape of the stone, the condition of the bladder, and the constitution of the patient. Most commonly, the severity of the symptoms is in proportion to the size of the calculus. This, however, is not always the case. In a patient whom I once cut, the most intense suffering and repeated attacks of cystitis had been occasioned by a small but sharp-pointed calculus, not weighing more than a drachm; and some years ago I saw a patient in whose bladder five calculi nearly as large as chestnuts were found after death, though their presence had never been suspected during life by the different Surgeons under whose care he had been for stricture, so little distress had they occasioned. In some cases, the symptoms of stone declare themselves very suddenly; and then the Surgeon finds on examination that the patient has a calculus of some size, which must have been a long time forming without attracting attention. Rough and angular calculi necessarily give rise to more severe symptoms than smooth ones. Phosphatic calculi being deposited almost invariably as a consequence of cystitis with foul urine, are accompanied by much pain and constitutional disturbance.

The symptoms induced by stone are the result of the mechanical irritation produced by the presence of a foreign body in the bladder; they consist of Pain, Increased Frequency in Micturition, occasional Stoppage of the Urine, and Various Morbid Conditions of that Fluid.

The **Pain** in calculus is often the first symptom that attracts attention; it varies greatly in character and degree. It may be experienced not only in the region of the bladder and the perinæum, but may radiate widely in the course of the nerves of the lumbar and sacral plexuses, the patient complaining of a heavy and dragging sensation in the groins, extending down the outside or back of the thighs, and not uncommonly experienced in the soles of the feet. The penis is the seat of a good deal of uneasiness; frequently there is sharp and cutting pain at the end of the glans. This is especially noticed in children, in whom attention is often attracted to the complaint by their constantly squeezing and pulling the organ to relieve the distress they suffer in it. The pain is much increased by any movement by which the stone is jolted about in the bladder, as in driving, riding, or jumping; and is especially severe in those cases in which cystitis occurs. It is always most severe towards the termination of, or immediately after, micturition; as there is then a tendency for the calculus to roll forwards towards the neck of the bladder, where it comes into contact with and is grasped by the most sensitive part of that organ. Hence it is not infrequent, in cases of calculus in children, to find that the little patient instinctively lies upon his back or side whilst passing urine, and thus escapes much of the agony that he would otherwise suffer. In adults in whom the prostate happens to be enlarged, the calculus usually

lies in a depression behind this gland ; and hence, being prevented from being squeezed by the neck of the bladder in consequence of imperfect contraction, occasions less suffering than in other cases.

In consequence of the irritation of the stone occasioning chronic inflammation of the vesical mucous membrane, there is an **Increased Frequency of Micturition**, more by day than at night. The urine is passed in small quantities at a time, usually contains some mucus or pus, and is occasionally tinged with blood, or loaded with thick mucus ; but in many cases it remains remarkably clear. Albumen from blood or pus is commonly present, and in the later stages, when the kidney becomes affected, it may come from that source also. The presence of blood in the urine is often one of the earliest signs of stone in the bladder, and in children especially should lead to the suspicion of calculus. It may be in large quantities, and may continue for many weeks, especially in the earlier stages. The urine may then clear as the bladder becomes accustomed to the presence of the stone, and the blood may reappear only under the influence of active movement, or of any cause of increased irritation of the organ. But it is important to observe that the quantity of albumen, as shown by boiling the urine, will be very great whenever even a trace of blood is present. It very rarely happens that a stone has existed for any time without the urine becoming occasionally streaked or tinged by blood.

An occasional **Stoppage in the Flow of Urine** before the bladder is emptied owing to the stone being impelled against its neck, and thus blocking up the urethra, is a common symptom in children, but very rare in adults. On the patient lying on his back or on his side, the stream flows again, the situation of the calculus being changed.

As a result of the straining and general irritation about the genito-urinary organs, **Prolapsus of the Rectum**, accompanied by **Tenesmus**, is by no means uncommon, especially in children ; and in some cases there is very troublesome **Priapism**.

**Stone in Elderly Men** often gives rise to but feebly marked symptoms ; a fact which has been specially called attention to by Thompson. He states that partly from diminished sensibility of the bladder in elderly men, and partly from the frequency with which a moderately enlarged prostate may mask the symptoms, many a man may carry a uric acid calculus for three or four years with little or no inconvenience, so that the presence of the stone may easily be overlooked till it attains such a size as to make its removal a serious and possibly a dangerous operation. In these cases the symptoms he regards as most characteristic are slight pricking or smarting at and near the end of the penis, often but not invariably felt during and after the close of micturition, and increased frequency of micturition, less felt at night, and more manifest in the day, especially during exercise ; but if the patient lead a very quiet life this symptom may be wanting. Florid blood in small quantities may appear after more violent exercise, or jolting from any cause. The urine is acid and clear, and often deposits urates. By sounding the patient when these symptoms are present, a small stone may often be detected and removed without appreciable risk.

**Stone in Children.**—The symptoms in children present few peculiarities, except that the patient is often unable clearly to describe what he feels. **Pain** on movement is indicated by the child's disinclination to play or run about.

Screaming after micturition is common ; the irritation of the stone often leads to incontinence at night, and frequent wetting of the clothes during the day, often causing excoriation of the thighs. Constant handling of the penis, and pulling of the foreskin till it seems in some cases to be actually lengthened, are also important signs. With these, straining, with prolapse of the rectum during micturition, is usually present, and sudden stoppage of the stream during micturition is not uncommon. Whenever a child presents these symptoms, he should at once be sounded. If no stone be found, the child must be examined for worms, the irritation of which may give rise to symptoms closely resembling those of stone. A tight phimosis will also cause symptoms distinguishable from stone only by sounding.

**Encysted Calculus.**—When a stone is *encysted*, those symptoms that depend upon its being loose and rolling about in the bladder are necessarily absent : thus there is no stoppage of the urine, this fluid is seldom bloody, and the pain is not materially increased by jolts and rough movement ; though there are weight and pain in the usual situations, and increased frequency of micturition from the pressure and irritation of the calculus.

**PHYSICAL DIAGNOSIS OF STONE.**—The existence of stone is finally determined by **Sounding the Bladder.**

A **Sound** is a solid steel instrument shaped like a catheter, but shorter in the curve (Fig. 848), so that it may thoroughly explore all parts of the

Fig. 848.—Sound for Examining Bladder.

bladder, especially those behind the prostate. It should have a wide and smooth steel handle, and be slightly bulbous. Thompson prefers a hollow sound with a round handle, and a short beak bent at a sharp curve like a lithotrite. The operation of sounding is conducted as follows : The patient lies upon his back with his buttocks well raised on a pillow ; a full-sized sound, well-oiled and warmed, is then passed into the bladder, which should, if the patient can retain it, be allowed to contain three or four ounces of urine. The Surgeon then, using his left hand or crossing over to the patient's right side, whichever he finds most convenient, carefully directs the beak of the instrument towards the neck of the bladder, turning it from right to left over the whole of that region ; he next draws it forward on one side as far as the neck, tapping, as it were, gently with its beak ; he repeats the same manœuvre on the other side ; and, lastly, by raising the handle directs the end of the instrument into the lower fundus, which he carefully explores. Usually the stone is readily detected by these manœuvres, and its position in the bladder will often be dependent upon, and may to a certain extent be taken as an approximative indication of, its size. Thus, when moderately large, it will usually be found lying to one side, most generally the right, of the neck of the bladder ; when small, it will be placed towards the fundus, near the orifice of one or other ureter. These then are the situations in which the Surgeon should first seek for a stone, and in which he will generally find it when present. Should it not be met with there, the chances are,

more especially if the patient be elderly, that it will be found in a pouch behind the prostate, where it may be detected by depressing the handle and then turning the beak of the sound downwards (Fig. 849). Should the Surgeon not detect the calculus in any of these situations, he depresses the handle between the thighs, and tilts up the beak so as to examine the pubic portion

Fig. 849.—Sounding for Stone behind Prostate.

of the organ (Fig. 850). In the event of his not meeting with a stone, he may explore the bladder, first on one side, then on the other. Should the rational symptoms of stone be well marked, though no calculus be struck, the Surgeon must not give a decided opinion after one exploration. but should examine

Fig. 850.—Sounding for Stone above Neck of Bladder.

the patient again a few days later, with the bladder in a different state as to its contents. In making this second examination, I have found it of great service to use a hollow steel sound, by which the organ can be injected or emptied at pleasure (Fig. 851). The patient should on this occasion have his bladder injected through such an instrument as this, with four or six

ounces of tepid water, so as to distend the organ slightly, and prevent the folds of mucous membrane from overlapping any concretion that may exist in it. Its interior is then carefully explored in the way already described; and, if the stone cannot then be detected, the contents of the bladder are gradually allowed to escape through the sound, and the patient is desired to stand up whilst the exploration is being proceeded with. In this way, by examining a patient in different positions and in different conditions of the bladder as to capacity, a calculus is sure to be detected if one exist. A lithotrite may occasionally be used advantageously as a sound for the detection of small calculi lying behind

Fig. 351.—Hollow Sound.

the prostate, a situation more readily reached by its short beak than by an instrument of larger curve. These examinations must not, however, be too protracted. When a stone is struck by the sound, there is not only a characteristic and distinct shock communicated to the instrument, but a tolerably loud click is given, which can be heard by the bystanders, and frequently by the patient, as well as by the Surgeon.

Rough sounding is doubly injurious. It injures the bladder and fails to find the stone. The stone is often missed in sounding, especially when small,

Fig. 352.—Sounding for Encysted Calculus.

by being carried to and fro as the urine and the bladder are moved backwards and forwards by rough manipulation. It will be found, if the parts are allowed to become quiescent, that the stone falls to the bottom behind the prostate, where it will be found by a gentle tap of the sound.

By conducting the sounding properly, the Surgeon may usually ascertain not only the existence of a stone, but its size and hardness: whether it be single, if it be encysted, and the general state of the bladder; with all of which points it is of importance that he should be acquainted before undertaking

any operation. A good deal of this information may be elicited by the ordinary sound, but some of the points can be accurately determined only by sounding with the lithotrite.

The *hardness* of the stone may usually be judged of by the more or less clear ringing character of the click ; a uric acid or oxalate of lime calculus giving a sharper sound than a phosphatic concretion.

A calculus may generally be known to be *encysted* if the sound strike it at times, but not at others (Fig. 852) ; if the stone always appear to be fixed in one situation ; and if the beak of the instrument cannot be made to pass round it, so as to isolate it, but a kind of tumour projecting through the walls of the bladder is felt around or on one side of the point where the calculus is struck.

The *fasciculated, roughened, and sacculated condition of the bladder* may generally be detected by the way in which the beak of the instrument *grates* and rubs over the organ.

The *size* of the calculus is best determined by seizing it gently in a lithotrite. It is true that a Surgeon may sometimes come to a decision as to the bulk of a calculus, by observing the extent of surface along which the sound is in contact with the stone, as the instrument is being withdrawn. But only a very rough guess can be made in this way ; and I have frequently seen very experienced Surgeons deceived, mistaking perhaps several small stones lying together for one large one.

In order to determine that *several calculi* exist in the bladder, it is sometimes sufficient for the Surgeon to feel that the beak of the sound comes in contact with a stone on each side of the organ, or that it can be distinctly insinuated between two concretions. In some cases, however, these points cannot clearly be made out ; and then the Surgeon, introducing a lithotrite and seizing the first calculus with which he meets, should hold this between the blades of the instrument, and whilst it is so fixed move it and the lithotrite from side to side ; when, if a click be heard and felt, he may be sure of the existence of another stone.

Sounding is by no means free from danger, more especially if done roughly, or in patients who have chronic kidney disease. In the first case it may give rise to cystitis or profuse and continuous hæmorrhage ; in the second, to rigors and suppression of urine.

**Errors in Sounding** occasionally occur. The Surgeon may mistake a hardened and fasciculated bladder, having its ridges perhaps encrusted with phosphatic matter, for a calculus ; this is especially apt to happen in children. In these cases, however, the mistake may usually be guarded against by the absence of a distinct click, though a rough grating sensation be experienced, and by the Surgeon being unable to isolate a stone. Yet the difficulty in some cases is great ; Velpeau was acquainted with four instances, and S. Cooper with seven, in which patients had been cut and no calculus found ; and when we reflect that these accidents have happened to such men as Cheselden, who on three occasions cut a patient and found no stone, to Crosse, to Roux, and to Dupuytren, it is easy to understand that in some cases the difficulty of coming to a correct decision must be very great.

**Examination of the Bladder with the Cystoscope** may occasionally be of service in the detection of calculi. This method of examination is described at p. 1110.

**Examination of the Bladder by Manipulation** can be carried out easily in children. The patient is fully anæsthetized; the Surgeon then passes one finger into the rectum and presses firmly with the other hand above the pubes. If a stone be present it can be clearly felt by the finger in the rectum, and its size ascertained. In adults this mode of examination is of course impossible if there be much abdominal fat or any enlargement of the prostate, and even in the absence of these conditions it is very uncertain, as the finger does not reach far enough up to grasp the stone.

**Pathological Changes induced by Calculus.**—After a stone has existed for some time in the bladder, it induces serious pathological changes in the whole of the urinary apparatus. The *prostate* not unfrequently becomes somewhat enlarged and irritable, in consequence of which a kind of pouch is formed behind it, in which the calculus is apt to lodge. The most important changes, however, take place in the bladder and kidneys. The *bladder* becomes extremely sensitive, especially about its neck, and is consequently unable to contain as much urine as usual; hence it becomes contracted. In some rare instances, however, as will be more especially noticed when we come to speak of lithotrity, it falls into an atonic condition, and then is apt to become much dilated. The mucous membrane is commonly a good deal inflamed and irritated by the presence of the calculus; and the muscular coat becomes thickened and hypertrophied, so as to give it a very fasciculated appearance. Sacculi occasionally form, containing sabulous matter and fetid pus or urine, and in some cases lodging a concretion, which then constitutes an encysted calculus lying altogether outside the cavity of the bladder, with which it merely communicates by a very narrow aperture, as in Figs. 846 and 847, representing a case that was under my care, and which is fully described in the Journals for March, 1853. The *kidneys* are often congested, frequently in a state of chronic or subacute interstitial inflammation, and ultimately become the seat of such structural changes as are incompatible with life. When death occurs as the consequence of stone, the patient usually sinks, worn out by protracted suffering and kidney disease.

#### LITHOTOMY.

It is not my intention to enter into the general history of lithotomy, an operation that has been practised from the earliest ages; nor to give a sketch of the gradual modifications that have at various times been introduced, from the rude attempts of the Greek and Roman Surgeons to the barbarous and unscientific procedures adopted by the itinerant operators after the revival of letters. For all this, I would refer the reader to the classical works of Deschamps and of John Bell.

The various methods by which a stone has been removed from the male bladder by a cutting operation may be arranged broadly under the following four heads: 1. The Suprapubic or High Operation, in which the stone is removed from an incision into the bladder above the symphysis pubæ. 2. The Lateral Operation, in which the bladder is reached through an incision in the left side of the perinæum. 3. The Median Operation, in which the stone is removed through an incision in the middle line of the perinæum; and 4. Various extensions and combinations of the last two methods, such as the Bilateral, Medio-bilateral, Medio-lateral, and the Recto-vesical.

Up to a comparatively recent period the Lateral Operation, as practised by Cheselden and modified by Liston, was that which was generally performed by Surgeons, and one which in skilful hands yielded excellent results. Since the general application of lithotripsy to the removal of stones of small and medium size, and the consequent restriction of lithotomy to those of considerable magnitude, the suprapubic operation has taken the place of the lateral as being the method by which large calculi can more safely be extracted.

Although the suprapubic operation has now very largely superseded the median and lateral, and their modifications in those cases of vesical calculus that do not admit of the removal of the stone by lithotripsy, yet it is not universally employed, the lateral and the median having still their advocates. For this reason, and also for the fact that no description of lithotomy can be considered complete without an account of those methods that have so largely filled the minds of the greatest Surgeons of all times, I have thought it best to describe and to compare as heretofore the various methods which have been devised for "cutting for the stone," as the operation was termed by the older Surgeons.

**SUPRAPUBIC LITHOTOMY.**—The high or suprapubic operation was first performed by Pierre Franco in 1560 at Lausanne. He had commenced to cut a child by the apparatus minor, when he found the stone to be of the size of a hen's egg, and too large to be extracted by the perinæum. The parents insisted, however, that it should be removed in some way, and seeing the stone forming a prominence above the pubes when pushed forward from the rectum, Franco cut down upon it and successfully removed it. He did not, however, repeat the operation, and suprapubic lithotomy cannot be said to have become a recognised surgical proceeding till the early part of the eighteenth century, when it was practised and perfected by Douglas and Cheselden. The results obtained were certainly better than those of the median operation then chiefly in vogue; but after the perfection of the lateral operation by Cheselden, suprapubic lithotomy again went out of fashion, being reserved only for those cases in which the stone was too large to be extracted by the perinæum. The objections to the operation were its tediousness and painfulness, and the dangers of wound of the peritoneum and urinary extravasation. Lately the operation has again been revived, at first with the idea that by antiseptic treatment the wound in the bladder could be closed by sutures, and union by first intention obtained. The revival of the operation has led to improvements in the details of its performance, and to a large extent it has replaced other methods.

**Operation.**—The high operation consists in making an incision through the abdominal wall, above the pubes, and opening the anterior part of the bladder below the reflection of the peritoneum. In order to do this safely it is necessary to raise the apex of the bladder, and with it the peritoneum, as high as possible above the pubes. For this purpose the most important measure consists in distending the bladder with water or air. The former is usually employed; but Bristowe, of Brooklyn, found by experiment that by means of inflation with air the bladder is more thoroughly raised. In 1878 Garson showed by experiments on the dead body that by injecting the rectum at the same time, the whole bladder could be pushed upwards so as to become an abdominal rather than a pelvic organ, and the reflection of the peritoneum was carried from two to three inches above the pubes. In 1880 Petersen, of

Kiel, independently arrived at the same conclusion, and practically applied it to suprapubic lithotomy by introducing an india-rubber bag into the rectum, which was distended with water before commencing the operation. Although the rectal bag has been extensively employed, it must not be regarded as altogether a safe procedure, and more than one case of fatal rupture of the rectum has resulted from the distension. In children the rectal bag should never be employed; in them the bladder lies high, and can easily be raised sufficiently by moderate distension. In adults, also, it should be dispensed with unless the bladder is much contracted, and raised with difficulty.

The operation is thus performed: The patient should lie flat on a table. His legs should not hang over the end, as over-extension of the thighs tends to tilt the pelvis and arch the back, making the recti tense. The shoulders should be slightly raised by a pillow. The pubes is first shaved and the whole region rendered aseptic by washing with soap and water and afterwards with carbolic lotion (1 in 20) or perchloride of mercury (1 in 500). If the rectal bag is likely to be required this should be well oiled and introduced by an assistant. Petersen's bag is pyriform, but MacCormac recommends a sausage-shaped bag as more closely resembling the natural form of the rectum. A soft catheter is then passed, to which an india-rubber tube is attached with a funnel at the end. Through this a concentrated cold solution of boric acid, warmed to the proper temperature, is poured into the bladder, and withdrawn again by lowering the tube below the table. In this way the bladder must be repeatedly washed out. Finally, by raising the funnel from two to three feet above the body the bladder may be sufficiently distended if the patient be fully under the anæsthetic. Forcibly injecting a fixed amount into the bladder is not free from danger, and has been known to cause rupture. The catheter is now withdrawn, and an india-rubber band or a piece of tape fastened round the penis to prevent the escape of the fluid. If it be preferred the bladder may be injected through a metal catheter, which may be plugged and left in as a guide to the bladder. If by this means the bladder is not sufficiently raised above the pubes, the rectal bag may be distended with water, great care being taken to avoid using much force lest the rectum be ruptured. The quantity injected must not exceed ten ounces in the adult. In children, as already stated, the bag should not be used.

The Surgeon may stand on whichever side he prefers, but the left will be found most convenient in the later stages of the operation. No special instruments are required. The incision is made accurately in the middle line, and should be from two to four inches in length, according to circumstances, the longer incision being necessary when the patient is very fat. It should extend over the pubes at its lower end for about half an inch. The pyramidales, if present, are drawn apart, and if necessary, notched. The incision is carefully deepened exactly in the middle line, between the recti or through the muscular tissue, if the interspace is not recognised, until the transversalis fascia is reached. This is divided, and the wound held widely opened with retractors. A varying amount of fat which lies in front of the bladder is thus exposed, and must be carefully dissected through. Some large veins are often present in this region; these should be seized with forcepressure forceps before being divided, and subsequently ligatured. After carefully dividing the fat and pushing it somewhat upwards, so as possibly to raise the reflection of the peritoneum, the bladder comes into view. If an instrument have been re-

tained, its handle may be depressed so as to make its point project, pushing the bladder before it. The bladder is recognized in the adult by its muscular fibres; in children, Dulles states that its bluish-grey colour is characteristic. The bladder having been fully exposed and recognized, the next point is to secure it before an opening is made. Unless this be done it will collapse as soon as it is punctured, and, sinking down in the pelvis, may only be recovered with difficulty. The safest method is to pass two silk stitches through its muscular coat, so as to obtain a firm hold on each side of the middle line. If the coats are thin, or if it be not intended to suture the bladder after the operation, the threads may include the mucous coat also. The bladder being thus secured, and the muscular fibres being clearly visible, showing that it is not covered by peritoneum, a scalpel is thrust into it with the back directed upwards, and an incision of sufficient size to admit the finger is made downwards towards the pubes. The finger is then inserted, and the size of the stone ascertained. If it be small it may at once be seized and removed in an ordinary pair of lithotomy forceps. If it be larger the wound must be carefully enlarged downwards with a probe-pointed bistoury. It is better to do this by cutting than by stretching or tearing, as there is but little bleeding, and if it is intended to suture the bladder the wound should be made as cleanly as possible. Thompson finds that in many cases the stone may conveniently be removed between the two forefingers, the others being locked together so as to convert the two hands into a kind of forceps. If the contents of the bladder are foul it is well to wipe the wound over with chloride of zinc (40 gr. to 3j), and to dust it with iodoform before making the incision into it. The stone having been extracted, the bladder may be cleaned with a sponge to remove any clots of blood. If the wall of the bladder be thick and healthy and its contents free from decomposition, the wound may be closed with fine carbolized silk or catgut sutures. To do this a stitch must first be passed beyond the upper part of the wound, taking a hold on the muscular coat only on each side of the line of the incision. By means of this the bladder can be drawn up while a series of stitches are inserted about a sixth of an inch apart in the same way as in Lambert's suture of wounded intestine. The last stitch must be beyond the lower end of the wound. The two stitches beyond the wound, above and below, are essential to prevent leakage. The bladder is then tested by distending it again with boric acid solution, and its cavity is at the same time washed free from blood. If the bladder wall be very thin, if there is much cystitis, and especially if in the case of a large stone the edges of the wound have been bruised during extraction, no attempt should be made to close the vesical opening by sutures, as it would certainly fail. Even when the bladder is healthy, suture not uncommonly fails, and for this reason many Surgeons never attempt it. If the opening is not closed by sutures a short india-rubber tube should be inserted.

The treatment of the external wound varies with that of the bladder. If the latter has been closed by sutures, a drainage-tube must be inserted at the lower end of the external wound, and the upper part may be closed and an antiseptic dressing applied. By this means an exit is left for the urine if the sutures give way. If a tube is inserted into the bladder the external wound should be left open or its upper part closed, according to its size. The strictest antiseptic precautions should be observed throughout the operation.

In the after-treatment, if the bladder has been closed by sutures, especially in children, the patient may be allowed, if he can, to pass water naturally. If, however, this be long delayed so that distension of the bladder is to be feared, a catheter must be passed. If a drainage-tube has been inserted into the bladder from the wound, the urine will escape readily from it, and should be received in a large sponge or in moss pads. The patient may lie on one side to facilitate drainage. The tube may be removed after three or four days.

Other means of drainage have been adopted. Thus a soft rubber catheter may be tied into the urethra, and a long tube applied to it to maintain drainage; but this is apt to cause urethritis, and is perfectly useless if the bladder wound is freely opened. Perineal incisions have been made, but these are always not only needless but injurious. The best mode of treatment is not yet certainly determined; but probably the wisest course is only to suture the bladder in well-selected and favourable cases, and then to leave the external wound partly open in case of failure. In all other cases drain from the wound with a good-sized rubber tube retained for three or four days.

Various modifications have been suggested of the method of performing suprapubic cystotomy above described, whether the operation be undertaken for the removal of a calculus or for other purposes. Trendelenburg recommends that the patient, instead of lying on a flat table, should be so placed that the pelvis is well raised. This position is secured by raising the lower part of the operating table, which is hinged at the middle, whilst the patient's bent knees are held over the shoulders of an assistant who stands on a stool at the foot of the table. This position, which obviously presents several disadvantages, has not found much favour in this country. Among the advantages claimed for it are, that the intestines fall away from the hypogastric region, and that thus the danger of wounding the peritoneum is lessened; and secondly, that it allows a more thorough examination of the parts about the trigone—a point chiefly of importance when the bladder is opened in cases of ulceration or new growth.

Trendelenburg has also advocated the use of a transverse incision instead of the longitudinal one usually employed, chiefly with the objects of more certainly avoiding the peritoneum and obtaining a better view of the interior of the bladder. The incision is made close above the pubes, and divides the recti muscles; the bladder also is opened transversely. Any advantages which this method may present are probably more than counterbalanced by the increased severity of the operation and the slower healing of the wound.

The **special dangers and difficulties of the operation** are very few. Hæmorrhage from veins superficial to the bladder is best avoided by securing them in forcipressure forceps before they are divided. Wound of the peritoneum is the most serious accident that can happen, and if it occurs before the bladder is opened the operation should be abandoned, and repeated at a subsequent time if possible. It is avoided by the proper distension of the bladder, and if necessary of the rectum, by making the opening downwards towards the pubes, and by seeing the muscular fibres of the bladder clearly before the incision is made. Rupture of the bladder or rectum by too forcible injection is not likely to happen if the operation is performed as above described.

If the calculus be encysted—and the suprapubic operation should always be adopted if such a condition is suspected or known to exist—the Surgeon must

be guided by the position of the stone and the character of the pouch in which it lies. If the stone be found in a deep pouch behind the prostate it may be possible to prize it out with a narrow scoop, as in a case successfully treated by Buckston Browne. The removal of a stone from a sacculus which communicates with the bladder by a small opening is attended with considerable danger. If an attempt be made to enlarge the opening by incision the greatest care must be taken not to perforate the bladder. The disproportion between the size of the calculus and that of the opening of the calculus may be such that the removal of the calculus entire is out of the question. Rivington and Hurry Fenwick have successfully adopted the expedient of breaking up the stone with a chisel and mallet, and removing the fragments separately.

The **dangers after the operation** are various. Infiltration of urine in the loose tissue around the bladder is perhaps the most serious and fatal. It is best prevented by disturbing this tissue as little as possible during the operation, especial care being taken not to make a cavity with the finger between the symphysis pubis and the bladder. If the wound be not closed too tightly and if good drainage be maintained the danger of infiltration is very small. Secondary hæmorrhage is very rare, and should it occur it is the consequence of ulceration of one of the large veins superficial to the bladder. Septicæmia and pyæmia are not more common than in other operations on the urinary organs, and are best prevented by the strictest attention to antiseptic details during the operation, and the adoption of some antiseptic treatment afterwards. The formation of a urinary fistula rarely occurs.

The **State of the Kidneys** influences the result of lithotomy in the adult more directly than any other condition. If these organs be sound, the patient will usually recover; hence in children, in whom the complication of renal disease rarely exists, lithotomy is very successful, even though the operation is proportionately far more severe in them than in adults. If, on the other hand, the kidneys be extensively diseased, the patient will commonly die, even though he have been operated upon with the utmost skill. The condition of the kidneys that is especially fatal has been described in Chapter LXV.

**Mortality.**—The older statistics are of little value, partly because until the recent revival of the operation it was undertaken only when the size of the stone or some other complication made the perinæal methods impossible, and partly because the older operations were undertaken without the advantages of antiseptics, and without the present means of raising the bladder and its peritoneal investment above the pubes, and usually without efficient drainage. Dulles of New York, a strong advocate of the operation, collected a total of 465 cases in both sexes; of these 135 died, or 1 in 3·44. He found that for calculi under one ounce it contrasted very unfavourably with the lateral, for those between one or two ounces there was little difference, whilst for calculi above two ounces it gave by far the best results. Of 124 cases operated on since 1879 collected by Dennis of New York, only 18 died, or 1 in 7; but of these deaths 7 might fairly be eliminated as having had no direct connection with the operation. MacCormac collected a total of 91 operations performed in this country from January 1st, 1885, to March, 1887. Of these 57 were adults, of whom 18 died, or 1 in 3·1. Only one patient died from peritonitis, and none from urinary extravasation or pyæmia. The cause of death in one case was rupture of the rectum by the bag. In 38 cases the patients were under 15, and not one died. The stones in the adults varied

from 24 ounces to 10 grains in weight, and in the children from 2½ ounces to 35 grains. The bladder was sutured in 18 children, with 8 successes, and in 8 adults with only 2. In one case the operation had to be abandoned owing to the peritoneum covering the bladder as low as the pubes.

Lastly, Gilbert Barling has collected 169 operations performed in thirteen Hospitals in this country during the years 1888 to 1892 inclusive. Of these 26 died, or 1 in 6·5, giving a mortality of 15·4 per cent. Four of the deaths can hardly be attributed to the operation, as in 3 lithotrity and in 1 lateral

Fig. 853.—Lithotomy Scalpel.

lithotomy had been attempted before it was undertaken. Of the remaining 22 deaths, 7 were due to disease of the kidneys, 3 to peritonitis, 2 to shock, 2 to septicæmia, 1 each to cellulitis, bronchitis, pneumonia, scarlet fever, secondary hæmorrhage, exhaustion ; in 2 no cause was given.

**LATERAL LITHOTOMY.**—The removal of a stone from the bladder through an incision in the left side of the perinæum was first performed by Frère

Fig. 854.—Probe-pointed Lithotomy Knife.

Jacques, who demonstrated his operation in Paris in 1697. The operation was first performed on definite anatomical and surgical principles by Cheselden of St. Thomas's Hospital, and his method, modified by Liston, is that now generally adopted.

**Instruments, &c.**—The table for operating must be of convenient height, so that when the Surgeon sits on a rather low stool the patient's nates will be on a level with his breast ; a few blankets doubled should be laid upon the

Fig. 855.—Open-bladed Lithotomy-forceps, lined with linen.

table, and covered by a piece of mackintosh cloth hanging over the end ; and a tray of sawdust placed under it on the floor. The instruments necessary are the following :—a pair of lithotomy-tapes, a sharp and probe-pointed scalpel, a staff, forceps, and scoops of various sizes, and a tube. To these may be added a searcher, and a brass injecting syringe.

The *tapes* should be of coarse flannel, about three yards long by three inches broad.

The *scalpel* should be broad-bladed and straight-backed. For the adult it may be of the size and the shape represented (Fig. 853) ; for children it may

be made a little smaller. A *probe-pointed lithotomy knife* of the size and shape here represented should also be at hand (Fig. 854).

The *staff* should have a deep groove on its left side, occupying nearly one-third of the instrument; it should be well curved, of as large a size as the urethra will admit, and have a roughened handle (Fig. 860).

The *forceps* must not be too heavy, but should be of a good length in the handles, and have the joint well set back; the inside of the blades, as recommended by Liston, should be lined with linen, to prevent the stone from slipping (Fig. 856). Coxeter has made them with open blades, but lined with linen as heretofore (Fig. 855); in this way, as there is less metal, the weight is diminished, and the diameter of the instrument with a stone in its grasp is materially lessened. The ordinary forceps are straight, but it is advantageous to be provided with some that are curved (Fig. 857). The handles should be made with a loop on one side and a ring on the other; the ring for

the thumb should be placed somewhat obliquely. The *scoops* of different sizes, and curved, can be used most conveniently when fixed in roughened handles (Figs. 858 and 859). The *tube* should be of gum-elastic, well rounded at the end, and provided with silver rings, and may be petticoated. The *searcher* is a slightly curved sound, having a bulbous extremity (Fig. 861). The *syringe* should be provided with Gross's ball nozzle, which propels a reversed current.

In describing the operation of lateral lithotomy, we shall first of all examine *seriatim* the different steps of an operation that presents no unusual complication or difficulty; we shall then consider the difficulties that may be met with, the accidents that may occur during the operation, and the principal sources of danger and the causes of death after its performance.

**Operation.**—The patient should be kept as quiet as possible for about a week or ten days preceding the operation; his diet should be properly regulated, and the bowels properly relieved. On the day preceding the operation, a dose of castor-oil or some other aperient should be administered, and on the

morning of the operation the rectum must be emptied by means of an enema. If necessary the perineum should be shaved.

After the anaesthetic has been administered all the urine in the bladder should be drawn off, and the organ injected with about six or eight ounces of warm boric acid lotion, in order to steady it and to facilitate the seizure and extraction of the stone. The Surgeon then introduces a full-sized staff, which he uses as a sound, in order to feel for the calculus. If he detects it, he proceeds with the operation; if he cannot detect it, the operation must be deferred, for it is an imperative rule that lithotomy should never be performed unless the stone can be felt *with the staff* immediately before cutting, as the point of this, though apparently in the bladder, might be actually engaged in a false passage. The stone, then, having been felt, the patient is to be firmly tied up. This is done by making a clove-hitch on the tape, and passing it round the wrist, after which the ends of the tape are passed round the instep and hand in a figure-of-8, as in Fig. 862. Some Surgeons prefer leather

Fig. 862.—Position of Patient and Line of Incision in Lateral Lithotomy.

anklets, which are attached to collars round the wrists by hooks; but these take longer to apply, and have no particular advantage over the tapes. The patient is now brought to the end of the table, so that his nates project beyond it, where he is to be securely held on each side by an assistant, who grasps the foot in his hand, places the patient's knee under his arm, and draws the limb well aside, so that the perineum may be fairly exposed. In a patient on whom I once operated this could not be done, owing to the left hip being stiffened by chronic rheumatic arthritis; but I did not experience any particular

difficulty in the operation, though somewhat inconvenienced by the position of the limb. The Surgeon then, seating himself before the patient, introduces his finger into the rectum. This is done with three objects: first, to ascertain the depth of the perineum by feeling for the apex of the prostate; secondly, to make sure that the rectum is empty; and thirdly, to cause a contraction of the gut, which will keep it out of the way during the first incision. The staff must then be given into the charge of a trusty assistant, who stands on the patient's left, and raises the scrotum with the left hand whilst he holds the staff in the right (Fig. 862).

The Surgeon then sees that the staff is held in the way in which he prefers it. There are two ways in which it may be held: it may either be drawn well up under the arch of the pubes, or it may be pushed somewhat down, and slightly turned towards the left of the perineum. Liston always employed the first method, which I certainly think is the better, as it increases the space between the urethra and the rectum, and lessens the danger of wounding the gut, which more than counterbalances the advantage of the

other method—that of bringing the membranous portion of the urethra nearer to the surface.

The external incision is made by entering the knife in the *raphé* of the perinæum, one inch and a half above the anus, and carrying it downwards and outwards, until it reaches a point that is just below the anus, but about one-third nearer to the tuberosity of the ischium than to the margin of the anal aperture (Figs. 862 and 864). The depth to which this incision should be carried must vary according to the fatness of the patient; usually from about three-quarters of an inch to an inch, but not so deeply above as below. By this incision the skin, superficial fascia, subcutaneous fat, and inferior hæmorrhoidal vessels are divided. After it is completed, the knife is again introduced a little below the upper part of the wound, and the blade is run lightly

Fig. 863.—Second Stage of Lithotomy.

downwards over any resisting structures; the left forefinger being placed at the middle of the wound, so as to protect the rectum. In this way the triangular space is opened between the *accelerator urinæ*, the *erector penis*, and the *transversalis perinæi* muscles; and as the knife is carried downwards, the last-named muscle, the *transversalis perinæi* artery, and some areolar tissue are cut through. The lower border of the triangular ligament also is notched so as to open up the space between the two layers of the ligament, in which the membranous part of the urethra lies. The knife is then withdrawn, and the left index-finger is pushed deeply into this space until the edge of the nail is lodged in the groove of the staff, which can be felt just anterior to the prostate, thinly covered by the membranous portion of the urethra and the *constrictor urethrae* muscle. The point of the knife is then pushed through the urethra at its membranous

part into the groove of the staff, above the index-finger, which protects and presses to the right the rectum lying beneath it (Fig. 863).

When the knife is felt to be well lodged in the groove, its handle is slightly depressed, so that the point may be raised; at the same time the blade should be somewhat lateralized so that its side lies parallel to the ramus of the ischium. If the edge be turned too directly downwards towards the mesial line, the rectum may be wounded; and if it be directed too much outwards, the internal pudic artery will be endangered; hence the mid course is the proper one.

The Surgeon, keeping the knife steadily in this position, and pressing the point firmly against the side of the groove of the staff, which he must never for a moment lose, pushes it forwards, dividing the membranous part of the urethra, the anterior part of the prostate gland and the sheath enclosing it, and a few fibres of the levator ani (levator prostatae), and thus makes an entry

Fig. 864. — Muscles of Perineum (from a model by Ranber). The extent of the superficial incision is indicated — by a thick line; that of the deep part of the incision by the continuous part of the line only.

into the bladder (Fig. 683); he then withdraws the knife, keeping its back against the staff, so as not to enlarge the extent of the incision in the prostate. Through this, and along the staff, he then pushes his left index-finger until it reaches the bladder, when he endeavours to feel the calculus with its tip. Should his finger be short, the perineum deep, or the prostate enlarged, he may be unable to reach the bladder in this way; and must then introduce a blunt gorget, as recommended by Cheselden, in order to dilate the aperture in the prostate. If he use his finger for this purpose, he gives it a twist or two after passing it through the prostate, so as to enlarge the aperture through which it is entered. Having made sure that it is in the bladder, and having, if possible, felt the stone, he directs the assistant to withdraw the staff from the urethra.

Here let us pause, and examine the principal points in the first and second stages of the operation. It will be observed that, in accordance with the best authorities upon this subject, and with my own experience, I have recom-

mended the external incision to be free, the rectum to be protected by the left index-finger, the knife to be lateralized during and after the opening of the urethra, and the deep incision to be limited.

1. The **Position of the Knife** must be carefully attended to, especially during the deep or second incision. At this stage of the operation the edge should be *lateralized*; that is, directed about midway between the horizontal and perpendicular positions, so that the surface of the blade lies nearly parallel to the ramus of the ischium. The manner of holding the knife has been much discussed, and necessarily varies with different Surgeons. I believe it signifies little how the handle of the instrument is held between the

Fig. 865.—Position of Hand and Knife (Fergusson).

Fig. 866.—Position of Hand and Knife (Liston).

Surgeon's fingers, provided the edge be never turned upwards, but be always kept well lateralized, with the point steadily pressed into the groove of the staff. In the first incision, most operators, I believe, hold the knife *under* the hand, as represented in Fig. 865; a position which that excellent lithotomist, Fergusson, preserved throughout the operation. Liston, in the early part of his career, appears to have held the knife, in the second stage of the operation, *above* the hand; and in all the representations that he has left of his operation, he has depicted the knife and hands in the position shown in Fig. 866. There can be no doubt, however, as Fergusson has pointed out, that in actual practice, at least after his first few years as an operator, he held the knife under the hand, with the index-finger upon the side or the back of the blade.

For my own part, I should say that, in operating on a child, or on an adult with a shallow perinæum, the knife is most conveniently held as represented in Fig. 865. But if the patient be fat, and the perinæum deep, then I think

that it is a question whether greater steadiness may not sometimes be secured by holding the knife somewhat in the manner of a gorget, with the index-finger perhaps a little more upon the side of the handle (Figs. 863 and 867); in this way the point is firmly pressed into the groove of the staff, out of which it cannot slip, as it is supported by the index-finger being somewhat under it. The section of the prostate is thus made by a steady thrust of the knife forwards and not by any cutting movement downwards. No danger can result in the deep incision from pushing the point of the knife up into the groove of the staff; but there is great danger of missing the bladder, and

Fig. 867.—Position of Hand and Knife (Author).

entering the recto-vesical space, if it be at all depressed and the handle raised, though this cannot always be avoided if the staff be pushed deeply into the bladder. It may happen that the knife will not run readily along the groove, if its blade form too small an angle with the part of the staff, with which it is in contact. The hand must then be slightly raised and depressed again as the knife glides along the curve of the staff into the bladder, so that the point may be kept well in the groove, and all risk of slipping out avoided.

2. The **Incision into the Prostate** must be at least of sufficient size to admit the tip of the index-finger readily. The extent to which it should be carried has been the subject of much discussion, and of wide diversity of opinion; John Bell advising that the incision should reach backwards to the bladder, and Scarpa, that it should not exceed five lines in adults and two in children. The danger, however, it must be borne in mind, does not consist in the section of the prostate itself but in cutting beyond it to such an extent as to open up the loose areolar tissue surrounding the bladder, which would expose the patient to the danger of urinary infiltration and diffuse inflammation.

It was formerly supposed by some Surgeons that a stone of moderate size could be extracted through the prostate without tearing the fibrous capsule of the gland derived from the recto-vesical fascia, which was asserted to remain uninjured, and to prevent infiltration of urine into the surrounding parts. Experiment on the dead body, and the *post-mortem* examination of those who died after lithotomy, clearly demonstrated the fallacy of these views. No stone of one inch in diameter can be removed through a healthy prostate without dividing the gland and its capsule for a considerable part of their length, and if the calculus be of considerable size, the rent will be found to extend backwards in the floor of the bladder, some way towards the left ureter. The danger of urinary infiltration is not in the external parts of the wound, but in the loose subperitoneal tissue; and that distinguished anatomist, Ellis, taught many years ago that the separation between the cavity of the pelvis and the external parts in which a lithotomy wound can be safely made is not the sheath of the prostate but the lateral and anterior true ligaments of the bladder, or, in other words, the recto-vesical fascia. Hence the incision may be safely carried through the whole length of the lower and outer side of the prostate up to the very neck of the bladder, provided it do not pass beyond the attachment of the lateral ligament, and so open up the loose subperitoneal tissue.

There are, however, other dangers besides extravasation of urine that may arise from too free use of the knife in the deeper parts of the wound, especially hæmorrhage from the venous plexus surrounding the prostate and wound of the rectum. For these reasons I prefer to incise the prostate to a moderate extent, enlarging the aperture by stretching with the finger.

In the section of the prostate, then, two points have specially to be attended to: one is, that the knife in entering be not pushed forwards at too great an angle with the staff, so as to cut widely; and the other is, that in its withdrawal the blade be kept steadily in contact with the staff. Indeed, I believe that there is more danger of doing mischief in the withdrawal than in the entry of the knife; for, if it leave the staff for a moment, all guide is lost, and the edge may sweep downwards through the base of the prostate and the neck

of the bladder. As the knife is withdrawn, the left index-finger is pushed forwards into the aperture in the prostate, which is then dilated by its pressure to a sufficient extent for the introduction of the forceps, which are slipped in as the finger is withdrawn, and for the extraction of the stone. This part of the operation may very conveniently be performed, as was usually done by Liston, at the moment when the Surgeon is stooping down, engaged in selecting his forceps. The dilatation of the prostate is readily effected; for this structure, though dense, is friable, and breaks down easily under somewhat forcible pressure with the finger. In this way, by a moderate section of the apex of the prostate, followed by simple dilatation with the finger, sufficient space will be obtained for the extraction of all moderate-sized calculi, without the employment of any violence.

But another obstacle exists which will prevent the dilatation of the neck of the bladder to any very material extent, without an amount of bruising, or laceration, or even rupture that would probably prove fatal to the patient. This obstacle consists of a firm resisting tissue, which has been described by Tyrrell as "an elastic ring," surrounding the neck of the bladder; by Liston as "a fibrous or ligamentous band surrounding the orifice of the bladder, into which the muscular fibres of the organ are inserted." If this ring or band be ruptured, either by the finger or by the expansion of the forceps, fatal consequences will ensue; but if it be divided, the other tissues, as Liston observes, will yield to an inconceivable extent, without injury to the recto-vesical fascia. The division of this ring must be practised only to a very limited extent. I believe that it is always effected in the act of pushing the scalpel inwards into the bladder; a mere notching of the fibres of the ring, indeed, is sufficient to allow the requisite expansion to take place when pressure is applied.

In thus describing the mode of incising the prostate and neck of the bladder, I have generally used the term "dilatation;" and I believe that, by a simple process of dilatation or expansion of these parts, and without any violence whatever, small calculi under an inch in diameter may be extracted. But in removing stones of greater magnitude than this, I believe that the process of expansion of the prostate and neck of the bladder, whether effected by the finger, by a blunt gorget, or by the opening up of the blades of the forceps, is a process of laceration rather than of dilatation, as I have frequently had occasion to observe in experiments made on the dead subject. If this laceration be, however, confined to the substance of the prostate, and do not extend through the lateral ligament of the bladder, no harm results. It is difficult, with ordinary force, to lacerate the dense ligament. This structure, therefore, remains as a barrier between the pelvic areolar tissue and the external wound, preventing the possibility of the infiltration of urine into the subperitoneal areolar tissue, and lessening materially the chance of diffuse inflammation. But if, in the withdrawal of the stone, or by an undue expansion of the blades of the forceps, the Surgeon feel the sudden giving way of a tense annular structure, he may be sure that the lateral ligament has been torn, and fatal mischief will probably ensue.

**Extraction of the Stone.**—A forceps of sufficient length, of a size proportioned to that of the calculus, and previously warmed by immersion in tepid water, must be slid along the index-finger, which is kept in the wound, and by which the neck of the bladder should be drawn somewhat down so as to meet the instrument. In this way, also, the stone may often be fixed by

the point of the finger, and its position thus accurately determined. The forceps having been introduced closed, the finger is withdrawn, when a gush of fluid will usually take place through the wound, if it have not already escaped at the time when the incision is made through the prostate. By this gush the calculus may sometimes be carried into the grasp of the instrument : most commonly, however, the stone requires to be felt for with the closed forceps. When its position has been ascertained, usually at the fundus, the blades of the instrument are opened ; and by pushing one against the wall of

Fig. 868.—Direction of Forceps in Extraction of Stone.

the bladder, and giving it a slight shake, the calculus generally drops between them ; though occasionally it is somewhat troublesome to seize, and this, indeed, often constitutes the most tedious and annoying part of the operation. Fergusson advised holding the forceps transversely, opening them as widely as possible, then giving a quarter turn so as to make the lower blade scoop along the floor of the bladder, when on closing the forceps the stone will usually be caught. The stone is then drawn downwards through the wound. If it be small, it may be extracted at once without any difficulty ; if it be of moderate

size, the finger should be introduced along the blades, in order to feel whether it is in a proper position for extraction. If its long axis lie across the wound, this must be changed ; and it must then be withdrawn by a kind of to-and-fro movement in the direction of the axis of the pelvis (Fig. 868). Should the stone unfortunately be broken,

Fig. 869.—Position of Finger and Scoop in Extracting Stone.

or should there be several small calculi, the fragments may generally be best removed by means of the scoop (Fig. 869). In the event of fracture occurring, it will be necessary to wash out the bladder repeatedly with tepid water, injected by means of a brass syringe through a tube introduced by the wound.

If the perinæum be very deep, and the prostate enlarged, it may happen that the neck of the bladder is so far removed from the surface that the finger cannot reach its interior. In these circumstances, the Surgeon must be careful, in passing the forceps, that the instrument do not slip to the side of the incision, the guide and support of the index-finger being lost. In two or

three cases of this kind that have occurred to me, I have directed the assistant who held the staff not to withdraw it, but using it as a guide, have slipped the forceps along its groove and over its concavity, in this way making it enter the bladder with the greatest ease.

It is of the first importance to extract the stone without breaking it, or even chipping fragments from it with the blades of the forceps. No effort consistent with the safety of the patient should be spared in attaining this desirable result ; not for the sake of any vain display of manual skill, but from a regard to the well-being of the patient. If the stone be broken by the attempt at extraction, what happens ? The Surgeon is obliged repeatedly to introduce the forceps and the scoop in his attempts to clear the bladder ; the mucous membrane of which is liable to be bruised and excoriated in the endeavour to seize the fragments. The bladder requires to be frequently washed out with copious injections of tepid water, and the operation thus becomes dangerously prolonged. Even after much time has been spent in these efforts, fragments are apt to be left behind which may occasion great irritation, and, if retained, will form the nuclei of future calculi.

In children, and indeed in most cases in which the perinæum is not very deep, so that after the introduction of the finger the stone can be felt and hooked forwards, the scoop is a most convenient instrument for its extraction ; and in these cases I have often employed it in preference to the forceps.

After the calculus has been removed, it must be examined for facets, and the finger must be passed into the bladder and its cavity explored while firm pressure is made above the pubes. In this way the whole interior of the bladder is easily explored except in those cases in which the perinæum is unusually deep. The interior of the bladder may be further explored by means of a *searcher* ; and if other stones be found, they must be dealt with in the same way as the first.

If the urine has been foul before the operation, it is well to sponge the surface of the wound over with chloride of zinc (gr. 40 to 3j.), and to apply iodoform.

The *gum-elastic tube* may then be introduced, and secured with tapes to a band round the patient's abdomen. This tube must be kept free from coagula by introducing a feather into it from time to time. The tube is of great service in preventing the wound from becoming blocked up by coagula, by which a free escape of the urine would be interfered with. By means of this tube a ready outlet is given to the urine, the chance of infiltration is lessened, and if there be hæmorrhage the wound may readily be plugged round it.

**After-treatment.**—After the operation, the patient must be removed to a bed, which should be properly arranged by having a large square of macintosh put across it. On this a folded sheet should be laid, which must be rolled up on the further side, so that, as it becomes wetted by the escape of urine, it may be drawn across from under the patient. This must be changed frequently in order to keep him clean and dry. A full dose of tincture of opium in barley-water should then be given ; a warm flannel laid across the abdomen ; plenty of barley-water allowed for drink, and nothing but rice-milk or light pudding for diet during the first three or four days. After this some broth may be allowed, and the quantity of food gradually increased. Occasionally, however, it may be necessary to depart from this routine system of dieting :

and I have, with great advantage, allowed wine, and even brandy, a day or two after the operation.

At the end of thirty-six or forty-eight hours the tube may be removed, the sides of the incision by that time having become glazed over, and little danger of infiltration existing. The patient, who up to this time has been lying on his back, should then be directed to change his posture, first to one side and then to the other. The buttocks and hips should be well smeared with vaseline, so as to prevent the irritating effects of the urine, which continues to flow entirely through the wound, and may be received in a large carbolised sponge, which must be changed frequently. About the fourth or fifth day the urine frequently ceases suddenly to flow from the wound, escaping by the urethra. This is owing to the prostate becoming turgid from inflammatory swelling, and thus blocking up the aperture in it; but as this swelling goes down, in the course of a day or two, the urine usually escapes by the wound again, and continues to do so in gradually decreasing quantities until the aperture is finally closed, which happens usually at about the end of fourteen or eighteen days; though in patients who have suffered from phosphatic calculus it sometimes takes a longer period, owing to the broken state of the general health. Should the wound fall into a sloughy state, the patient must be put on a very generous diet, with even a free allowance of stimulants; and the tincture of benzoin may be daily applied. When slow in healing, it may be stimulated with nitrate of silver applied to the bottom; and, should a fistulous aperture be left, that may be touched with the cautery. After the operation, appropriate constitutional treatment should be continued for some time in order to prevent the recurrence of the disease.

**Lateral Lithotomy in Boys** under the age of puberty is one of the most successful of the great operations in Surgery. The following points are worthy of note, and should be remembered by the Surgeon in proceeding to operate on children:—

1. The urethra will commonly be found larger than would perhaps at first be expected, readily admitting a No. 8 or 9 staff.

2. The perinæum is usually very vascular in consequence of the straining produced by the irritation of the calculus.

3. There is often from the same cause a tendency to prolapse of the rectum.

4. As the prostate is a rudimentary organ, the deep incision necessarily passes beyond its limits into the neck of the bladder.

5. The tissues are more yielding, and more readily lacerable under the finger.

6. The most important point, however, is, that the bladder lies high, being rather in the abdomen than in the pelvis; hence, it is of importance to raise the point of the knife somewhat more than in the adult in making the deep incision, and to be careful that it do not slip into the tissues between the rectum and the bladder, which may happen unless this precaution be taken. I have known this to occur in several instances to experienced Surgeons, the forceps being passed into this space under the supposition of its being in the bladder; and in every case the patient died unrelieved. This accident is the more likely to happen, because in boys the parts are very yielding, and readily admit of being pushed before the knife or finger; and the finger may thus pass between the neck of the bladder and the pubes, or

into the loose areolar tissue between the rectum and the bladder. The urethra being opened, urine escapes ; and the Surgeon introduces his finger into a distinct cavity, which he believes to be the interior of the bladder, but which is not this, but the recto-vesical space. The liability to the occurrence of this fatal accident is materially lessened by injecting the bladder fully with tepid water, by which it is steadied and brought lower down. But in young boys lithotomy is from this cause always an anxious operation. It falls to the lot of but few Surgeons of experience in lithotomy to pass through an active professional life without meeting with difficulty and anxiety in operating on boys ; and when such an untoward accident occurs, those will be the most charitable in their judgment of others, who have themselves had the most experience in the operation and have had most frequently to encounter its intrinsic difficulties.

In order, then, to obviate the special dangers that have just been mentioned as likely to occur in lateral lithotomy in boys, the following points should be attended to :—

1. The bladder should be injected with two or three ounces of tepid water.
2. The knife should not be too narrow, as it has to make an opening of sufficient size to admit the forefinger of the operator in the child as in the adult. Its point, when it has entered the groove of the staff, should be kept very firmly pressed against its side, and carried somewhat upwards instead of straight forwards.

3. When the knife is laid aside and the Surgeon proceeds to pass his finger into the bladder, he will find the following manœuvre facilitate this step of the operation very greatly, and lessen materially the danger of pushing the neck of the bladder before him : Placing the nail of the left index finger in the groove of the staff, he should not carry it along the convexity of this instrument, but, sliding it over to the concave side, gently work his way along this into the bladder. In doing so, he passes the finger between the roof of the urethra, which is a fixed part of the canal, and the staff, instead of between this and the floor of the urethra, which is mobile and yielding. There is the additional advantage that, by pressing down the staff as the finger goes above it, the urethra and neck of the bladder are somewhat dilated.

C. Heath recommends the following plan, which will be found most efficient : As soon as the knife is withdrawn he inserts a strong director with a handle like that of a staff set at a convenient angle. This is passed along the groove of the staff like the conductor in median lithotomy. The staff is then withdrawn and the finger passed above the director, which is at the same time pressed downwards.

4. As soon as the finger enters the bladder and the staff is withdrawn, the calculus should be fixed with its point against the floor of the bladder, where it may then be seized easily by the forceps.

**Difficulties during Lateral Lithotomy.**—The difficulties before and during the operation are three-fold : 1, in Finding the Stone ; 2, in Entering the Bladder ; and 3, in Seizing and Extracting the Calculus.

1. **Difficulty in Finding the Stone**, either by the staff or by the sound, may exist before commencing the operation ; and sometimes it is impossible to find the stone, although its presence may have been distinctly ascertained a few days previously. In these circumstances, the Surgeon must on no account be tempted to proceed with the operation ; but, after a carefully conducted

exploration has failed to elicit the actual presence of the stone, all further proceedings must be deferred to another opportunity. The stone may escape detection in three ways: 1. It may have been passed by the urethra, between the first examination and the time fixed for the operation. A small calculus, especially if spindle-shaped, may give a very distinct click against the sound, and yet be not too large to pass through the urethra. 2. The stone may have become encysted. 3. It may have become enveloped in folds of the mucous membrane of the collapsed bladder, and so may escape contact with the sound. All these events, except the presence of an encysted calculus, are more likely to happen in children than in the adult, and it is in them that, for want of attention to these precautions, the unfortunate accident of cutting into the bladder and finding no stone has most frequently occurred.

**2. Difficulty in Entering the Bladder.**—This is rarely experienced in adults. It may, however, arise in consequence of the Surgeon neglecting to keep the point of the knife well lodged in the groove of the staff, and thus letting it slip between the rectum and the bladder; the tissue of which, being

broken up, leaves a kind of cavity that he mistakes for the interior of the bladder. If the perinæum be very deep and the prostate enlarged, he may also experience some difficulty in reaching the bladder; but he can scarcely fail to do so if he push the knife well on the groove of the staff, and dilate the incision in the prostate with a blunt gorget, if his finger fail to reach the cavity beyond it.

Fig. 870.—Tumour of Prostate, natural size, removed during Lateral Lithotomy from a man aged 64.

Perhaps the most serious obstacle to entering the bladder consists in the presence of large tumours in the prostate. The combination of a deep perinæum, an enlarged prostate, and a tumour, certainly constitutes a formidable series of obstacles. In these

cases, the finger when slipped along the staff does not enter the bladder, but becomes involved in the smooth and irregular sinuosities that wind between the prostatic tumours (Fig. 870). In such cases it is well to practise the manœuvre that has already been described: viz., of using the staff as a guide into the bladder, slipping the forceps along the side and concavity of this instrument before it is withdrawn.

In *boys*, great and sometimes insuperable difficulty has been experienced in reaching the bladder. This difficulty arises in consequence of the small size of the urethra, the mobility of the bladder, and the ready lacerability of the tissues. If, after the groove in the staff has been exposed, care be not taken to insinuate, as it were, the nail into the opening in the urethra thus made, the membranous portion may be torn across; and the neck of the bladder, receding before the finger, may easily be pushed away from the surface, so that the Surgeon may fail to reach the cavity of the organ. When the road is once lost in this way, there is the very greatest difficulty in finding it again. The course that should be pursued is, I think, as follows: If the staff have not been withdrawn, the Surgeon must again place the knife in its groove, and carefully push it on towards the neck of the bladder,

notching that structure and passing the finger cautiously along the groove, and hooking down the parts with his nail until he reach the inside of the bladder. Should the staff have been withdrawn, the Surgeon must endeavour to pass it again; if he succeed in this, he may act as just stated; but if he cannot succeed in introducing the staff fairly into the bladder, he must on *no account whatever* endeavour to open that viscus, or continue his attempts at the extraction of the calculus, but must at once abandon the operation until the parts have healed, when he can repeat it. The great danger in these cases arises from the Surgeon losing his presence of mind, and endeavouring to enter the bladder without a guide—a procedure which must be unsuccessful, and can only end in the death of the patient.

In adults, the difficulty is to get out the stone; in children to get into the bladder.

**3. Difficulty in Seizing and Extracting the Stone** is far more frequently met with than in reaching the bladder. This may be owing to a variety of causes. It is likely to happen in all those cases in which, either from the depth at which the bladder lies from the surface, or from the peculiar position of the calculus, the stone cannot be felt with the finger after the incisions have been made into the neck of the bladder.

**Difficulty from the Position of the Stone.**—The calculus may be lodged in the *lower fundus*. This is especially apt to happen if the patient be old and fat, and have a deep perinæum, perhaps with an enlarged prostate, behind which the stone may be lodged. Here the best plan is to use a much-curved pair of forceps, and to tilt the bladder up by introducing the finger into the rectum, so as to bring the stone within reach.

When the stone is situated in the *upper fundus* of the bladder, it is altogether out of the axis of the incision, and in such a case can be extracted only with great difficulty. Aston Key recommends that in such cases the abdomen should be compressed, and the calculus thus pushed down into reach. This suggestion is a very useful one; and it was only by employing this manœuvre and using a very curved scoop, that I could remove a calculus lodged above the pubes, in the first patient whom I cut at the Hospital.

**Difficulty in consequence of the Stone being Fixed to the Bladder.**—A small calculus may be enveloped by the folds of the mucous membrane or between hypertrophied fasciculi, and in this way elude the grasp of the forceps. In these circumstances there is nothing for the Surgeon to do, but patiently to try to disentangle and remove the calculus by means of the finger and scoop, if it can be so reached; if not, by expanding the forceps in the bladder, to try to push aside the mucous membrane that surrounds the stone.

In consequence of **Spasm of the Bladder**, it is said to have occasionally happened that a calculus has been so firmly fixed as not to admit of the application of the forceps. I am disposed to think that this "spasm of the bladder" is purely imaginary, and that the real difficulty has arisen from some other cause, as perhaps a contracted and rickety pelvis. But, whatever may be the real cause of a difficulty that has undoubtedly been encountered, I think it would be safer for the Surgeon to desist from the operation, and in the course of a few days or weeks endeavour to complete the extraction, and thus perform the operation "*à deux temps*" of Deschamps.

When the calculus is **encysted**, its extraction will probably be impracticable, or attended with most dangerous consequences. Hence, it is expedient not

to perform the lateral operation in cases of encysted calculus that are known to be such. If, however, the Surgeon have been unfortunate enough to do so he must be guided in the course he adopts by the condition in which he finds the stone. If the aperture leading into the cyst be very small, as in Fig. 847, the better plan will be to proceed no further with the operation, as it will be clearly impossible to remove the stone. If, on the other hand, the aperture into the cyst be large, he might feel disposed to make an effort to extract the calculus. With this view he might adopt the plan pursued by Brodie, and endeavour cautiously to enlarge the orifice of the cyst by means of a probe-pointed bistoury, and then finish the extraction by means of a scoop. Such a proceeding, however, is in the highest degree hazardous, on account of the readiness with which the incision may extend into the peritoneal cavity; as well as difficult in execution, from the depth at which the parts are lying. If a calculus be known to be encysted the suprapubic operation should be performed.

I believe that a calculus may occasionally become encysted, or rather encapsuled, in another way,—by being covered in by a kind of false membrane whilst lying on the floor of the bladder. This condition I found in a boy on whom I operated for stone some years ago. After removing a calculus of about the size of a pea, I felt, with the end of the finger, a hard irregular body, covered apparently by mucous membrane, lying at the inferior fundus of the bladder. On scraping through the membrane covering this with the point of my nail and a curved scoop, I exposed the calculus (Fig. 844), and removed it, with a cyst attached to it. On examining the structure of this cyst, which was of about the thickness of ordinary writing paper, of a reddish colour, and resembling a piece of mucous membrane, it was found to be a false membrane, composed of organized fibro-cellular tissue. The patient made a good recovery, with the exception of a slight attack of secondary hæmorrhage, which occurred on the eighth day after the operation.

**Fibroid Tumours in the Prostate** constitute sometimes rather a serious difficulty in lateral lithotomy. They may do this in two ways: first, by elongating the prostatic part of the urethra to such an extent as to carry the neck of the bladder far from the surface; and, secondly, by being in the way during extraction of the stone. A tumour of this kind, an inch or more in diameter, necessarily fills up to a very serious extent the space in the wound through which the stone has to pass: it jams up the orifice and prevents the free play of the forceps. These tumours, however, when caught between the blades of the forceps, soon shell out, and allow the easy exit of the calculus (Fig. 870).

**Deformity of the Pelvis from Rickets** may constitute a serious or even insuperable obstacle to the extraction of a calculus. This condition may act in two ways. It may narrow the brim of the pelvis in its antero-posterior diameter, to so great an extent as to prevent the passage of the stone downwards after it has been seized by the forceps. This condition is more to be feared in children, in whom the bladder, being an abdominal organ and lying high, is altogether above the brim of the pelvis in these cases. Or there may be difficulty in the extraction of the stone through the inferior outlet, owing to the approximation of the rami on each side. The first cause of difficulty once occurred to me, in operating on a very rickety boy four years and a half old. Of the second I have had no experience. The rickety condition of the

pelvis may be suspected in cases in which the lower limbs are much distorted. Its existence may be ascertained, by digital exploration of the rectum, and by external measurements. If it be found to exist to an extreme degree, the suprapubic operation must be performed.

In old men the outlet of the pelvis may be greatly narrowed as a consequence of senile osteomalacia. This is recognized by the approximation of the ischial tuberosities.

**Difficulty depending upon the Shape and Size of the Stone.**—If the stone be very round, it is usually more difficult to seize than when flat or elongated. Flat, disc-shaped calculi, however, occasionally fall into the fundus of the bladder behind the prostate, and then cannot readily be reached by the forceps, which passes over them. In these circumstances, they are best extracted by the curved scoop. Very flat, broad calculi, and those that are round, egg-shaped, or branched, are the most difficult to remove, even though their size be not very great. As a general rule, however, it may be stated that, the larger the calculus, the more difficult is its extraction. There will always be considerable difficulty in extracting calculi weighing six or eight ounces and upwards; though cases are recorded by Cheselden, Klein, and others, in which calculi from twelve to fifteen ounces in weight have been extracted by the lateral operation. Any calculus above one inch and a half in its shorter diameter will be hard to extract through an incision of the ordinary length in the prostate, even though this be considerably dilated by the pressure of the fingers: and I think it may safely be said, that a calculus two inches and upwards in diameter can hardly be removed by the ordinary lateral operation with any degree of force which it is safe to employ. The practice adopted in such a case, more than a century ago, by Gooch, of Norwich, is probably the best that can be pursued. It consists in drawing the stone well down with the forceps, and then letting an assistant carefully divide the tissues that resist. In this way, by a process of traction, twisting, and division, the stone may be brought out with safety. In the facility with which the calculus is extracted, however, much will depend upon the make of the forceps. As Liston most truly observes, "There can be no more fatal error than to attempt the extraction of a large stone with short and shabby forceps." In these cases the open-bladed forceps (Fig. 855) will be found useful, the absence of metal in the most convex part of the blade lessening materially the bulk of the instrument when grasping a stone.

In the event of the calculus being too large for extraction through the ordinary lateral incision, the Surgeon should at once perform the suprapubic operation. The presence of the perineal wound increases the difficulty of the operation, as the bladder cannot be injected; but nevertheless this treatment is certainly to be preferred to either of the other two alternatives which are open to the Surgeon, viz., incision of the right side of the prostate and crushing the stone in the bladder. Should the unusually large size of the stone have been detected before the operation, lateral lithotomy should not be attempted.

**Difficulty from Fracture of the Calculus.**—The difficulty of extraction is greatly increased if the stone be broken. Fracture of a calculus is of two kinds. In the one case the stone is simply broken into several fragments, or splinters, so to speak, are detached from it. This accident may happen with hard as well as with soft calculi, and is generally owing to the Surgeon employing

too much pressure on the blades of the forceps, fearing that the stone may escape from between them ; or it may arise from the large size of the calculus requiring some force to be exercised in its extraction, when the Surgeon is very apt to compress the forceps as he draws the stone down. When this accident is found to have occurred, the Surgeon must remove with small forceps or the scoop the fragments that have been detached. He should then wash out the bladder by copious injections of tepid water, and very carefully examine its interior for any loose pieces. It is seldom that any worse consequence than delay in the completion of the operation results from this occurrence.

The second mode of fracture consists in the crumbling down of the calculus, as soon as it is seized by the forceps, into a soft mortary mass. This can occur only in phosphatic calculi, and is in no way the fault of the Surgeon. It is an unpleasant accident, as it becomes extremely difficult, if not impossible, to clear away the whole of the soft mortary detritus from the interior of the bladder, to the lining membrane of which it tenaciously adheres. As much as possible should be removed by the scoop, and the remainder washed away, as far as practicable, by copious injections ; with all care, however, some will be left, and may be discharged through the wound some days, or even two or three weeks, after the operation. When this happens, the bladder should be thoroughly washed out every day, or every second day, by warm water injections thrown in through a catheter passed down the urethra and allowed to regurgitate through the wound. Should the wound have healed, the detritus must be treated as in lithotrity ; and the bladder must be washed out every second or third day by a large-eyed catheter, until all is removed.

**Accidents during Lateral Lithotomy.**—The principal accidents that may occur during the performance of lateral lithotomy are Hæmorrhage ; Cutting the Bulb ; Missing the Membranous Portion of the Urethra ; Wound of the Rectum ; or Wound of the Posterior Part of the Bladder.

**Hæmorrhage** during lithotomy may occur from three sources : 1. The Superficial Arteries of the Perinæum ; 2. The Deep Arteries ; and, 3. The Prostatic and other Veins. When excessive, from whatever source it proceeds, it is always a very serious complication ; for, even if it do not prove fatal by the induction of syncope, &c., which I believe to be very rarely the case, it is apt to lead to a fatal termination indirectly at a later period, by predisposing to the occurrence of infective processes either local or general. I believe that patients who lose a large quantity of blood at the operation seldom recover.

1. Hæmorrhage from the *Division of the Superficial or the Transverse Artery of the Perinæum* is seldom very dangerous, though occasionally, if these vessels be larger than usual, they may furnish a serious quantity of blood ; in such circumstances their ligature would be required, and might be practised either before or after the extraction of the calculus. It is better, if possible, to wait until the completion of the operation, lest the ligature be pulled off during the extraction of the stone.

2. The *Division of the Deep Arteries* of the perinæum, that of the bulb and the internal pudic, would be attended with far more serious, perhaps even fatal, consequences ; as, from the depth of the vessels, it would be almost impossible to ligature them, unless the patient were very thin, and the perinæum proportionately shallow. The facility of ligaturing any of these

arteries, especially that of the bulb, when wounded, is greatly increased by enlarging the incision upwards. In the event of a ligature not being applicable, the Surgeon would have to trust to plugging the wound round the tube, as described further on, or to the pressure of an assistant's fingers continued for a considerable time, or to the application of forcipressure forceps. The pressure of the fingers of relays of assistants, kept up for a considerable length of time, although it seems to have been an efficient mode of treatment, is painful to the patient, and is difficult to carry out. The pressure must be kept up for many hours: thus South relates a case in which it was maintained for fourteen hours; and Brodie one in which, after twenty-four hours, it succeeded. The assistants should not be changed more frequently than necessary, each keeping up pressure for two or three hours, and removing his fingers as cautiously as possible. It is, doubtless, very rare for these arteries to be wounded when they follow their usual course; though such accidents have happened in the hands of some of the most skilful lithotomists, such as Home, Bell, Roux, and Desault. It was the opinion of Aston Key that the artery of the bulb was generally cut during lithotomy; but in this he was mistaken, so far as its trunk is concerned, though doubtless in many cases the bulb itself may be wounded, and the mesh of twigs, in which the vessel terminates, divided; this, however, would not yield an alarming hæmorrhage. The trunk of the artery of the bulb would, however, be endangered by opening the urethra too high up, and lateralizing the knife too early, and if wounded it bleeds very freely.

It may happen that on pulling the wound widely open the bleeding point may be seen, but at such a depth that it is impossible to apply a ligature. It may then be seized in torsion or forcipressure forceps and immediately twisted, or if this does not succeed the forceps may be left hanging on the vessel for a few hours. For this purpose the forcipressure forceps are the best, as they more efficiently crush and obliterate the vessel.

The internal pudic artery, bound down by a strong fascia, and under cover of the ramus of the ischium, runs but little risk unless the knife be lateralized too much, and the incision be carried too far outwards. In children in whom the ramus of the ischium is to a great extent cartilaginous, this accident could more easily happen. It is in some of the anomalous distributions of these vessels that the greatest danger would be occasioned. The artery of the bulb, the inferior hæmorrhoidal, the dorsal artery of the penis, or the internal pudic, may take so anomalous a course that its division is inevitable; and, as the Surgeon has no possible means of knowing beforehand whether the distribution of the arteries is regular or not, he is not to blame in the event of a vessel being accidentally divided, when it takes an abnormal direction.

If the incision be commenced too high up, and especially if the upper part of the first incision be made by pushing the knife in too deeply, the corpus spongiosum and its vessels may be wounded.

It may be stated as a general rule, that serious hæmorrhage is usually best avoided by making the incisions low; and indeed, I believe that the great secret of success in lateral lithotomy consists in making all the deep incisions as low as practicable; the knife entering the groove of the staff from below upwards, rather than from above downwards.

3. *Venous Hæmorrhage* may occur from two sources—the superficial or the

prostatic veins. It is very seldom that any trouble arises from superficial veins; but in one case I have seen very considerable loss of blood occur from a large vein, running transversely near the upper angle of the wound, lying almost immediately under the skin, which had been incompletely divided. From the prostatic plexus hæmorrhage is most likely to occur in old people, in whom the veins in this situation are often enlarged—almost varicose.

Whether the blood come from a superficial or from a deep source, it is very apt to find its way back into the bladder, to mix with the urine, and thus to escape through the tube rather than from the wound itself; or the blood may probably coagulate in the interior of the bladder, distending that organ and producing a feeling of dysuria. Should it proceed from a superficial source, it may be necessary, as was done in the case just alluded to, to pass a ligature under the vessel, and thus arrest it. If it occur from the prostatic veins, the better plan will be to plug the wound. This is done by passing long strips of lint along the side of the tube, which must be left in the wound and kept pervious: or the lithotomy tube may have a "petticoat" of thick muslin tied around it, into which the strips of lint are stuffed. The advantage of this arrangement is, that the whole apparatus may very easily be removed together at the end of forty-eight hours.

A far more efficient means of applying pressure is the "Air Tampon," invented by Buckston Browne. It consists of an ordinary gum-elastic lithotomy-tube, surrounded by an india-rubber bag, which can be distended with air from a syringe. It is inserted into the wound, so that the india-rubber bag fills its whole length. On distending the bag, firm uniform pressure of any desired force can be applied. After from twelve to twenty-four hours, a little air can be let out so as to reduce the pressure, and this is repeated at intervals till the tube can be removed.

Hæmorrhage from any of the above-named sources, but more especially from the deep arteries and veins, may take place into the bladder. When this occurs, the urine that escapes will be seen to be deeply mixed with blood, and coagula will form in the interior of the viscus, which becomes distended and rises above the pubes, with dulness on percussion in the hypogastric region. The patient will become pale, faint, and cold. In such circumstances, the coagula must be washed out of the bladder with cold water, the source of hæmorrhage ascertained by an examination of the wound, the further flow of blood arrested by plugging or ligature, restoratives administered, the pelvis placed high, and the patient kept cool. If there is any difficulty in washing the clots out of the bladder they may easily be sucked out by applying the aspirator to the tube.

**Wound of the Bulb** is not of very uncommon occurrence in lithotomy: and, I believe, is of no consequence beyond furnishing a small additional quantity of blood. Indeed, the bulb is so situated, in many cases overlapping the membranous portion of the urethra, that this can scarcely be opened without wounding it.

**Missing the Urethra** altogether, and opening up the bladder through, or even altogether beyond, the prostate, is an accident that may happen if the Surgeon miscalculate the depth of the perineum, and keeping the incisions too low, thrust the knife too deeply. It is, I believe, an inevitably fatal accident, as in it the base of the bladder and the recto-vesical fascia are opened, and the patient is thus exposed to the occurrence of diffuse inflammation of, and

infiltration into, the pelvic areolar tissue. I was present many years ago at the *post-mortem* examination of a case in which perhaps the most skilful operator of that day had opened the bladder beyond the prostate, leaving the urethra untouched; the patient died from the cause just stated.

**Wound of the Rectum** occurs more frequently than is generally supposed. It may happen either in consequence of the staff being too much depressed, of the edge of the knife being turned too directly downwards, or of the rectum being distended and overlapping the sides of the prostate. I have also known the lower part of the rectum perforated by the Surgeon's finger, whilst depressing the gut so as to keep it out of the way of the knife. The *Treatment* of this accident will vary according to the size and situation of the aperture. If it be of but moderate extent and low down, just above the anus, it will probably close as the wound granulates and the urine resumes its passage through the urethra. If the incision be more extensive and higher up, the patient will incur the risk of the miserable infirmity of recto-vesical fistula. In such circumstances, the proper treatment is to divide the sphincter and from the opening downwards, and thus to lay the gut and wound into one cavity which will probably fill by granulation, and thus close the urinary passages.

**Wound of the Posterior Part of the Bladder** is very rare; yet it has happened in consequence of the knife being thrust too deeply along the groove of the staff, more particularly in operations on children, and would be specially apt to happen in such cases if the bladder did not contain sufficient fluid at the time. This is an additional reason for injecting the bladder before operating.

In *children*, lateral lithotomy presents certain special difficulties which have already been adverted to. These are: 1, the Surgeon missing the bladder and opening up the recto-vesical space (p. 1058); 2, not opening the urethra and neck of the bladder sufficiently with the knife, but pushing these parts before the finger, and so tearing across the urethra, and thus necessarily being unable to complete the operation (p. 1060); and 3, running the knife too far along the groove of the staff into the bladder, and thus wounding the posterior part of that organ.

#### **Sources of Danger and Causes of Death after Lateral Lithotomy.**

—It will be convenient to describe here only the special dangers of the lateral operation. The influence of kidney disease on the results of lithotomy has already been mentioned at p. 1047, and the effect of age will be subsequently considered.

The **Shock of the Operation** occasionally proves fatal, though probably much less frequently since the introduction of chloroform than was formerly the case. Yet, even now, patients occasionally die from this cause, induced either by a very much prolonged operation, or by the system being weakened in consequence of disease of the kidneys, perhaps of a latent character.

**Hæmorrhage** does not prove fatal so often as might be expected from the great vascularity of the parts incised. Secondary hæmorrhage, of a dangerous or even fatal character, may, however, come on six, eight, or ten days after the operation. I have known it as late as the fourteenth day. It must be borne in mind that, when hæmorrhage takes place after the operation, the blood may find its way into the bladder, distending it with coagula, but not giving any external evidence of the mischief that has occurred. Secondary hæmorrhage will usually cease on plugging the wound with sponge or lint soaked in alum

solutions. Should it prove serious, however, the actual cautery may be employed. In a case that occurred to me, the bleeding on the ninth day was stopped by applying the actual cautery.

**Cystitis** is, in my experience, a rare sequence of lateral lithotomy. I have, however, seen it occur, attended by the secretion of large quantities of viscid, ropy mucus from the bladder, coming away two or three days after the operation, with tenderness in the suprapubic region. It may exist before the operation, or may be produced by long-continued or rough manipulations with the forceps in searching for the stone, or by the irritation of the tube. It is more commonly caused by accumulation of putrid urine in a pouch behind the prostate. The symptoms are apt to simulate those of pelvic peritonitis. The *Treatment* consists of fomentations above the pubes, abundant diluents, and washing out the bladder through the wound with Condyl's fluid diluted with tepid water.

**Diffuse Inflammation of the Areolar Tissue of the Pelvis**, especially of the layers around the neck of the bladder, between it and the rectum, which extend thence under the peritoneum, is the most frequent cause of death after lateral lithotomy. This inflammation, which is always diffuse, followed by rapid sloughing of the textures that it invades, may arise from two causes: 1. From the urine being *infiltrated into the areolar tissue*, in consequence of the incision extending beyond the limits of the prostate, into the loose layers of tissue that lie behind the recto-vesical fascia and around the bladder: 2. In consequence of the *bruising and laceration* to which the neck of the bladder, the prostate, and the textures between it and the rectum, are subjected, in prolonged attempts to extract a large calculus through too small an incision.

1. The danger of *Cutting beyond the Lateral Ligament of the Bladder* in the adult, and thus opening up the loose areolar tissue beyond it, has already been referred to at p. 1054.

The urine, as it escapes through the wound, soaks into the meshes of the loose tissue over which it flows, and thus gives rise to infiltration, followed by rapidly extending inflammation and sloughing, which speedily involve the whole of the neighbouring textures. This mischief generally occurs within the first forty-eight hours; indeed, I have never seen it come on after the third day. It is indicated by the patient being seized with rigors, followed by dry heat of skin, a quick pulse, which, after a time, may become intermittent, and a dry and brown tongue. At the same time he will complain of some tenderness about the lower part of the abdomen, and in the groins; the belly becomes tympanitic, the body is covered with a profuse sweat; hiccough comes on, the pulse becomes fluttering, and death usually occurs about the fourth or fifth day after the operation. In some cases, there are more decided signs of peritonitis; but, as Brodie very truly remarks, this is only induced secondarily by the inflammation of the areolar tissue of the pelvis spreading to the peritoneum.

The *Treatment* of such cases must be conducted on the ordinary principles that guide us in the management of diffuse inflammations. It is only by administering ammonia, with such a quantity of wine or brandy as the state of the system may indicate, together with such nourishment as the patient can take, that life can be preserved. Brodie recommended that a free incision should be made through the sloughy tissues about the wound into the rectum. In one case he saved the patient by passing a curved probe-pointed bistoury

into the wound to its furthest extremity, to the left side of the neck of the bladder; he then pushed it through the tunics of the rectum, and, drawing it downwards, divided the lower part of the gut together with the sphincter; thus laying the wound and the rectum into one. The relief was immediate, and the patient recovered. This plan of treatment certainly seems rational, and worthy of trial in similar cases.

2. Diffuse inflammation of the areolar tissue around the neck of the bladder and prostate arising from *Bruising and Over-distension* of the parts during the extraction of a large calculus is, I believe, a more frequent occurrence than infiltration of urine, and fully as fatal. This sequence of lateral lithotomy is especially apt to occur in those cases in which, in consequence of diseased kidneys, or the existence of other organic mischief, the patient is more than ordinarily liable to the supervention of diffuse inflammation.

In the extraction of large calculi, considerable traction is required, and force must be exerted; hence undue bruising and laceration are very apt to be inflicted upon the parts that constitute the line of incision. It is in this way that the danger of the operation increases almost in exact proportion to the size of the calculus: for here the Surgeon is often placed between the horns of a dilemma. He must either cut beyond the limits of the prostate, and thus incur the risk of inducing urinary infiltration into, and diffuse inflammation of the pelvic fasciæ; or else, by limiting his incision to the gland, and thus having an aperture of insufficient size, he may inflict severe injury by the bruising and laceration of parts during forcible and possibly prolonged efforts at extraction. It must, however, be borne in mind that, the larger the stone the greater probability is there of the existence of old-standing disease of the bladder or kidneys, and of an unfavourable result from this cause. Crosse has drawn up a table that shows very strikingly the influence of the weight or, in other words, of the size of a calculus on the results of lithotomy. He found that when the stone was one ounce and under in weight, the deaths were in the proportion of 1 in 11.25 cases; when it was from 1 to 2 ounces in weight, there was 1 death in 6.61 cases; when from 2 to 3 ounces, 1 death in 2.18 cases; when from 3 to 4 ounces, 1 death in 1.57 cases; when from 4 to 5 ounces, 1 death in 1.66 cases. This table, which has been constructed on the results of 703 cases, illustrates very clearly these facts, that the operation for the removal of a large calculus is far more dangerous than that for the extraction of a small one, and that the danger increases in the direct ratio of the size of the stone.

The symptoms of diffuse inflammation of the areolar tissue arising from this cause very closely resemble those from infiltration of urine, and the treatment must be conducted on precisely similar principles.

**Peritonitis** may occur after lateral lithotomy, as a consequence of the extension of inflammation from the bladder or the pelvic areolar tissue to the serous membrane, from wound of the posterior part of the bladder, or from extension of inflammation from a sacculus of the bladder to its immediate investment of peritoneum. To one or other of these conditions, more especially inflammation of the pelvic fasciæ, it will always be found to be secondary.

**Sloughing.**—In feeble and cachectic persons, especially in those who are the subjects of phosphatic calculi, the wound will often assume a sloughy condition, and heal slowly, and its surface may become coated with phosphates.

In such cases a liberal allowance of stimulants will be required, together with the local application of compound tincture of benzoin; and, in order to facilitate healing at a more remote period, a solution of nitrate of silver may be applied to the wound. The phosphates may be removed by injection of the dilute nitric acid lotion.

**Pyæmia** and **Septicæmia** are occasionally causes of death after lateral lithotomy. Septic poisoning is usually the immediate cause of death in diffuse pelvic cellulitis. Pyæmia, when it occurs, usually sets in after the first week. The secondary abscesses are not uncommonly confined to the joints and subcutaneous areolar tissue, and the pyæmia may assume a chronic form. The treatment presents nothing special.

**Mortality.**—Lateral lithotomy, even in healthy subjects, is always a dangerous operation; and, though the rate of mortality doubtless depends greatly upon the dexterity of the operator, more is, I believe, due to the constitution and age of the patient, and especially to the state of his kidneys. Brodie justly says, "Success in lithotomy most undoubtedly depends in a great degree on the manual skill of the Surgeon, and on the mode in which the operation is performed; but it depends still more on the condition of the patient with respect to his general health, especially on the existence or non-existence of organic disease." As in all other methods of lithotomy the most common cause of death is chronic disease of the kidneys (p. 1042). As examples of the success attained by individual Surgeons in former years, it may be mentioned that Cheselden lost one case in every 10½; Green, at St. Thomas's, cut 40 patients in succession, and lost only one; Bransby Cooper, of Guy's, cut 30 patients in succession without a death, but then lost several, thus bringing the rate of mortality to the usual standard. Liston, during a period of six years, in which he operated 24 times, lost no patient from lithotomy at University College Hospital; but out of the whole 37 cases which he cut during the period of his connexion with that institution, there were 5 deaths; reducing the average to 1 in 7·2. This success was, however, very great when it is taken into consideration that most of these cases occurred in adults, and that many of them were of a very serious character. I find on reference to the Hospital records, that only 7 of the patients were under 10 years of age, whilst 14 were above 50; of these two were 80 years of age, of whom 1 died and the other recovered. I believe that Liston lost only one patient under 60 years of age, and that was a lad of 18, in whom he found it necessary to divide the right side of the prostate as well as the left, and who died of infiltration of urine.

Turning to the general statistics of the operation, we find that of 871 cases tabulated by C. Williams in which lateral lithotomy was performed at the Norwich Hospital in the years 1772 to 1869 inclusive, 116 or 1 in 7·5 died, thus showing a mortality of 13·32 per cent.

Of 1,827 operations performed in various hospitals in this country between 1790 and 1840, collected by Thompson, 229 or 1 in 7·9 died, giving a mortality of 12·5 per cent.

The most important recent statistics are those giving the result of Thompson's practice between 1857 and 1889. Of 127 cases of perineal lithotomy, chiefly lateral, 44 or 34·6 per cent. died. The explanation of this high rate of mortality is not far to seek, for the cutting operation was only undertaken in preference to lithotripsy in a small group of exceptionally

hazardous cases. Thus it follows that no comparison can possibly be made between the mortality following the operation in the hands of a Surgeon who reserves it for exceptional cases, with that which obtained when lateral lithotomy was practically the only method adopted. Thompson's list, being chiefly composed of cases treated in private practice, contains only twelve cases in which the operation was performed on youths and boys; of these only one died. Gilbert Barling finds that of 96 lateral lithotomies performed in thirteen Hospitals in this country during the five years 1888 to 1892, 5 or 1 in 19·2 died, giving a mortality of 15·4 per cent.

As in all other methods of lithotomy **Age** exercises a marked influence on the mortality of the lateral operation. Thus C. Williams found the mortality at the Norwich Hospital, at different ages, to be as follows: below 10 years, 1 in 15·95; 10 to 20 years, 1 in 8·69; 20 to 40 years, 1 in 10·3; 40 to 60 years, 1 in 4·94; 60 to 80 years, 1 in 3·94. The reason of the small mortality after lithotomy in boys, as compared with adults, is most probably the healthier condition of the urinary organs, more especially the kidneys. Hence when boys die it is usually from some accident occurring in the course of the operation, and not from unavoidable circumstances which may follow it. As an example of the success which may follow perineal lithotomy in boys it may be mentioned that Freyer has performed 191 consecutive operations in India without a death—a result probably dependent in no small measure upon the well-known fact that the inhabitants of India bear surgical operations remarkably well.

**MEDIAN LITHOTOMY.**—The median operation of lithotomy is that procedure by which a stone is extracted through an incision in the raphé of the perinæum extending into the urethra behind the bulb. The history of the operation affords an illustration of the mutability of professional practice, and makes it appear as if there were a cycle of opinion in surgery, as in fashion, politics, and philosophy. The median operation was introduced three or four hundred years ago, and continued to be practised up to the middle of the last century, when its tediousness, its painful character, and the excessive mortality following it, caused it to fall into disuse as soon as the safer and simpler method of Cheselden was introduced. However, it was revived under a somewhat modified form; and it is this modern operation that we must here consider.

The old median operation—called also the “Marian,” from Sanctus Marianus, who wrote on it, though it did not originate with him, and the “operation of the apparatus major,” from the number of instruments used in it—was, according to John Bell, performed in the following manner: A grooved staff was introduced into the bladder, and the patient tied up in the usual way; the lithotomist then, kneeling or sitting before him, made an incision in the perinæum, not exactly in the raphé, which was thought to be dangerous, but very slightly to the left side, and terminating just above the anus. The incision was then carried on to the membranous part of the urethra, which was opened on the groove of the staff; and, the knife being kept firmly pressed against the staff, a long probe was introduced into the bladder by its side. The knife and the staff were now withdrawn, nothing but the probe being left in the bladder, to serve as a guide. Along this probe, two iron rods, called “conductors,” were now passed, and with these the operator dilated the prostate and neck of the bladder, by separating the handles; at least, it was said that he dilated them, but, as John Bell *pitifully*

observes, "he dilated, or, in plain language, tore open the prostate gland." These conductors being held aside, "dilators" were introduced so as to enlarge the opening, the forceps was then pushed into the bladder, and the stone extracted.

The principles of this operation were—a limited incision in the membranous part of the urethra above the anus; dilatation, and not incision of the prostate and neck of the bladder: or, to use the words of Le Cat, "small incision: much dilatation."

Its results were, however, so unsuccessful, that it fell entirely into disuse here, and almost so on the Continent, merely appearing from time to time under various modifications at one or other of the Continental schools, and this condition of things prevailed until a new form of the median operation was devised by Allarton.

The **Operation** is performed as follows: A staff, grooved along its convexity, having been inserted into the bladder, the patient is tied up in the usual manner; the Surgeon then, sitting in front, introduces his left index finger

Fig. 871.—Median Operation with Rectangular Staff.

into the rectum, and feels for the apex of the prostate, against which he keeps it lodged, in order to judge of the distance of the prostate from the surface, to act as a guide to the knife, and prevent the rectum from being wounded. A straight-backed bistoury is now entered half an inch above the anus, and pushed straight forwards, to a depth of about an inch and a half in the mesial line, so as to enter, if possible, the groove of the staff at the apex of the prostate. A small incision for-

wards is then made in the groove of the staff, and, as the knife is withdrawn, the incision in the skin is also extended forwards: the knife is then laid aside, and a long ball-pointed probe is introduced into the bladder along the groove of the staff, which is then withdrawn. The probe is now the only guide to the bladder. The forefinger is next introduced along the probe, and by working it forwards the prostate is dilated, and the finger enters the bladder, when, the probe being removed, the forceps is introduced, and the stone extracted. Thus it will be seen that the only real point of difference between this and the old Marian operation, is that in the former the finger is used as the dilator, whilst in the latter the prostate and neck of the bladder were forcibly expanded or torn open by instruments; a difference, however, of no slight moment.

I have found it advantageous to modify this operation in one or two points. The first, which I think of some utility, is to use, instead of the ordinary curved staff, a rectangular one grooved from about one inch above the elbow nearly to the point, resembling the staff introduced by Buchanan of Glasgow (Fig. 871). Its use and advantages are that, when in the bladder, the angle rests against the apex of the prostate, and can be felt in the perineum, and

the Surgeon can judge of the exact point where to enter the knife (directing it so as to enter the groove just below the angle), which he cannot do with the curved staff; the incision upwards also is limited, and there is, besides, less danger of wounding the rectum, the urethra being drawn upwards away from it, and not pushed down against it, as with the ordinary staff. The knife should be straight-backed, having the blade not more than two inches long; so that the Surgeon can tell to what depth he has entered it. I have found it advantageous in practice to carry a beaked director, shaped like a large hernia-director, along the groove, after the incision has been made in the urethra, so as to open up the canal and thus to clear the passage for the finger. And having opened the urethra, I think it better to dilate the prostate before withdrawing the staff; by pushing the finger slowly, with a rotatory movement, along its side, the bladder is entered with more ease and certainty; whereas, if only the probe be used, it may not be stiff enough, and the Surgeon is apt to push the bladder before him. It has been proposed to employ mechanical means of dilatation, instead of the finger, to open up the prostate and neck of the bladder; and I had some dilators for this purpose constructed by Coxeter on the principle of the two-bladed dilator of the female urethra. I tried them on the dead subject; but I have not ventured to use them on the living, lest, by the employment of screw-power, the same deep lacerations of the neck of the bladder should result that were so fatal in the old Marian operation. Indeed, I believe that no safe dilatation can be effected except by the finger, with which no harm can be done, whilst it appears to me that the greatest possible mischief may be done with screw-dilators.

**The Difficulties and Dangers of Median Lithotomy** may best be considered in such a way as to contrast them with those encountered during the lateral operation.

1. **Difficulty in entering the Bladder** is on the whole more common than in the lateral operation; but, although in adults the difference in this respect is probably little marked, in boys it is considerable. In them, the prostate not being developed, the bladder tends to be pushed upwards and backwards before the finger; and, unless the neck of the bladder be well opened, there appears to be great danger of tearing across the membranous part of the urethra, and of pushing backwards the separated bladder. In boys, also, the parts are so small and undeveloped, and the space to work in is so narrow, that an ordinary finger can only with great difficulty be got through the neck of the bladder unless this has been freely incised. But, by doing this, we depart entirely from the guiding principle laid down by the advocates of the median operation, viz., dilatation and not incision.

2. **Hæmorrhage** is rarely troublesome if the incision be made accurately in the middle line, and the bulb be not wounded. At times, however, the primary bleeding is tolerably free, although there is no vessel that can occasion dangerous secondary hæmorrhage.

3. **Wound of the Bulb** is especially apt to occur in the median operation, and sometimes the bulb so overlaps the membranous part of the urethra that it is impossible to avoid cutting it. It is true that division of the bulb in the middle line seldom gives rise to much hæmorrhage, but cases have occurred in which it has proved fatal.

4. **Wound of the Rectum** is much more likely to occur in the median than in the lateral operation. If the median operation be performed on the

dead body, it will be found that the back of the bistoury comes very close to the finger in the rectum; and if another finger be placed in the wound, they will come into very close apposition just anterior to the prostate. In the old Marian operation, the rectum used to be very frequently cut, gas and feces issuing from the wound.

5. **Opening up the Pelvic Fascia**, which has already been shown to be one of the most serious accidents in lateral lithotomy, on account of the infiltration of urine and diffuse inflammation which are likely to follow, cannot occur in the median operation if the knife be not used after the urethra is opened, the prostate being dilated solely with the finger. Although the so-called "dilatation" of the prostate with the finger is undoubtedly in reality a process of laceration, this does not extend into or through the capsule, and thus the lateral true ligament of the bladder cannot be wounded as occasionally happens in incising the prostate with the knife in the lateral operation.

6. **Difficulty in Extraction of the Stone**.—The weak point in the median operation consists in the limited space allowed for the introduction of the forceps and the extraction of a large stone. The incision is made, and all the manipulation is practised, towards the apex of the narrow triangle formed by the rami of the pubic bones. The base of this triangle is represented by a horizontal line corresponding to the level of the membranous portion of the urethra, and consequently does not occupy the widest part of the perinæum: it is formed by the lower portion of the triangular ligament, the space behind it being filled up by the rectum and its muscles, and the ischio-rectal fat. The ligament forms a barrier stretching across the perinæum, which cannot be depressed, and requires to be divided laterally into the ischio-rectal fossa before a stone of any considerable size can be removed. It was in consequence of the extensive bruising and laceration of these structures, and the difficulty experienced in bringing the stone through them, that the old Marian operation fell into disuse.

The second obstacle to the extraction of the stone lies in the prostate; but as this is easily overcome by dilatation, it cannot be considered a serious one.

The third and most important obstacle is situated at the neck of the bladder, and is dependent upon the narrow tense ring beyond the prostate which remains intact in spite of the dilatation and laceration to which the prostate has been subjected. I have found, by experiments on the dead body, that this inner ring of the neck of the bladder cannot be expanded to a size more than sufficient for the extraction of a calculus of one inch in diameter without laceration or incision: and its laceration or rupture is well known to be one of the most dangerous and fatal accidents in lithotomy. A calculus over one and a half inches in diameter cannot be extracted by the median operation without the employment of great violence. But, though much force is usually required in order to extract a calculus of even moderate size through this tense ring at the neck of the bladder, it is an undeniable fact that serious consequences seldom follow the violence so used, and that a degree of force which would be fatal in lateral lithotomy, may be employed without danger in the extraction of a calculus by the median operation. In this respect the extraction of a calculus by the median operation resembles the removal of one through the dilated urethra of the female; the great point in favour of the median over the lateral procedure, and the cause of its comparative safety, being that the lateral true ligament of the bladder is not incised, nor otherwise

opened. But, it may be said, what is easier, when the finger is in the bladder, than to push a probe-pointed bistoury along it, and cut downwards and outwards through these structures into the ischio-rectal fossa, if the stone be large, and thus get plenty of space? Nothing could be easier or more simple; but what would be the consequence? We at once reduce the median to the conditions of the lateral operation. A free incision in the neck of the bladder and prostate increases the tendency to hæmorrhage, opens up the fascia, and exposes the patient, in fact, to all the dangers of an ill-contrived lateral operation, destroying at once and altogether the principle of the median operation—viz., dilatation and not incision; and, if we do not gain space by incision, but attempt to extract a moderately large stone by dilatation of the parts, we shall certainly not succeed, but our dilatation will end in a laceration, not only of the substance of the prostate, which is safe, but of the neck and perhaps of the base of the bladder, which will be fatal.

**Mortality.**—It is not easy to determine the death-rate following this operation, as the results are generally included with other methods of perineal lithotomy. Barling has collected 48 operations performed between 1888 and 1892; of these 6 died, giving a mortality of 12·5 per cent.

**OTHER METHODS OF PERFORMING LITHOTOMY.**—Having fully described the suprapubic, lateral, and median operations of lithotomy, it remains only to mention very briefly certain other methods which have been adopted, but which at the present day have been almost, if not entirely, discarded.

**Bilateral Lithotomy.**—This operation, which was introduced by Dupuytren, consisted in making a curved transverse incision with its concavity backwards half an inch in front of the anus. The dissection was carried down to the central point of the perinæum and the membranous urethra opened on a grooved median staff. Along this a *lithotome caché* was passed, which divided both lateral lobes of the prostate in a direction downwards and outwards. The stone was then extracted in the usual way.

**Medio-Bilateral Lithotomy** was recommended by Civiale for the extraction of stones too large for the ordinary median operation. It consisted of a combination of the median and bilateral. The membranous part of the urethra was opened on a rectangular staff as in the median operation. The lithotome was then introduced and the prostate and the soft structures between it and the surface incised. If the stone was not very large, the deep incision was confined to one side only, and used with a probe-pointed bistoury.

**Recto-vesical Lithotomy** was suggested by Sanson in 1847 as a means of removing large stones and avoiding the dangers of hæmorrhage. It was thus performed. A staff grooved on its convexity was passed into the bladder, the finger was then passed into the rectum, and the part of the staff lying in the membranous portion of the urethra felt for; a knife, with its edge directed forwards, was then passed along the finger into the groove of the staff and withdrawn, dividing the internal and external sphincters and the skin at the margin of the anus; it was then reintroduced with its edge directed downwards, and run along the groove of the staff, dividing the prostate and notching the neck of the bladder, and the stone was then extracted in the usual way.

Having now described the various operations of lithotomy it will be convenient to reserve the consideration of the relative advantages of the principal methods until after the operation of Lithotrity has been described in the following Chapter.

## CHAPTER LXVIII.

URINARY CALCULUS (*continued*).

## LITHOTRITY.

THE operation of **Lithotrixy**, by which the stone is crushed in the bladder and the fragments expelled or extracted through the urethra, is of modern invention ; for, though various rude attempts may at different times have been made with this view, it was not until about the year 1818 or 1820 that the subject began to attract serious attention ; and to the French Surgeons is undoubtedly due the great merit of having introduced this operation. About this time Civiale, followed by Amussat, Leroy, and others, began constructing instruments, which, though very imperfect, yet were sufficient to break down a calculus in the bladder. This was publicly done by Civiale in 1822. From this period lithotrixy made rapid progress ; and the successive improvements made by the Surgeons whose names have just been mentioned, together with the ingenious mechanical adaptations introduced by Charrière and Weiss, enabled Surgeons to attack the stone with certainty and effect.

The importance of lithotrixy was urged upon the profession by Civiale, Amussat and Heurteloup in France and Brodie and Costello in this country. The practice thus established by these Surgeons has from time to time been improved by the ingenuity of others, amongst whom Fergusson, Coulson and Thompson are conspicuous. Up to the year 1878 the operation of lithotrixy was practised on the lines originally laid down by Civiale and Brodie, the main features of which were to crush the stone by repeated operations, each limited to a few minutes, and to allow the fragments to be passed by the natural efforts of the patient. In 1878, however, Bigelow of Boston demonstrated that it was possible to break the stone up at one prolonged operation, and completely to wash out the fragments at the same time through a large catheter or evacuator. To this method of operating he gave the name of "Litholapaxy," but its enormous advantage over the older methods was so quickly recognized, and it so speedily became universally adopted, that the distinctive name is now unnecessary, and when we speak of lithotrixy we mean crushing the stone and removing the fragments at the same time by Bigelow's method. By this great improvement Bigelow not only reduced the sufferings of the patient and the dangers of the operation, but made it applicable to much larger stones than could possibly be removed by the older method.

**Instruments.**—The instruments required for lithotrixy are the following :

An ordinary **sound** with a short beak is required to examine the condition of the bladder. The steel sound should be hollow, so that the bladder may, if necessary, be injected through it after or during sounding, without the necessity of changing the instrument (Fig. 872). This will be found of much service in the later stages of the operation for detecting small fragments.

A **brass syringe** should be at hand with which the bladder may be injected if necessary.

An Otis's **Urethrometer** is often useful, by which the size of the passage can be measured as a guide to the evacuator to be used.

Some large-sized **conical steel bougies**, from 12 to 18 of the English scale, are of great use in measuring and dilating the passage before inserting the lithotrite or the large evacuator.

The instrument for breaking the stone is called a **lithotrite**. This has

Fig. 872.—Lithometer Sound for measuring Stone. It is hollow, so that the bladder can be emptied and injected through it.

undergone various modifications and improvements at the hands of Mechanics and Surgeons. To Weiss in this country, and to Charrière in France, we are especially indebted for having brought it to its present state of perfection. In the earlier days of lithotripsy Weiss's thumb-screw lithotrite was generally used. Fergusson invented a rack-and-pinion instrument,

Fig. 873.—Civiale's Lithotrite for Crushing Fragments.

which, however, found little favour with Surgeons. Civiale's instruments, having the double action of screw and hand pressure, were those to which many gave the preference until the invention of the cylindrical handle by Thompson.

The lithotrite must be made of well-tempered steel ; and should be tested

Fig. 874.—Position of Hand in using Civiale's Lithotrite.

by being made to crush a piece of sandstone grit, of about the size of a walnut. It should be of as full a size as the urethra will readily admit ; it must have the male blade well serrated, and the female or under blade pierced at its root by an oval aperture, through which the detritus of the crushed stone is forced, and thus any jamming of it in the angle between the blades is prevented. The female blade should be considerably wider than the male to avoid nipping of the mucous membrane of the bladder.

The larger lithotrites, intended to break stones of considerable size, are made with a fenestra in the female blade; those intended to crush small fragments with a broad blade without a fenestra.

The lithotrite should be cut out of a bar of solid steel, and not, as is the

Fig. 875.—Thompson's Improved Lithotrite.

case with some instruments, made of a plate of this metal, turned up at the edges; as such a one possesses too little strength to be used with safety on large and hard calculi.

Civiale's lithotrite, such as is represented in Fig. 873, has a most ingenious

Figs. 876, 877, 878, 879.—Bigelow's Lithotrite.

double action, enabling the Surgeon to work it either by the pressure of the hand or by a screw. In this instrument, there is no fenestra in the female blade. It is of two kinds. In one, the male blade is much narrower than the female; in the other, it is nearly as broad. The first kind is useful in

crushing through moderate-sized stones; the second kind, with the broad male blade, is used in completely crushing and removing the detritus of small calculi, and the large fragments into which a stone has been broken by the open-bladed lithotrite.

Thompson's lithotrite (Fig. 875) somewhat resembles Civiale's in its action, but is more handy. The handle of the female blade is round, which gives the operator a better grasp of the instrument, and the sliding movement is converted into a screw action by drawing up the button on the handle with

Fig. 880.—Clover's Lithotrity Injection-Apparatus. 1. Elastic Stylet for Lithotrity Catheter. 2, 3, 4, 5. Lithotrity Catheters with large eyes at end or in different sides, to be used with or without the Injection Apparatus.

the thumb of the right hand without relaxing the grasp of the left on the handle.

Bigelow introduced several modifications in the lithotrite. For large stones he had constructed instruments larger, heavier, and more powerful than any previously in use. The handles are large and massive, and oval in form to fit the hand (Figs. 876, 877). The blades are somewhat longer, and the female blade has a long blunted point, curved towards the floor of the urethra, so as to protect the membranous part, against the roof of which the point of the instrument is directed as it passes through (Figs. 878, 879). The sliding is converted into the screw movement by twisting the cap shown in the figure with the right hand. These very massive instruments are only required for large

and hard stones which it would formerly have been considered unwise to crush. For smaller stones Bigelow uses instruments of the ordinary size.

After the stone has been crushed the **evacuator** is required to remove the fragments. This consists essentially of a powerful india-rubber bottle which

Bigelow's Catheters, Full Size.

Fig. 881.—Bigelow's Straight Catheter.

Fig. 882.—Bigelow's Curved Catheter.

can be connected with a large catheter. The bottle is emptied into the bladder by squeezing, and when the pressure of the hand is removed it sucks the fluid back with considerable force, bringing out at the same time the

Fig. 883.—Removal of fragments of Stone by Bigelow's original Evacuator. Below, point of one of Bigelow's Catheters.

crushed fragments of the stone. In all forms of evacuator a glass vessel is attached to the lowest part of the bottle, into which the fragments gravitate. Clover's simple instrument (Fig. 880) may be considered the parent of the evacuators now in use. It was provided with a number of catheters open at the end or having large eyes. When passing the open-ended catheter a gum

elastic stylet with a round metal point was introduced. The instrument was intended to wash out the detritus and smaller fragments after each operation, but did not meet with the favour it deserved, partly owing to its inefficiency from the weakness of the rubber bottle commonly provided.

In Bigelow's instrument the catheters are much larger than in Clover's, No. 29 French (18 English) being the largest size. The eye is very large and

Fig. 884.—Tubc for filling the Evacuator.

Fig. 885.—Bigelow's Evacuator.

is placed in the front of the instrument close to the end. The catheters are of different forms, the most convenient being one with a short curve like that of a sound. A perfectly straight instrument is also often very useful, and is preferred by Bigelow.

The actual size and shape of the evacuating catheters most commonly used are shown in Figs. 881 and 882.

The various modifications of the evacuator are represented in the accompanying figures. Fig. 883 represents Bigelow's original evacuator, which he, however, abandoned for the improved form represented in Fig. 885. By

turning the stopcock connected with the catheter and fixing the india-rubber tube shown in Fig. 884 to the cock at the apex of the bottle, the contents may be expelled and fresh water drawn in without disconnecting the bottle from the catheter. I have to thank Professor Bigelow for furnishing me with the accompanying woodcuts, which represent the latest instruments used by

Fig. 886.—Sir H. Thompson's Improved Evacuator.

himself. Modifications of Bigelow's evacuator suggested by Thompson and Otis are shown in Figs. 886 and 887.

**Preparation of the Patient.**—Before proceeding to the operation of lithotripsy, it is necessary that the patient's constitution should be carefully

Fig. 887.—Otis's Evacuator.

attended to; the bowels should be freely opened, and the condition of the digestive organs regulated, and, more especially, all local irritability about the urinary organs should be subdued by ordinary medical treatment. This is even of greater importance than in lithotomy, as the prolonged mechanical disturbance to which the bladder is exposed may aggravate any existing cystitis. The urine should be carefully examined, and the condition of the kidneys ascertained as far as possible. In a subsequent part of this Chapter, when we come to the comparison of lithotomy and lithotripsy, we shall examine the conditions which either indicate or negative the performance of the latter operation. At present, we will suppose a case in which the Surgeon may have recourse to lithotripsy, with every prospect of readily and

permanently ridding the patient of his calculus.

**Use of Anæsthetics.**—In former times many Surgeons habitually performed the operation without an anæsthetic, believing that the sensations of the patient were a useful guide to the Surgeon, helping him to avoid nipping or otherwise injuring the bladder. For the success of the present method of

operating an anæsthetic is essential, both to enable the Surgeon to continue the operation till the stone is completely crushed, and to facilitate the subsequent washing out of the fragments.

**Operation.**—The operation of lithotritry may be divided into four stages : 1. The introduction of the lithotrite ; 2. The search for and seizure of the stone ; 3. The crushing of the stone ; and 4. The evacuation of the fragments.

As a **preliminary step before the operation**, Bigelow recommends that the urethra be measured with Otis's urethrometer, in order to ascertain the size of the evacuator that should be used. Thompson recommends the passage of a large conical steel bougie, which answers the same purpose, and at the same time slightly dilates the canal. The bougies passed should be from Nos. 14 to 18 of the English scale at the thickest part. With a urethra admitting No. 16 no difficulty need be anticipated in the operation, even if the stone is large. If the orifice is too narrow to admit this, it should at once be divided with a probe-pointed bistoury.

1. **Introduction of the Lithotrite.**—If the size of the stone is known,

Fig. 888.—Introduction of the Lithotrite.

the lithotrite must be adapted to it. If it be large and probably hard, a full-sized, fenestrated lithotrite should first be passed, with which the calculus may be broken into several small fragments. After this it may be withdrawn, and a smaller non-fenestrated instrument used to complete the crushing.

The operation may most conveniently be performed with the patient lying on his back upon a flat table close to its right edge. The pelvis must be raised by a hard pillow, so as to allow the stone to roll up on the posterior surface of the bladder. The Surgeon, standing on the right side of the patient, carefully introduces the hollow sound, or catheter, and draws off the urine ; he then slowly and very cautiously injects the bladder, by means of

the brass syringe, with from four to six ounces of some antiseptic solution, such as boric acid lotion. The use of drawing off the urine is to make sure of the bladder holding the proper quantity of fluid when it is afterwards injected; and the object in injecting it, is to distend it to such an extent as to prevent the mucous membrane from being seized in the grasp of the lithotrite, or injured by the splintering of the stone. The instrument is then withdrawn, after the situation of the stone has been detected by it, and the lithotrite is introduced. Should the patient be able to hold enough urine, viz., from three to four ounces, to protect his bladder from the action of the lithotrite or the fragments, the injection may be dispensed with, and the lithotrite may be used at once. As this is straight, with a sharp elbow near the beak, some little skill is required in passing it. In doing this the Surgeon must keep his eye upon the short curved beak of the instrument, the direction and position of which must constantly be judged of; and especial care must

Fig. 889.—Brodie's Method of Seizing the Stone.

be taken, in carrying it under the pubes, not to injure the urethra by pushing the beak of the lithotrite forwards too suddenly, instead of winding it, as it were, under the arch of that bone. The instrument should first be introduced nearly parallel to the abdomen, the penis being held between the fore and middle fingers, and drawn over it. As the lithotrite passes down, it must be gradually raised to the perpendicular position; and as its curve passes under the pubes, the handle should be depressed between the thighs (Fig. 888). The direction of the curve must be borne in mind, and the position of the handle varied in accordance with the course which this takes. No force must on any account be used. The weight of the handle is quite sufficient to make the instrument enter the bladder. The lithotrite should be well greased with carbolized oil, so that the blades and screw may work smoothly.

**2. Seizure of the Stone.**—The next point is to seize the stone, which will generally be found in the situation where its presence was detected during the sounding of the bladder. If large, the stone will probably lie low, near the neck of the bladder; if small, it is most frequently met with at the inferior

fundus. In seizing the calculus a good deal of tact may be required. The plan recommended by Brodie should first be adopted. The closed lithotrite is pressed gently against the inferior fundus of the bladder, so as to make a conical depression in this situation. The male blade is then gently withdrawn till some slight sense of resistance is felt, indicating that it is touching the other side of the bladder. A gentle shake may then be given to the handle, and the blades closed, when, in a large proportion of cases, the stone will be found to be between them (Fig. 889). During the whole of this proceeding the left hand, holding the instrument, must be kept perfectly steady, and no force of any kind should be used. If the stone is not at once grasped in this way, the manœuvre must be repeated, turning the blades slightly first to one side and then to the other. If this does not succeed, the plan recommended by Civiale may be tried: The closed lithotrite is used as a sound, and the situation of the stone determined. The beak of the instrument is then very gently turned towards the opposite side of the bladder, and the blades opened. The open instrument is then turned back again to the side on which the

Fig. 890.—Civiale's Method of Seizing the Stone behind the Prostate.

stone lies, and the blades closed. If the stone is not seized by either of these plans, it is possible that it is lying in a pouch behind the prostate. To reach it in this situation the handle of the lithotrite must be depressed between the patient's thighs, and the instrument turned round, so that the beak is directed towards the floor of the bladder (Fig. 890). It may then be carefully opened and closed again. This manœuvre is very frequently necessary in patients above 60, in order to crush the last fragments towards the end of the operation. If the stone be round and smooth it may be grasped only after many failures; the calculus slipping away between the blades of the instrument, and being merely scraped by them.

The essential conditions during this stage of the operation are that the utmost gentleness be used in all movements of the lithotrite, that the female blade be kept as steady as possible with the left hand, while the instrument is opened and shut by moving the male blade only, which, from its lightness, can be manipulated with great delicacy, and lastly, that the operator should picture to himself with each movement of the instrument the exact position in which the blades are placed.

3. **Crushing the Stone.**—When the stone has been seized, it is held by pressing the blades together with moderate firmness, while the instrument is turned from whatever position it may be in till the beak looks forwards, and the calculus is placed about the middle of the bladder. It is highly improbable, with the instruments at present in use, that a portion of the mucous membrane of the bladder has been seized with the stone; but should such an accident have happened, it will be detected by the sense of resistance while attempting to bring the stone to the middle of the bladder (Fig. 891). If this were felt it would be necessary to release the stone again. If, however, the instrument moves freely in the bladder, as soon as it is in the proper position the blades must be pressed firmly together, while the sliding movement is converted into the screw movement by drawing up the button in Thompson's lithotrite or by turning the cap in Bigelow's. In both these instruments this can be done with the right hand, while the left keeps the instrument perfectly steady. If the stone be small and not too hard, the mere pressure of the hand, without using the screw, may suffice to crush it. When the screw is used it should be gradually worked by a series of short and sharp turns, so as to constitute almost percussive movements. In this way the calculus is generally made to crumble down, rather than to fly asunder; and, as it yields, the screw

Fig. 891.—Position of Lithotrite in Crushing the Stone.

must be worked tightly home. The blades of the instrument may then be opened again, and a fragment of the broken calculus seized and crushed in the same way as before; and thus the complete disintegration of the stone is gradually effected.

If a large fenestrated lithotrite has been used, it must be withdrawn as soon as the stone has been broken into fragments of moderate size, and the smaller non-fenestrated instrument passed to complete the crushing. This should not be removed from the bladder, if possible, till from the impossibility of catching any definite fragments it may be hoped that the whole calculus is thoroughly crushed. Repeated withdrawal and reintroduction of the lithotrite wastes time and increases the risk of bruising the urethra and prostate. Before withdrawing the lithotrite, the Surgeon must be careful to see, by the scale on the handle, that the male blade is well home. If this be not the case, and the instrument be enlarged by any fragments or detritus entangled between the blades, laceration of the neck of the bladder or urethra might occur in attempting to withdraw it. If the blades do not close perfectly, the screw must be forcibly turned, and if that fails the female blade must be held very firmly with the left hand, while the male blade is unlocked, and rapped sharply upon it two or three times; this will usually dislodge any fragments between the blades.

4. The last stage of the operation consists in **Removing the Fragments by means of the Evacuator**. For this purpose an evacuating catheter (Figs. 881, 882, p. 1080) is passed into the bladder. This should be the largest the urethra will safely admit. This has already been determined by measurement with the urethrometer or conical sound. Bigelow generally uses No. 29 French (18 English), but Thompson states that he seldom finds it necessary to exceed No. 15 or 16 of the English scale. Bigelow prefers the straight instrument (Fig. 881), but the curved catheters usually pass more easily. Firm pressure is commonly required to pass the catheter, but no undue force must be used. It is better to use a smaller size than to run the risk of injuring the urethra by attempting to force in a larger instrument than it can safely take. The catheter having been passed, the bladder is completely emptied; the fluid that escapes being caught in a vessel and strained through muslin to collect any fragments of the stone that it may contain. It is essential that the india-rubber bulb should be of sufficient strength; otherwise the regurgitant stream will not be sufficiently forcible to withdraw any but the smallest fragments from the bladder. The fluid in the bottle should always contain some antiseptic: boric acid is perhaps the best. The evacuator, previously filled, having been attached to the catheter, by alternately compressing and relaxing the rubber bulb of the instrument the bladder is filled and emptied. At each injection the fragments are thrown up. At each relaxation of the bulb, some are sucked out in the rush of water. These drop into the glass receiver, where they can be seen by the Surgeon, who thus judges of the progress he is making. This process is continued until all fragments are evacuated. Should some have been left behind, too large to pass through the evacuating catheter, the lithotrite must again be introduced, and these broken up sufficiently for evacuation, which must then be resumed and continued until the bladder is emptied of all calculus. The Surgeon knows when fragments are left behind too large to pass, by their falling against the eye of the catheter, blocking it, and thus preventing the return of water into the bulb of the evacuator, as shown by its failing to expand. This may arise also from the eye of the instrument having come in contact with the wall of the bladder, or from the catheter having been accidentally withdrawn till its end lies in the prostatic urethra. Before concluding that the obstruction is due to a fragment, these two conditions must be excluded, by pushing the catheter a little further in and rotating it. A more certain sign of a fragment is a loud and distinct click every time the bulb is allowed to expand.

The removal of every fragment is the essence of Bigelow's operation. No stone must be left behind. The operation should be concluded at one sitting, however prolonged.

The **Time Occupied by the Operation** varies with the size of the stone and the ease with which the fragments are caught. Before Bigelow demonstrated the safety of prolonged operations under anæsthetics, the strictest rules were laid down as to the duration of the sitting. The first was not to exceed four minutes, and it was considered sufficient to break up the stone, leaving the fragments to be dealt with subsequently. The subsequent sittings were also limited to a few minutes. The sittings were repeated every three or four days till the whole stone was broken up, a longer or shorter interval being allowed according to the amount of irritation caused by the operation. It was

only in the case of a very small stone that the operation was finished at one sitting. At the present time the crushing is completed in all but very exceptional cases at one sitting, and the results of the practice have shown that the irritation caused by a prolonged operation carefully performed is infinitely less than that set up by a mass of sharp fragments such as are left after partial crushing of a stone. If the stone is of any size an hour or an hour and a half may be occupied in completely crushing it. The longest time that Thompson has occupied in an operation at a single sitting has been 70 minutes. This was in the case of an unusually hard uric acid calculus weighing  $2\frac{3}{4}$  ounces. In a case recorded by Surgeon-Major Keegan, of Indore, the stone weighed  $3\frac{1}{2}$  ounces, and was at first too large to be grasped by the lithotrite, but by gradually nibbling at it he reduced it till it could be fairly seized and crushed. The operation lasted four hours, but the patient went home well on the fourth day. In the performance of prolonged operations at a single sitting Thompson enjoins the very important caution that the patient's lower extremities should be encased in long woollen stockings, and that especial care be taken to prevent his getting chilled by exposure.

**After-Treatment of Lithotritry.**—After the operation a half-grain morphia suppository should be administered and the patient put to bed with a hot fomentation over the lower part of the abdomen. If the operation has for any reason been incomplete he should pass water lying on his back lest any fragments should be washed on and lodge in the urethra. When the operation is complete this precaution is not necessary. In very rare cases some retention of urine may follow owing to slight swelling of the neck of the bladder, necessitating the passage of a soft catheter. The diet should be chiefly milk and barley-water for a few days, and if any stimulant is required Hollands and barley-water is the best. The slight cystitis that usually follows the operation requires no special treatment. If there is much irritability of the bladder, hyoscyamus is often of use. If the cystitis is more severe it must be treated as described in the Chapter on Diseases of the Bladder.

**Complications in Lithotritry. Size of the Stone.**—Before the invention of rapid lithotritry with evacuation no stone over one inch and a half was considered suited to lithotritry. At the present time any stone that can be grasped in the blades of the lithotrite, and is not too hard to be broken, may be removed by this method. It must be remembered, however, that a large stone necessarily means a long operation, and in very old or weak patients, and especially in those suffering from chronic bronchitis and emphysema, two hours under an anæsthetic is accompanied by considerable danger. In such cases, possibly, a better chance of life would be given by suprapubic lithotomy.

**Cystitis before the Operation** need not prevent its performance if the stone is small. The removal of the source of irritation, and the washing out of the foul mucus with the evacuator, will often bring immediate relief. If the stone be large, and the cystitis acute, lithotomy would probably give the best chance if the condition of the patient renders some interference urgently necessary.

**Chronic Enlargement of the Prostate** was formerly one of the most serious complications of the operation of lithotritry, not so much from the difficulty it caused in the introduction of instruments as from the obstacle it offered to the expulsion of the fragments. With the present

evacuators, however, moderate enlargement of the prostate can scarcely be termed an inconvenience. When the prostate is enlarged, the stone, if small, or the fragments after the first crushing, fall into a pouch behind the neck of the bladder, and it is then impossible to seize them except by reversing the blades in the manner already described (p. 1085). When the stone is seized the blades must be carefully turned into the ordinary position before it is crushed. In such cases Buckston Browne has found the introduction of the rectal bag (p. 1044) useful as a means of preventing the fragments falling into the pocket behind the prostate.

In cases of extreme enlargement lithotripsy may be impossible, as the lithotrite may not be able to enter the bladder, or if it can be introduced its blades may be too short to reach the stone in the pouch behind the middle lobe. In such cases suprapubic lithotomy is the preferable operation.

**Stricture of the Urethra**, if it can be dilated to a size sufficient to admit the necessary instruments, is not a serious complication in lithotomy at a single sitting. In former times it was considered an almost insuperable obstacle to the operation from the obstruction it offered to the expulsion of the fragments.

**Sacculation of the Bladder** is a most serious complication, the existence of which we have unfortunately no means of determining before the operation. The fragments are very apt to fall into the sacculi, from which they are with difficulty dislodged by the evacuator. If they are left they may cause recurrence of the stone in the bladder, or give rise to encysted sacculi. If septic cystitis follows, it is possible that a fragment lodged in a sacculus might lead to ulceration and perforation.

**Accidents during Lithotripsy** can hardly arise except from carelessness or the use of improper force. The large instruments can scarcely make false passages, unless used with great violence; yet I have known of a case in which the beak of the instrument was driven through the urethra into the space between the bladder and the pubes by too early and forcible depression of the handle. Nipping the coats of the bladder is almost impossible with the instruments now in use. Bending or breaking of the lithotrite can scarcely occur if the instrument has been properly tested before being used. Jamming of the instrument by a hard fragment becoming wedged in the angle between the male and female blades where they join the shaft is practically impossible with the modern instruments. If it should happen, the bladder may be opened in the perinæum using the lithotrite as a staff, and the blades brought out and freed, or they may be exposed by suprapubic cystotomy, and cleared or cut off with a file according to circumstances.

**Accidents after the Operation.**—**Hæmorrhage** is a rare occurrence. Should the bladder become filled with clots they may easily be removed by reintroducing the evacuating catheter and sucking them out with the evacuator, or by the introduction of a large sized gum-elastic catheter, to which an aspirator may be applied.

**Impaction of Angular Fragments of Stone in the Urethra.**—This most dangerous and painful accident was not uncommon in the old system of lithotripsy. In modern lithotripsy it can happen only if a large fragment has been accidentally left behind or if from any cause the operation has to be left incomplete. If there is any reason to believe that fragments are left in the bladder the patient must be kept in a recumbent position, as **impaction**

most commonly arises from moving about too much or straining to pass water in an upright position. The lodgment of a fragment not only occasions great local irritation, ending perhaps in cystitis or abscess, but may give rise to severe rigors and nervous prostration. The fragments are especially apt to lodge in the prostatic urethra, or about the bulb. When the pieces are impacted low down in the urethra, it is absolutely

Fig. 892.—Urethral Lithotrite.

necessary to remove them from the canal as speedily as possible, lest the constitutional disturbance occasioned by them prove fatal to the patient. This may be done in various ways. Most frequently, they may be pushed back into the bladder, by passing a large catheter carefully down to them. The most convenient instrument for this purpose is one that is open-ended, so

Fig. 893.—Urethral Forceps.

that the fragment may be received in the aperture at the end of the instrument, and so pushed on before it. Through such a catheter as this a stream of water may be injected, and the fragment thus forced back. Should these manœuvres fail, it has been proposed to crush the fragments in the urethra with a small lithotrite (Fig. 892); but this plan is somewhat hazardous, as it

Fig. 894.—Urethral Forceps, with Alligator-jaw action. The smaller figure presents the Jaws of Forceps open.

is very difficult to avoid pinching up the mucous membrane of the canal with the bits of stone. The safest practice seems to be, either to extract them through the urethral orifice, or to cut them out through the perineum. Extraction through the urethral orifice may be effected with forceps (Figs. 893, 894), or with Civiale's instrument (Fig. 318, Vol. I.). Should these means fail, or should the fragment be very deeply seated, as in the membranous portion of the urethra, and the local and constitutional irritation produced by

it be so great as to threaten abscess or a fatal termination, the better plan would be to remove it through a median incision in the perinæum. If such an operation as this be required, the Surgeon might feel disposed to extend the incision a little, and empty the bladder of any remaining detritus by means of a scoop.

**Cystitis.**—The occurrence of cystitis was formerly attributed solely to the mechanical irritation to which the bladder is subjected during the operation. The success which has attended lithotripsy at a single sitting has however demonstrated beyond a doubt that the bladder is much more tolerant of mechanical irritation than was at one time believed. The effect produced directly by the operation is, in most cases, limited to slight catarrhal inflammation, with an abundant secretion of mucus and some irritability of the bladder. In the operation by numerous sittings this was frequently aggravated by the presence of large and angular fragments. The thick mucus secreted under these circumstances is never perfectly expelled, but a certain amount remains adhering to the mucous membrane of the bladder after micturition. This speedily undergoes decomposition, and the most potent cause of cystitis is the contact of this foul mixture of mucus and urine within the interior of the bladder. When decomposition sets in, the alkaline products of the decomposing urine render the mucus thick and ropy, and this still further adds to the difficulty of its complete expulsion. Under these circumstances the patient becomes poisoned by the absorption of the putrid contents of the inflamed bladder, the temperature rises, the tongue becomes brown, and if not relieved the condition will very likely terminate in death, the immediate cause of the fatal result being, in most cases, extension of the decomposition to the pelvis of the kidney and suppurative nephritis. Such a condition necessarily offers an insuperable obstacle to any further crushing operation, supposing any stone to be still present, and the only course that gives a chance of life is to perform median cystotomy, by which not only are the fragments removed but the bladder is efficiently drained of its decomposing contents. The prevention of this complication is best accomplished by the use of antiseptics. The instruments should be oiled with carbolized oil and washed in carbolic lotion before being used, and the water used to wash out the bladder should contain some antiseptic. Decomposition may, however, reach the bladder along the partially stagnant layer of mucus which forms in the urethra as the result of catarrhal inflammation of the mucous membrane. It is not sufficient therefore merely to carbolize the instruments and to use antiseptic solutions in the evacuator; the end of the penis should be constantly covered with a strip of lint soaked in glycerine and carbolic acid. In spite of all precautions, however, decomposition sometimes takes place, and then the bladder must be washed out twice a day with an antiseptic solution. The mechanical irritation caused by so doing is of little importance when compared with the dangers of a septic accumulation in the bladder.

**Atony of the Bladder** is one of the most dangerous conditions that can occur in lithotripsy. This happens usually in old people, in whom the urinary organs may appear to be in a peculiarly favourable condition before the operation, the patient being able to hold his urine for six or eight hours, and to bear the injection of ten or twelve ounces of fluid. The danger of the condition is, that the bladder does not possess sufficient contractile power to expel

its contents. These consequently accumulate in the lower fundus, and irritate the mucous membrane; and thus the foundation may be laid for fatal septic cystitis. The atony of the bladder appears to arise partly from that natural want of expulsive power which is not unfrequent in old people, and partly from paralysis of the organ, induced by the contact of the instruments, especially after a prolonged operation. The bladder must be regularly emptied with a catheter, and antiseptic injections if there be any evidence of cystitis.

**Disease of the Kidneys** is in Lithotrity, as in all other operations on the urinary organs, the most common cause of danger and of death. The various forms of fatal kidney disease have been fully described in Chapter LXV.

**Pyæmia and Septicæmia** are occasional but uncommon causes of death.

**Constitutional Disturbance.**—Very considerable constitutional disturbance occasionally follows lithotrity. The patient is seized with severe and long-continued rigors, followed by profuse sweating, lasting for many hours. These serious symptoms were formerly most apt to come on after the first sitting; but the experience of Bigelow's method has shown that they are not more prone to occur after a prolonged operation than after the short sittings formerly adopted. They may pass off quickly, as in the analogous conditions to those that are apt to follow the introduction of instruments in stricture, &c., or they may persist and assume the character already described as indicating septicæmia or renal inflammation. These serious consequences are especially apt to happen when there is previous disease of the kidneys. Indeed, there is no condition that is more directly antagonistic to the success of lithotrity than interstitial nephritis. In other instances, again, the fatal result is more directly dependent on the irritation induced by the operation leading to the formation of abscesses in the neighbourhood of the prostate, or around the neck of the bladder; and in other instances, again, on the supervention of unhealthy suppuration in some of the sacculi that are occasionally met with in this organ. The *Treatment* of this state of things should consist in the free administration of stimulants—brandy, ammonia, and ether—followed by a full dose of opium, and abundant warm diluents. If the bladder contains foul urine this must be removed by washing out with antiseptic solutions. Especial care must be taken in those cases in which any stone remains not to repeat the sitting for at least a week or ten days after the rigors have passed off.

**Mortality.**—The rate of mortality following lithotrity in the adult, in the hands of a Surgeon especially skilled in the performance of the operation, is shown by the results recorded by Thompson in a paper read before the Royal Medical and Chirurgical Society in 1890. The record includes 800 operations performed upon 685 patients. Of these 475 were performed by multiple sittings, with 33 deaths, or 7 per cent.; whilst of 325 cases in which the modern operation at one sitting was performed only 12, or a little over 3½ per cent., died. This list does not include uric acid or oxalate of lime concretions of less than twenty grains in weight, nor the phosphatic concretions so frequently removed from the bladder of patients with enlarged prostate.

Barling has collected 300 cases of lithotrity performed in thirteen hospitals in this country during the years 1888 to 1892; of these 24 or 8 per cent. died. In 43 cases the patients were under 10 years of age; of these only one died.

**LITHOTRITY IN BOYS.**—Until Bigelow introduced his method, although lithotrity had occasionally been performed on boys, it was not considered a satisfactory or advisable proceeding, partly because of the small size and delicate structure of the child's urethra, and partly because of the difficulty of expelling the fragments. During the last few years, however, it has been extensively practised with the most satisfactory results, especially in India, by Keegan, Freyer, Dennis and others, and in this country by Walsham, Southam, Barling and others. Keegan has clearly shown that the urethra of a male child is much more capacious than is generally supposed. The smallest lithotrite used in any case was No. 4½, but in the great majority of children over three years of age, No. 8 could be passed with ease. The urethra should be measured before selecting the instrument, either by a urethrometer or a conical bougie. If necessary the meatus must be enlarged. Keegan finds that the narrowest part of a child's urethra, except the meatus, is at the junction of the penile and scrotal portions, 2½ to 3 inches from the meatus. The lithotrite must be fully fenestrated, so that the risk of the instrument becoming clogged may be as small as possible.

The size of the evacuators varies from No. 5 to No. 10; as a rule, No. 8 or No. 9 can easily be passed. The evacuating catheters must be provided with stylets, which should be introduced before the instrument is withdrawn, with the object of displacing any fragment which may be engaged in the eye of the catheter. The details of the operation are the same as in the adult, and all the manipulations must be carried out with the greatest gentleness. The bladder should be emptied and then injected with 2 or 3 ounces of warm boric lotion. Keegan lays it down as a rule that no instrument must be used which will not pass freely in and out of the bladder, and he states that he has met with cases in which no lithotrite could be safely used, and cutting became necessary. He states that small fragments are apt to remain at the neck of the bladder; these can be felt with a finger in the rectum and pushed back on to the floor of the bladder. The aspirator must be worked very gently.

The **special dangers** of lithotrity in young children depend on the small size of the parts in which the manipulations are carried out, and the ease with which, unless the greatest care be taken, the urethra may be lacerated or the bladder wall torn. Edmund Owen has recorded a case in which rupture of the bladder occurred during the use of the aspirator. The rupture, which was extraperitoneal, was sutured through a suprapubic incision, and drainage was established by a perineal incision, but unfortunately the child died of collapse in eight hours.

The **Mortality** attending lithotrity in children in the hands of Surgeons skilled in the operation has been remarkably low. Thus of the first 125 cases recorded by Keegan only 4 died, the fatal result in each case being due to organic kidney disease. The ages of the children varied from one year and nine months to fourteen years, the average age being 6·38 years. The average weight of the stone was 89·15 grains, and the average stay in hospital was 4·5 days. In only one case was there known to be recurrence of the stone. Of a total of 663 lithotrities in children performed by eight Surgeons in India only 18 died, giving a mortality of 2·71 per cent.

**PERINEAL LITHOTRITY.**—Although the treatment of a stone in the bladder by crushing it through a perineal incision had been advocated by

many distinguished Surgeons, more especially by Malgaigne, under the name of "Lithotriptic Lithotomy," the operation was first performed on definite lines by Dolbeau of Paris in 1862. He opened the membranous urethra on a grooved staff, dilated the neck of the bladder with a six-bladed "dilator," crushed the stone with a powerful "lithoclast," and extracted the fragments with small forceps and a scoop. The operation found little favour with Surgeons, for it has generally been considered that, when lithotripsy is not available on account of the large size of the stone, suprapubic lithotomy is the proper treatment.

Reginald Harrison has, however, recently advocated the revival of the operation in certain cases. He opens the membranous urethra and passes the finger along a Wheelhouse's small gorget into the bladder. The stone is crushed with forceps shaped somewhat like the blades of a lithotrite, the larger ones being provided with a screw in the handles. The fragments are removed with an aspirator or forceps. Among the advantages claimed for perineal lithotomy by Harrison, are, the rapidity with which a large stone can be removed, the opportunity which it allows of introducing the finger into the bladder, the possibility of dealing with some forms of prostatic enlargement, and the benefit of the temporary drainage when there is cystitis. Harrison has performed the operation fourteen times.

#### CHOICE OF OPERATION FOR STONE.

The various methods by which a calculus may be extracted from the bladder have now been described, together with the dangers attending the different operations and the mortality following them. It now remains to consider the relative merits of the available methods, in such a way as may help the Surgeon to decide in any given case by which operation he may most safely proceed to remove the stone. Both lithotomy and lithotripsy have been reduced to great simplicity and certainty; but neither can be exclusively practised. It is undoubtedly the duty of the Surgeon to make himself familiar with the practice of both, and to adopt that which promises best in the particular instance with which he has to do.

In dealing with this important subject it will be convenient to consider children and adults separately, for the circumstances which determine the decision of the Surgeon are somewhat different in the two cases.

In **Boys under Puberty** a stone in the bladder may be removed by lithotripsy, by lateral lithotomy, or by the suprapubic operation. Median lithotomy should never be undertaken in children, for reasons already given at p. 1073. Until recently the routine treatment was lateral lithotomy, and the operation was attended with great success. Thus, of 35 children under 10, operated on by Cheselden, only 1 died; of 58 children cut for stone at St. Thomas's, but 1 case proved fatal; and the average mortality in children is not more than about 1 in 14. Of 48 cases recently performed in hospital practice in this country only 2 died. Since suprapubic lithotomy has been revived, however, and lithotripsy in young children has been proved by Keegan and others to be a highly successful operation, the lateral operation has to a considerable extent been abandoned, some Surgeons regarding the suprapubic operation as the best method for routine adoption, and others practising lithotripsy as the operation of choice and reserving suprapubic lithotomy for

exceptional cases, chiefly those in which the stone is very large or the introduction of the necessary instruments impracticable. At the present time it is impossible to decide with certainty which plan of treatment will prove superior for general adoption. In the hands of a Surgeon skilled in the necessary manipulations it may justly be concluded that lithotritry for the majority, and suprapubic lithotomy for exceptional cases, yield results equal to, if not exceeding, those obtained by any other line of treatment. When, on the other hand, a Surgeon who has had but limited experience of lithotritry in the adult, is called upon to treat a case of stone in the bladder of a child, he will probably be wise to resort to lithotomy rather than to the crushing operation. Concerning the choice between the lateral and the suprapubic operations in a case in which either is available, it may be said that no very reliable guidance can be obtained from statistics, which in the case of the high operation are derived largely from cases in which it was performed on account of the large size of the stone or other unfavourable conditions. No evidence is so far forthcoming to show that the suprapubic operation is attended with a lower mortality than the lateral, when performed by practised hands. It must, however, be allowed that the suprapubic operation is the easier and requires no special manipulative skill or experience, and thus recommends itself to the general Surgeon, whose opportunities of operating for stone are limited, and who bears in mind the important fact that when a child dies after lateral lithotomy it is almost invariably as the result of some accident connected with the operation. In the treatment of large stones the high operation should certainly be preferred, as also when the case is complicated by deformity of the outlet of the pelvis or ankylosis of the hip. Lastly, the lateral operation is said, especially in children, to leave the patient sterile, from injury to the ejaculatory ducts; Haemetadt found that of eighteen married men in whom lateral lithotomy had been performed in childhood only one had children. The remarks which will subsequently be made regarding the influence of disease of the urinary organs in determining the choice of an operation in the adult have but little bearing in the case of children in whom the bladder and kidneys are rarely in a condition of advanced disease.

In **Adult Males** the general question may be considered by a reference to statistics, whilst in dealing with an individual case the Surgeon is guided in his choice chiefly by the size and character of the stone, and the condition of the urinary organs.

As Thompson pointed out in his admirable course of Lectures, delivered at the Royal College of Surgeons, the only method by which we can ascertain the effect of lithotritry in reducing the mortality from stone in the bladder, is to contrast the results obtained when lithotomy was the sole operation practised with those of the present day, when lithotritry has become the rule and the cutting operation the exception. For this purpose he contrasts the statistics of three periods: first, when lithotomy only was performed; secondly, the transitional period from 1835 to between 1860 and 1870, when about an equal number of cases were submitted to each operation; and lastly, the modern period, when lithotomy has been the exception. For the first period he selects the statistics of the Norwich Hospital from 1770 to 1830, as published by Crosse. During that period 326 adult males were cut for stone; of these 64 died, or 20 per cent. 75 cases were over 60 years of age; of these 22 died, or 29·3 per cent. These figures correspond very closely with the

larger statistics collected by Thompson, including 1,827 lithotomies. Of these 799 were adults, of whom 161 or 20·2 per cent. died.

For the second period Thompson gives the statistics of Keith of Aberdeen and Fergusson. Keith operated on 277 male adults, of whom 45 died, or 15 per cent. Of these 161 were cut, with 38 deaths or 24 per cent.; 116 were submitted to lithotripsy, with 7 deaths or 6 per cent. Fergusson operated on 219 male adults, of whom 45 died or 20 per cent. Of these 110 were cut, with 33 deaths, or 30 per cent.; 109 were crushed, with 12 deaths, or 11 per cent.

For the third period we may take Thompson's own recent statistics, giving the results of his practice between 1878 and 1889.

Of 434 male adults submitted to operation 32 or 7·3 per cent. died. Of these 378 were crushed (325 at one sitting), with 14 deaths, or rather over 3½ per cent. In 39 perineal lithotomy was performed, with 14 deaths, and in 17 suprapubic lithotomy was performed, with 4 deaths.

The general result of these figures is to show that when lithotomy was the sole mode of treatment, about 1 in 5 of all adult males operated on died. During the transition period the death-rate was about 1 in 6; since lithotripsy at one sitting has become the operation of choice, it has fallen to about 1 in 13·5.

It may therefore justly be decided that lithotripsy should be the operation undertaken for the treatment of a stone in the bladder of the adult male, unless some condition be present which offers a definite contra-indication to its performance. In this connexion we must consider the character of the stone and the condition of the urinary organs.

**Size and Character of the Stone.**—With regard to the size of the stone, there is no doubt that a small stone is more favourable for lithotripsy than a large one. All calculi below one inch in diameter may easily be crushed provided no circumstance is present rendering the operation undesirable. In regard to larger stones, it is difficult at the present day to lay down any hard and fast line. Formerly, it was not considered advisable to attempt to crush a stone that was above one inch and a half in diameter; but since the introduction of Bigelow's method, stones considerably above this size have often been successfully removed. Much will depend on the composition and density of the calculus. The chief objection to lithotripsy in large stones was not so much that the stone could not be broken, because unless it was too large to get into the blades of the lithotrite this usually could be done; but that the mass of fragments to come away by the urethra, and the repeated operations required for their removal generally caused a dangerous amount of irritation. The use of evacuators has overcome these objections for stones of two inches in diameter; but we are not in a position as yet to say what is the maximum size that can safely be attacked. The different forms of stone vary as regards the ease with which they are broken up. *Uric acid* calculi, giving a clarringsound, do not disintegrate readily, but split up into sharp and angular spicula and scales. *Oxalate of lime* calculi, occurring chiefly in young people, break up very readily; and, as there is usually a co-existing healthy state of the urinary organs, the cases have a favourable issue. *Phosphatic calculi*, which are soft and friable, and do not yield angular fragments requiring repeated disintegration, may, even if of larger size than that mentioned, be broken up. At the same time the patient may often derive great benefit from

the thorough washing out of the bladder with the evacuator, as these concretions are commonly the result of chronic cystitis, with alkaline decomposition of the urine. But the shattered state of system, and the irritable condition of the urinary organs accompanying phosphatic calculi, often counterbalance the advantage that would otherwise have been derived from the character of the stone.

The presence of *several stones* does not add materially to the difficulties of lithotrity. If, however, the numbers are very large and the size small, it would perhaps be safer to remove them by lithotomy than by a prolonged crushing operation which might take one or two hours. Thus, in one case I removed 50 small calculi, varying from a quarter to half an inch in diameter, by the median operation. Occasionally multiple calculi are very small, so that they can mostly be washed out uncrushed through the evacuator; from 50 to 100 separate stones may be thus removed.

The rule may, therefore, at the present time, be summarised thus:—Any stone which can be grasped by the lithotrite and broken may be removed by lithotrity provided other conditions are favourable.

2. **The Conditions of the Urinary Organs** that influence the propriety of performing lithotrity or lithotomy have reference to the state of the *kidneys*, the *bladder*, the *urethra*, and the *prostate*.

The question of the advisability of lithotrity was, before Bigelow's improvements in the operation, much influenced by the degree of irritability of the bladder and urethra, and the ease with which the patient bore the introduction of instruments, but these points have little influence now that the operation is done at one sitting under an anæsthetic. In fact an irritable patient would suffer far less from lithotrity than from lithotomy.

Cystitis, if moderate in degree, is no bar to lithotrity at one sitting unless the stone be very large; in fact the removal of the calculus and the thorough cleaning of the bladder by the evacuator frequently leads to rapid improvement. If, however, the stone is large, the cystitis severe, the irritability of the bladder great, and more especially if the patient be old and the inflammation has not yielded to the ordinary treatment, lithotomy will probably be the safer proceeding. Great hypertrophy of the bladder with fasciculation and sacculation are disadvantageous for lithotrity owing to the difficulty of completely removing the fragments with the evacuator. Still by thorough washing and by repeating it, perhaps in a few days, the difficulties may be overcome. The difficulties in lithotrity from atony of the bladder have already been described (p. 1091). At the present time atony of the bladder is no objection to lithotrity. Stricture of the urethra under ordinary circumstances offers no great obstruction to lithotrity (p. 1089). In fact, if a staff can be passed on which lithotomy could safely be performed, the stricture can easily be stretched up to the point necessary to admit the lithotrite and the evacuating catheters. Enlargement of the prostate, unless very excessive, offers but little difficulty in lithotrity (p. 1088). Acute inflammatory disease, or abscess of the prostate, necessarily prevents the performance of lithotrity.

In encysted calculus lithotrity is obviously impossible.

The condition of the *kidneys* merits special attention. If these organs be the seat of consecutive nephritis (p. 1001), the danger of any prolonged operation in the bladder is greatly increased. If, therefore, the stone be a large one, and especially if cystitis also be present, lithotomy is probably the safer opera-

tion. If, however, the stone be of only moderate size it may more safely be crushed. In lithotrity the danger of renal disease consists chiefly in interference with the function of the kidneys following a prolonged operation; in lithotomy this danger is less in proportion as the operation is shorter, but there is an additional source of danger in the tendency to diffuse inflammation of the bladder and surrounding tissue that always coexists with kidney disease.

**Diabetes** is not commonly associated with calculus. I have, indeed, but very rarely seen the two conditions combined. The only form of calculus that I have seen in diabetic patients has been the uric acid. It is necessarily very hazardous to operate in such cases, at least by lithotomy. And even if lithotrity be determined on, it would be well to defer the operation until the glycosuria has been checked or removed, at least for a time, by proper treatment.

I have said nothing in this comparison between cutting and crushing of the comparative painfulness of the two operations, as both are in the present day done during anaesthesia. The suffering during the after-treatment, when all goes well, is about equal, while the discomfort is infinitely less in lithotrity.

To sum up, therefore, the rules of practice may be given as follows:—

In all ordinary cases in the adult, lithotrity by Bigelow's method at a single sitting should be the rule of practice for stones up to two inches, provided they are not too hard to be crushed by the lithotrite.

When the stone is above two inches in diameter, or when a large number of small stones are present, lithotomy is usually preferable.

Lithotomy is required in cases of extreme enlargement of the prostate, encysted calculus, or large stone with severe cystitis.

As a general rule the *suprapubic* operation should be selected in those cases in which lithotrity is contraindicated or impracticable. When the cutting operation is resorted to on account of the size of the stone, suprapubic lithotomy should always be performed. The same may be said of encysted calculus (p. 1038), and great enlargement of the prostate; in the latter case the Surgeon may thus be enabled to deal with the prostatic outgrowth as well as to remove the calculus (*see* Hypertrophy of Prostate). When lithotomy is performed because of very severe cystitis the *median* operation may be undertaken if the stone is small, but suprapubic drainage has proved so satisfactory that this condition also may be treated by the high operation.

**The Result of Operations for Stone** will depend in a great measure upon the condition of the bladder, and the character of the stone. If the bladder be healthy, all symptoms will cease on the removal of the calculus, and the patient will be restored to perfect health. This usually happens when the calculus is of the uric acid or the oxalate of lime variety, and of renal origin. If, however, the bladder be unsound, irritable, and the urine alkaline from decomposition, and disposed to the deposit of phosphatic matters, the calculus being phosphatic, and chiefly, if not wholly, vesical in its origin, then an irritable state of bladder may be left, or may speedily return after the operation, which will consequently have been productive of little, or only of temporary benefit.

**Recurrence of Calculus after Operation.**—This may take place from four distinct causes:—1, in consequence of a continuance of the constitutional condition, under the influence of which the calculus was originally formed; 2, from the descent of a renal calculus, which has existed in the kidney before

the first operation ; 3, from a fragment of calculus having been accidentally left in the bladder ; and 4, from the accumulation of phosphatic deposit in the fundus of the bladder, or in the line of imperfectly healed incisions.

Relapse from the first cause is probably not very common. When it occurs, the recurrent calculus is of course of the same composition as the primary one. The occasional occurrence of relapse shows the necessity of continuing constitutional treatment adapted to the particular diathesis, after the removal of the calculus from the bladder.

Recurrence of calculus from the descent of a new stone from the kidney is especially liable to be met with in those cases in which the primary calculi are multiple and small. In these cases, the relapse may take place very shortly after the first operation, and will be preceded by the usual symptoms of the descent of a stone from the kidney.

Relapse from the retention of a fragment which serves as the nucleus of another stone, will undoubtedly occasionally occur, although its occurrence is fairly attributable to want of due care on the part of the Surgeon. It is apt to happen more frequently after lithotritry than after lithotomy, and it is probably to this cause chiefly that we must refer the greater liability to relapse after the crushing than the cutting operation. But it may happen after lithotomy that a fragment is left behind when the stone has been broken, during extraction, and the bladder not thoroughly washed out. But even in this case, the bit of stone will usually be carried out of the wound by the flow of urine through it.

Recurrence from the formation of a phosphatic calculus in the bladder, as the result of chronic cystitis with decomposition of the urine, may occur occasionally after lithotomy, but is much more common after lithotritry. In these cases a lithotrite must be passed, and the soft mass crushed up and washed out with a catheter and evacuator. The patient must be taught to wash his own bladder out regularly every day with a dilute acid solution, to which some quinine may be added. I once had under my care a patient eighty years of age, on whom I performed lithotritry for a uric acid calculus. During the next five years I removed large phosphatic concretions on more than a dozen occasions. At last the tendency to recurrence ceased, and for three years before his death no new formation took place. On some occasions the mass measured over an inch and a half in diameter, yet under anæsthetics it was broken up and washed out with Bigelow's apparatus without the slightest irritation, the patient usually returning to the country on the second day after the operation.

Phosphatic deposit may take place also in the track of a partially healed lithotomy wound, forming a crust on its surface. I have known such a deposit to form in the perinæum, when the wound had degenerated into a sinus.

According to C. Williams, the relapses in the Norwich Hospital were 27 in 1015 operations, or 1 in 36, or in 935 lithotomies 1 in 33. Lithotomy was performed a second time on 24 patients; a third time on 3; and a fourth time on 1. Twenty-three were cured, 5 died. All the patients were males. The registers of the Louisville Hospital give 1 relapse in 116 cases of lithotomy ; and according to Civiale the return of calculus after lithotomy was in Bavaria 1 in 32, in Bohemia 1 in 46, in Dalmatia 1 in 43, and in France 1 in 74.

After lithotritry, relapse is more common ; although it is *probably less*

frequent now than formerly, and will become less frequent as the details of the operation come to be better understood and more carefully practised. In the practice of Civiale it occurred about once in every tenth case. It still occurs often enough to show the necessity of the Surgeon most carefully examining the bladder before he pronounces the patient cured; and even then watching him for some length of time, in order to meet a recurrent calculus at its first formation, and to adopt means for its early removal. Lithotripsy cannot therefore be said to be so complete a cure in all cases as lithotomy.

Not only is recurrence of calculus more common after the former than after the latter operation, but it occasionally happens that patients who have been lithotritized successfully, and in whom no recurrent calculus has formed, continue to suffer for a great length of time afterwards from very distressing irritability of the bladder, which resists in the most obstinate manner all the ordinary methods of treatment. This is not the case after lithotomy; when a patient once recovers his bladder usually regains its tone completely, and no trace of evil consequences is left.

*Treatment.*—In the event of a secondary calculus forming, whether after lithotomy or lithotripsy, either method may again be employed, according to the nature of the case. As a rule, the bladder may be cleared of the recurrent calculus by means of the lithotrite. If lithotomy be performed, the suprapubic method is probably the best, even though the primary stone had been removed from the perinæum. The scarring and altered relations of the parts would probably render a repetition of the perineal operation difficult, and if the rectum have become adherent to the membranous portion of the urethra and the apex of the prostate, in consequence of the contraction of the old cicatrix, the danger of wounding the bowel would be considerable.

#### URETHRAL CALCULUS.

Calculi are not unfrequently found impacted in the urethra, especially in boys. They are most commonly formed in the kidney, whence they pass into the bladder, and thence into the urethra, through which they usually escape; but in some instances they lodge in the latter channel, more especially at the bulb or in the navicular fossa. These calculi are commonly of the uric acid or oxalate of lime varieties; they are generally round, but not uncommonly elongated or spindle-shaped.

There can be little doubt, however, that in some more rare cases calculi may be formed primarily in the urethra. They will then be found to be phosphatic, usually consequent upon stricture, and perhaps of large size. In some cases these concretions are moulded in the prostatic and bulbous portions of the urethra, being elongated, rounded at one end, and pointed at the other. In other instances, again, they appear to be formed in a pouch that lies to the outside of the urethra, and is connected with it only by a small aperture. I have removed a stone of this kind composed of triple phosphate, weighing an ounce, and about the size of a walnut, smooth and rounded, from a point lying between the upper wall of the urethra and the symphysis pubis, in a clergyman who had for many years suffered from very tight stricture. One of the most remarkable instances of this kind is represented in Fig. 834, taken from a drawing in Carswell's collection at University College. The stone here was of very large size—equal in bulk to two horse-chestnuts.

**Impaction of a Calculus in the Urethra of an Adult** may be suspected by the difficulty that is occasioned in micturition, and ascertained by the possibility of feeling the stone through the walls of the canal, or of detecting it by introducing a sound into the urethra.

*Treatment.*—In the adult, urethral calculi may be removed by extraction, lithotrixy, or incision. When situated towards the anterior part of the canal, a urethral calculus may frequently be extracted by working it forwards between the finger and thumb, the patient being under chloroform. Should this plan not succeed, it may be removed with a long and very narrow-bladed pair of forceps; occasionally, when it has reached the navicular fossa, it will not pass through the meatus unless this be enlarged with a probe-pointed bistoury. If the calculus cannot be extracted in this way, it should, if possible, be pushed back into the bladder and removed by lithotrixy. If, however, it be firmly fixed, an incision must be made down upon it, through the urethra, by which it may be removed. It is a good rule not to make this incision in any part of the urethra anterior to the scrotum if it is possible to avoid it; for, in consequence of the coverings of the penile portion of the urethra being very thin, the aperture will probably not close, but a fistula will be left. When the stone is situated in the scrotal portion of the urethra, there would be some risk of abscess and of urinary infiltration if the incision were made through the lax tissues of the scrotum. Hence if, as it sometimes happens, the stone may be pushed back to the bulb or membranous urethra, but not into the bladder without using a dangerous amount of force, it is better to cut down upon it, and extract it through the perineum by an incision in the mesial line. This operation may readily be done by passing a staff, grooved along its convexity, or an ordinary director, as far as the calculus, and making an incision upon the end of it, so as to lay open the urethra; the staff is then removed, and the calculus extracted by means of a slender pair of forceps. A catheter should next be passed into the bladder, and retained there for a few days, in order to lessen the tendency to the formation of urinary fistula.

It may happen that the calculus, impacted in the urethra, is only one of several; others being lodged in the bladder. After removing the calculus from the urethra, the Surgeon should pass a sound into the bladder, so as to ascertain whether any other concretions exist in that organ; and if so, they should at once be removed by the median operation of lithotomy, the incision in the membranous portion of the urethra being extended backwards to the prostate. I once saw Liston extract two vesical calculi, after having removed one that had blocked up the urethra, by converting the perineal incision into that of lateral lithotomy.

**Impaction of a Calculus in the Urethra of a Boy.**—In boys the impaction of a calculus in the urethra is almost the sole cause of retention of urine. When called, therefore, to a child suffering from this condition, we should always examine the urethra from the perineum or rectum and

Fig. 895. — Extra-urethral Calculus.

by the introduction of a sound. Relief may be given in one of two ways: 1. If the stone be near the meatus, it may be extracted; and, 2, if situated more deeply, it may be pushed back to the perinæum, there fixed by the finger, and cut down upon in the mesial line. It should not be pushed back into the bladder unless the Surgeon is prepared to crush it; and as in children this operation requires special instruments, it can only be exceptionally that such a line of treatment would be justifiable.

If the stone is allowed to continue fixed in the urethra very serious consequences may ensue. If it completely obstructs the canal, the membranous part of the urethra may give way during the violent efforts at micturition, and extravasation of urine will take place. In other cases, if it be irregular in shape, a small quantity of water may pass. Under these circumstances there is intense irritability of the bladder, the urine passing with much pain every few minutes, or constant dribbling may set in. The distended bladder can be recognized above the pubes. The penis is usually turgid and semi-erect. Some purulent discharge will be observed about the meatus, and there will be some hard ill-defined swelling in the perinæum, with much tenderness in this region. The presence of the stone may at last cause ulceration of the urethra with the formation of urinary abscess in the perinæum, followed perhaps by extravasation of urine into the scrotum and its diffusion beneath the superficial fascia in the usual direction, with the ordinary disastrous results of inflammation and sloughing. On passing a sound, no stone probably will be found, as this has escaped from the urethra, and is lying in a pouch in some part of the perinæum, and in the midst of the broken-down areolar tissue and pus; into this cavity the sound will readily pass.

The *Treatment* in these cases is simple. It consists in introducing a grooved staff, placing the boy in the lithotomy position, and then freely incising the mesial line of the perinæum, so as to open up the urinary abscess; in this the stone may be found, or it may be so enveloped in the sloughy tissues as to escape detection; perhaps it will escape through the wound in a few days, and be found lying in the bed. Should there be much hæmorrhage a catheter may be tied in and the wound plugged with salicylic or iodoform-wool secured by a T-bandage. If extravasation of urine have occurred, free incisions must be made in the usual way, and the child be put upon a stimulating diet.

For **Foreign Bodies in the Bladder**, see Vol. I., p. 895.

#### CALCULUS IN THE FEMALE.

Stone is of rare occurrence in women; in London, certainly, it is not often met with. Thus, South states that, during a period of twenty-three years, 144 males were operated on for stone at St. Thomas's Hospital, and only 2 females. In some districts, however, stone would appear to be more common in women than this. Thus, according to Crosse, at the Norwich Hospital, the proportion has been about 1 woman to 19 men. Civiale stated, as the result of his researches, that in the North of Italy, the proportion was 1 to 18; and in France, about 1 to 22. At University College Hospital we had not had a case of stone in the female for many years until 1855, when three came under my care in the course of a few months; and since that period many have occurred.

Vesical calculi in the female are often nothing more than phosphatic incrustations deposited around some foreign body that has, either accidentally or from depraved motives, been passed up the urethra. In this way hair-pins, pieces of bougie, of catheter, or of pencil, will often be found to form the nucleus of the concretion.

The **Symptoms** of stone in the female closely resemble those that occur in the male, and its presence may usually be easily detected by means of a short and nearly straight sound, or a female catheter. It is often simulated very closely by the irritation occasioned by a vascular urethral caruncle, or by an irritable bladder. The larger calculi can be felt from the vagina if firm pressure be made at the same time above the pubes.

Large calculi may be met with in very young female children. I have removed a uric acid calculus encrusted with phosphates, measuring  $1\frac{1}{4}$  inch in length by  $\frac{3}{4}$  inch in breadth, from a little girl four years old. The stone was removed unbroken, by gradual dilatation of the urethra. In the adult they may attain a very large size. I have extracted one measuring 8 inches in its long, and 6 inches in its short circumference from a young woman.

Calculus in the female bladder, if allowed to remain unrelieved, will occasion the same morbid conditions in the urinary organs as occur in the male. The stone may be discharged spontaneously through the urethra—if of small size, without any bad results following; but if large, by a process of ulceration, in consequence of which permanent incontinence of urine will remain. It may slough through into the vagina; or lastly, it may offer a serious obstacle during parturition to the descent of the foetal head, when, if it cannot be pushed aside to be dealt with afterwards, it must be cut out, or craniotomy must be performed.

**Treatment.**—A stone may be extracted from the female bladder by one of three methods: 1, by Dilatation of the Urethra; 2, by Lithotrixy; 3, by Lithotomy. These different operations cannot be employed indiscriminately, but each one is more especially adapted to certain kinds of calculus.

1. **Dilatation of the Urethra** is the simplest method and is available for the removal of small stones. The dilatation may best be performed with Hegar's uterine dilators. In this way the canal can, in the adult, easily be dilated sufficiently to allow the introduction of the index finger and the extraction with forceps of a stone eight or ten lines in diameter, without any evil results. In the removal of moderate-sized calculi, however, the great objection to the operation is the liability to incontinence of urine resulting from it. This is not by any means necessarily complete; but a weakened state of the bladder results, so that the patient cannot hold her urine for more than an hour or two at the most.

2. **Lithotrixy** should as a general rule be practised in cases in which the stone is of moderate size, but too large to be removed whole through the dilated urethra. The operation requires to be practised on the same principles as in the male, but differs in certain details. The chief obstacle consists in the difficulty with which the bladder retains urine or water that is injected into it. In consequence of this there may not only be great difficulty in seizing the stone, the bladder collapsing and falling into folds around it, but also danger of injuring the mucous membrane with the lithotrite. In order to cause the bladder to retain the necessary quantity of urine, the pelvis must be well tilted up, and the urethra compressed against the lithotrite by the

fingers of an assistant. It is well not to dilate the urethra before the introduction of the instrument, as this difficulty is thereby increased.

The ordinary male lithotrite is not a very convenient instrument to use in the female bladder, the handle being awkwardly long. This is especially the case in female children. Hence I have found it convenient to have a shorter instrument constructed, with which it is far more easy to work in the female bladder. The stone should be completely pulverized, as in the male, and the fragments removed in the same way with an evacuator and large catheter. This plan is much better than that sometimes recommended of dilating the urethra and extracting the pieces with forceps, as in this proceeding the sharp fragments are very likely to lacerate the mucous membrane. The whole stone must be removed at one sitting.

For all calculi in the female bladder, except those of the very largest size, this operation is the most applicable. I have in this way crushed and extracted at one sitting, from the bladder of a lady about 50 years of age, a phosphatic calculus fully as large as a hen's egg. Lithotritry may be had recourse to at all ages, in the very young as well as the old. I have crushed and successfully removed a large calculus from a child three and a half years of age, the youngest patient on whom I have operated by this method. Although the urethra of so young a female child cannot, without danger of incontinence, be much dilated, yet it may safely and easily be enlarged sufficiently to admit a moderate-sized lithotrite.

3. **Lithotomy** should as a general rule be reserved for cases in which the calculus is of large size, or has formed around a foreign body, or in which very severe cystitis exists. The bladder may be opened above the pubes or through the anterior vaginal wall. The former operation is to be preferred, especially if, as is usually the case, the stone is large, or if cystitis is present. The vaginal operation is very easy, but is open to the objection of possibly leaving a permanent urinary fistula—a danger, however, which is probably not great if the lips of the incision have not been bruised by the forceps or by the extraction of the stone.

*Suprapubic Lithotomy* in women differs in no very material respect from the same procedure in men; except that it requires additional care in consequence of the difficulty there is in causing the female bladder to retain enough urine or water to make the viscus rise sufficiently above the pubes. The extraction of the stone is easy, as it can be raised into the grasp of the forceps by being pushed up from the vagina.

*Vaginal Lithotomy* is performed as follows: A short straight grooved staff is passed into the bladder and pressed downwards against the vesico-vaginal septum. A scalpel is then pushed through the anterior wall of the vagina and inferior fundus of the bladder into the groove in the staff, which it is made to enter just behind the neck of the bladder. The incision is continued backwards for  $1\frac{1}{2}$  inch, and through the opening the forceps is passed and the stone extracted. Unless there be severe cystitis the incision may be closed with silver wire sutures, after thoroughly washing out the bladder with boric acid lotion.

Vaginal lithotomy may, in some cases, be the only alternative. I extracted, by this operation, a calculus measuring eight inches by six in circumference, from the bladder of a woman twenty-three years of age, who had suffered from symptoms of stone from childhood. The stone by its size offered so serious an

obstacle to the descent of the foetal head during parturition, that craniotomy had been rendered necessary ; the anterior vaginal wall had been a good deal bruised, and I feared that sloughing of it might take place ; hence I extracted the stone by the vaginal method.

Lithotomy is not so dangerous an operation in the female as in the male : yet death occasionally occurs, especially in feeble children, from cystitis and peritonitis, more particularly if the extraction of the stone have been tedious and difficult, the bladder being much manipulated.

## CHAPTER LXIX.

## DISEASES OF THE BLADDER.

## CONGENITAL MALFORMATION.

**Extroversion of the Bladder**, consisting in an absence of the anterior wall of the organ, with deficiency in the corresponding part of the abdominal parietes, is a congenital malformation occasionally met with. It may occur in either sex, but is more common in males.

This condition consists in an arrest of development, in consequence of which the anterior part of the pelvic girdle is deficient, the bodies of the pubic bones being imperfectly developed and the symphysis absent. The recti muscles separate at their lowest part, and pass obliquely outwards to be inserted into the lateral abutments of the pubic bones. A triangular space is thus left, which is filled up by the posterior wall of the bladder, which is continuous with the common integuments, the anterior wall being absent. The cleft commonly extends up to the spot at which the umbilical cord enters, so that the umbilicus is wanting. The posterior wall of the bladder, being pushed forwards by the pressure of the abdominal viscera behind, forms a prominent mass, the surface of which is composed of red, vascular mucous membrane; at its lowest part the orifices of the ureters will be seen discharging urine in constant drops. For a full description of the mechanism of the passage of the urine in this malformation, I would refer to a case which fell under my notice, and in which I made a number of experiments on the rapidity of the passage of foreign matters through the kidneys; it is reported in the *Medical Gazette* of 1845.

The penis is cleft along its dorsal aspect, exposing the floor of the urethra, forming the condition known as epispadias.

The scrotum is imperfectly developed, and the testicles usually do not enter it, but remain in the inguinal canals or just outside the external abdominal rings.

This malformation is of a most distressing kind. The exposed mucous membrane of the bladder becomes inflamed and irritated, and the constant soaking of the clothes with decomposing urine renders the patient an annoyance to himself and to all around him. Death may result from extension of inflammation up the ureters to the kidneys.

*Treatment.*—Up to a comparatively recent period the only treatment for ectopia vesicæ consisted in the application of a properly constructed instrument to collect the urine. A hollow shield is strapped over the part, and is connected by means of a tube with an india-rubber bottle, which is attached along the inside of the thigh. Of late years, however, operations have been devised and practised with the view of covering in the exposed surface of the bladder, so as to prevent the pain and irritation arising from contact of the clothes with it, and, by giving a proper conduit to the urine, to which an

apparatus can be applied, to save the patient all the annoyance of constant dribbling.

The first operation for the remedy of this malformation that was successfully performed was done, in 1859, by Ayres of New York, in the case of a woman aged 28. The operation consisted in turning down a long flap of skin from the abdominal wall above the exposed bladder, so that the cuticular surface of the flap was next the exposed mucous membrane. Lateral flaps were then dissected up from the abdominal wall on either side, and by sliding these inwards and uniting them with sutures in the middle line the raw surface of the first flap was completely covered. Three weeks later a covering for the vulva was fashioned by dissecting up the integuments covering the pubic bones on each side, and uniting them to each other in the middle line and to the lower border of the reversed flap.

Ayres was soon followed by Pancoast of Philadelphia, and subsequently by Holmes and Wood of London. The principle of their operations is essentially the same as that practised by Ayres, viz., that of raising flaps from the abdominal wall, and covering in the bladder by turning the cuticular surface of these flaps towards it. But the details of the operations differ chiefly in this, that the flaps have been taken from the groins and lateral aspects of the abdominal wall, with their bases downwards, so that they might be nourished by the superficial branches of the femoral artery.

**Wood's Operation.**—A flap composed of the skin and areolar tissue of the abdominal walls above the extroverted bladder is first dissected up. This flap is somewhat square in shape; its base should correspond in width with the exposed mucous membrane. Its length should be sufficient to cover the whole of the latter. The flap is turned down with its skin-surface towards the bladder. Then a "pyriform flap," the base of which is about equal in width to the length of the "umbilical flap," is dissected up from each groin, the base of the flap being "directed towards the scrotum and thigh" (Fig. 896). These two flaps are brought together so as to meet in the median line, and to cover in the umbilical flap, the raw surfaces of the two groin-flaps being in contact with the raw surface of the reversed umbilical flap. The flaps are then secured in position by hare-lip pins, each pin being passed so as to transfix both the groin flaps and a fold of the umbilical flap beneath, holding the three firmly together (Fig. 897). No sutures are required in the flaps. The edges of the wounds left in the places from which the flaps have been raised are then brought together by hare-lip pins and wire sutures (Fig. 897), and broad strips of strapping placed across so as to support the flaps and to remove as far as possible any tension from them. The patient must be kept in bed in a sitting posture, with the knees drawn up.

If the operation be successful, all the pins and sutures may be removed by about the sixth or eighth day, and cicatrization will probably be complete before the end of a month; the exposed surface of the bladder being completely covered in, leaving only a small opening about the root of the fissured penis, to which an apparatus may readily be adapted to catch the urine. If the umbilical flap be not of sufficient length, very troublesome fistulæ are apt to be left at its angles, requiring further plastic operations for their cure. Experience has shown that, if the operation be left at this stage, the benefit is not permanent. The contraction of the cicatrices, and the constant tendency to protrusion of the mucous membrane of the bladder from beneath the new

covering at the opening left at the root of the penis (Fig. 896), lead to a gradual increase in the size of the opening and a partial return of the symptoms. To prevent this, the fissured penis may be covered in by the following method. The whole front of the scrotum, including the dartos, is raised so as to form a bridge of skin connected with the groin at each side. This is lifted over the penis, and placed upon a raw surface prepared by turning down a collar or flap from the lower arched border of the new bladder-covering and from the sides of the urethra and penis as far forwards as the glans. A continuous wire suture is applied to keep the flaps in place; and the transplanted scrotal

Fig. 898.

Wood's Operation by Lateral Reversed Flaps. (After Wood.)

Fig. 899.

structures are united to the border of the bladder-covering by a line of interrupted sutures. The scrotal wound is readily closed by wire sutures. By this means a sort of urethra is formed, containing the muscular tissue of the dartos in its roof, which may even give it a slight power of contraction, so as to enable the new bladder to contain small quantities of urine. The second stage of the operation is often somewhat interfered with by erections of the penis. These are best controlled by ice-bags. The knees should be drawn up so as to relieve tension, especially in the first stage of the operation. After the cure is complete, the patient is often troubled by the growth of hair from the under surface of the umbilical flap, and the accumulation of phosphates

upon the hairs and in the angles of the new bladder. This is best relieved by extracting the hairs with a pair of forceps, and by using weak acid injections to remove the accumulation of phosphates.

Other methods have been devised in which the flaps by which the exposed bladder is covered are so disposed that the subcutaneous surface is directed backwards towards the vesical mucous membrane. This plan has been successfully adopted by Thiersch, who covers in the upper and lower halves of the exposed bladder in separate stages by the use of two large lateral flaps. The flap for the lower half of the bladder is raised by vertical incisions, but both ends are left undivided until the deep surface of the flap has granulated, when the upper attachment of the broad bridge of skin is cut across and the flap is turned across the lower part of the bladder, and adjusted with sutures to the freshened edges. Subsequently a similar strip of skin is raised from the abdominal wall on the other side of the bladder but at a higher level, and after granulation is well established, it is separated at its upper end and adjusted across the upper part of the bladder. The operation is completed by freshening the contiguous edges of the two flaps and uniting them with sutures, similarly uniting the upper border of the superior flap and the margin of skin at the upper border of the bladder, and treating the epispadias by the method described at p. 1217. In all operations in which granulating flaps are used, great care must be taken to cut them of sufficient size to allow for considerable shrinkage.

W. Anderson has successfully modified Thiersch's operation in two important respects. He first dissected away the upper half of the vesical mucous membrane and covered in the resulting raw surface by two lateral flaps united to each other in the middle line by sutures. Subsequently the remaining lower part of the exposed bladder was covered by two lateral flaps raised chiefly from the front of the thighs, and allowed to cicatrize thoroughly on their deep surface before they were adjusted in position.

The only other method which needs special mention is that which has been suggested and practised by Trendelenburg of Bonn, and was first performed in this country by Makins. **Trendelenburg's Operation** has for its object the approximation of the separated pubic bones whereby the subsequent closure of the defect is facilitated, and this object is accomplished by a free division of the ligamentous structures of the sacro-iliac articulation on each side. The operation is performed as follows: The child is turned on to its face, and each sacro-iliac joint is opened by a vertical incision over it, freely dividing the posterior ligament. Trendelenburg states that the left index finger introduced into the rectum will help to indicate the position of the incisions.

By firm pressure on the sides of the pelvis it is now possible to bring the separated pubic bones nearly or quite into contact. The incisions are sutured, drained, and dressed antiseptically, every care being taken to prevent their becoming subsequently soiled by the urine. The approximation of the two halves of the pelvis is maintained by a pelvic girdle, the ends of which are split and crossed in front and attached to weights hanging over the sides of the cot. The second part of the operation is performed after an interval of a month or six weeks. The exposed bladder, which is considerably narrowed and depressed as the result of the previous operation, is covered by making an incision on each side at the junction of skin and mucous membrane, and continuing each upwards to meet at a point above

the bladder. The skin is dissected up for a short distance around, and the edges are drawn across the bladder and united with sutures in the middle line. Trendelenburg and Thiersch have obtained satisfactory results by this method; in Makins's case the second part of the operation was followed by sloughing, but in the end a fairly satisfactory result was obtained by the use of flaps. The operation does not appear to have been followed by any weakening of the pelvis or interference with the walking power, and it certainly seems worthy of further trial in these distressing cases. It is available only in young children.

#### THE USE OF THE CYSTOSCOPE.

Before proceeding to consider the more important affections of the urinary bladder, it will be convenient to describe briefly the method employed in the examination of the interior of the bladder by means of electric illumination. This method of examination was first carried out by Nitze of Berlin in 1879, and since then its practical utility has been demonstrated, amongst others, by Harry Fenwick in this country and by Meyer in New York.

The **Cystoscope**, in the improved form constructed by Leiter of Vienna, has the form of a hollow sound, with a short angular beak. The latter contains the electric lamp, which is exposed through a small window closed by a pane of rock-crystal. The rays of light from the illuminated object enter a window in the angle formed by the beak and stem of the instrument; they are here refracted by a prism, and, after passing through a series of lenses in the hollow stem, by which the size of the object is magnified, they enter the observer's eye, which is applied to the expanded ocular end of the instrument. For ordinary purposes the light and window are placed in the concavity of the instrument, but for examining the lower part of the bladder an instrument having the light and window on the convexity may be more convenient.

The bladder having been washed out and injected with at least four ounces of clear fluid, the cystoscope is passed in the same way as an ordinary sound. In health the mucous membrane of the bladder looks "very like the retina as seen through the ophthalmoscope."

The chief use of the cystoscope is as a means of examination in obscure urinary cases in which all other methods have failed to detect the nature of the disease. By its use the necessity of an exploratory operation may be avoided. It has been found of the greatest value in certain cases of painless hæmaturia, in which the vesical or renal origin of the blood has been doubtful. Among the conditions in which it may enable the Surgeon to make a diagnosis are certain forms of ulceration of the bladder; calculi which have not been detected with the sound in consequence of their being encysted, hidden in a pouch behind the prostate, or between folds of mucous membrane; tumours of the bladder; enlargements of the prostate; and suspected presence of a foreign body. Blood has been observed escaping from one ureter, and by observing the condition of the ureteral orifice, and the character of the jets of urine escaping from it, information has in some cases been gained as to the condition of the corresponding kidney.

The view of the bladder may quickly be obscured if the fluid in it becomes turbid or blood-stained.

There can be no doubt that cystoscopic examination is valuable as a last resource in many obscure cases. The passage of the instrument, followed, perhaps, by a somewhat prolonged investigation, must not be regarded as altogether free from danger, especially in the presence of renal disease. Damage to the mucous membrane by the heated beak of the instrument is an avoidable accident.

Considerable practice is required before the Surgeon acquires sufficient skill in the use of the instrument to enable him to feel confident of what he sees and to plan his subsequent treatment accordingly.

For the visual examination of the interior of the female bladder the simple cystoscope devised by Kelly of Baltimore will be found useful. It consists of a silver-plated cylindrical speculum, the ocular end of which is expanded and provided with a handle. For the first examination at least an anæsthetic should be administered, and as a rule the patient may be placed on the back, with the pelvis well raised. The urethra is dilated with Hegar's uterine dilators, and the cystoscope, fitted with a bullet-ended stylet, is introduced. For purposes of illumination direct sunlight is the most satisfactory.

With this instrument ulcers and other morbid conditions can be seen, and even treated. The orifices of the ureters may readily be examined, and special ureteral catheters may be introduced into them.

#### CYSTITIS.

ACUTE CYSTITIS is of frequent occurrence, and arises from many different causes. In many instances it is met with merely as a complication of some serious disease of the bladder, such as calculus or tumour.

**Causes.**—Acute cystitis may result from various forms of *injury*, such as occur during operations on the bladder or during parturition, or from the irritation caused by fragments of a broken calculus or by other foreign bodies lodged in its interior. The best example of cystitis resulting from the presence of a *chemical irritant* in the urine is that following the external or internal administration of cantharides. A mild form is described as being sometimes produced by partaking to excess of sour wine or new beer. To the same category probably belong at least some of the cases in which mild symptoms of cystitis occur in children who habitually pass urine which is highly acid or loaded with phosphates.

*Septic cystitis* includes a large proportion of the cases of acute inflammation of the bladder which are met with in practice. It results from simple putrefactive changes occurring in the bladder as a consequence of the introduction of septic micro-organisms from without. As predisposing causes of septic cystitis the presence of retained urine in the bladder and chronic congestion or inflammation of the mucous membrane are most important. The introduction of septic matter is most commonly brought about by the use of an imperfectly cleaned catheter; but independently of this it seems probable that infection may occur along the urethral canal, especially when the latter is imperfectly closed and filled with adherent mucus. Such conditions are doubtless sometimes present, more particularly when the bladder is completely paralysed as the result of injury of the spinal cord. In the female the entrance of septic matter along the short urethral canal is the most probable explanation of the frequency of cystitis without obvious cause in *that sex*.

In rare instances severe cystitis results from the bursting of a neighbouring abscess into the viscus; such a cause is occasionally met with in the female as the result of a pelvic abscess or pyo-salpinx. A severe form of septic cystitis may occur in females as a complication of retroversion of the gravid uterus. It is due to retention of urine, with dribbling from the over-full bladder; it may end in sloughing of the bladder wall, and is apt to assume the membranous form described below. The most common example of a true *infective cystitis* is that which occurs as a complication of gonorrhœa.

*Gout* is commonly looked upon as a cause of cystitis, but its exact relation to the disease is little understood.

Lastly, acute cystitis may occur without any obvious cause; it is then usually attributed to *exposure to cold*, but it is doubtful whether this is ever the sole cause of the inflammation, except perhaps in gouty subjects.

The **Symptoms** of acute cystitis consist not only in local pain and weight in the hypogastric and iliac regions, with tenderness on pressure in these situations, and a good deal of constitutional irritation; but in the existence of extreme irritability about the bladder. As soon as a few drops of urine collect, they excite so much irritation that they cannot be retained, and are expelled by a kind of spasmodic or convulsive effort, constituting *strangury*, often accompanied by a good deal of tenesmus and great suffering. The urine will be found to be high-coloured, mixed with more or less mucus or pus, and often tinged with blood. The constitutional disturbance varies greatly; in the more severe septic and infective forms there may be considerable elevation of temperature, sometimes with rigors.

**Pathological Changes.**—The mucous membrane is swollen and reddened, these changes being most marked on the summits of the rugæ. The membrane is often covered with a layer of mucus, pus, and phosphates. In some forms of septic cystitis with foul urine the surface of the bladder is lined by a thick membranous layer of inflammatory exudation and altered epithelium. This condition, to which the name “membranous” or “diphtheritic” cystitis has been applied, is most commonly met with in females, and in rare instances the false membrane has been passed by the urethra, forming a complete cast of the bladder. As a very rare result of acute cystitis the mucous membrane may slough over considerable areas, and separate in the form of shreddy masses, exposing the muscular tissue.

The presence of micro-organisms in the bladder can almost always be demonstrated in cases of acute cystitis. In 8 cases of puerperal cystitis Bumm found a diplococcus, resembling, but not apparently identical with, the gonococcus. The ordinary micro-organisms of suppuration are sometimes met with, and in a considerable number of cases the bacterium coli commune has been demonstrated.

**Termination.**—An acute attack of cystitis usually terminates in the chronic form of the disease, and thus gradually undergoes resolution. Occasionally, however, it terminates fatally; and when this is the case, the urine becomes excessively foul, and death takes place from septicæmia, suppurating kidney, or more rarely from peritonitis. The temperature, which at first may have been elevated, gradually falls, the tongue becomes brown and dry, the pulse rapid and weak, and the patient sinks into a drowsy semi-comatose state before death.

Should sloughing of the mucous membrane occur, collections of pus may form in the substance of the wall of the bladder, and not unfrequently the

peritoneum is implicated, and diffuse peritonitis set up. Occasionally perforation occurs, with infiltration of urine in the deep areolar tissue of the pelvis. Very commonly the mischief extends to the ureters and kidneys.

**Treatment.**—The first step in the treatment is, if possible, to render the urine less irritating by diluting it by the free administration of barley-water or mucilaginous drinks, and by giving liquor potassæ or bicarbonate of potassium in doses sufficient to neutralize it. The patient must be confined to bed, and hot fomentations or poultices applied over the lower part of the belly. Long-continued hot hip-baths usually give great relief. To these means may be added the administration of hyoscyamus in full doses and morphia suppositories. No specific medicines are of any use. No instruments should be used during acute cystitis if they can possibly be avoided; but should the urine become foul, an attempt may be made to wash out the bladder, as the mechanical irritation of the catheter is a lesser evil than an accumulation of putrid mucus and urine. If it be necessary to do this, great gentleness must be used, the quantity of fluid injected being limited to about an ounce. The diet must be carefully regulated; no salt or spiced food must be allowed. As a rule a pure milk diet will be found the best.

In some severe forms of membranous cystitis occurring in females it has been recommended to clear out the bladder through the dilated urethra and apply a strong solution of nitrate of silver.

**CHRONIC CYSTITIS.**—Chronic cystitis is by far the most common morbid condition of the bladder. It may follow acute inflammation, the intensity of the process gradually subsiding, or it may from the first be chronic. It is met with in all cases of stone in the bladder after the disease has existed for a certain time; in all old and tight strictures; and it is the inevitable consequence of the presence of decomposing urine in the cavity of the bladder. In some cases it is apparently of gouty origin; but perhaps the most persistent form is that which sometimes follows gonorrhœa, which may be acquired in youth, and lead to life-long misery.

**Pathological Changes.**—On examining the bladder of a patient who has suffered from chronic cystitis, the mucous membrane will usually be found to be of a dark grey or slate colour. As in most cases there has been some exacerbation of the condition immediately before death, dark red or purple patches are usually seen in various parts, especially on the summits of the rugæ. Dilated and tortuous veins commonly ramify on the surface, the blood in which is usually blackened by the contact of the decomposing urine after death. The mucous membrane is tougher and thicker than natural, and not uncommonly there is distinct thickening with induration of the submucous tissue. Ulceration of the mucous membrane is occasionally met with. The muscular coat of the bladder is seldom unaltered, as in the great majority of cases chronic cystitis is associated with conditions which interfere with free micturition. If the obstruction has been of such a kind that no amount of increased force could have emptied the bladder, as in many cases of enlarged prostate, the bladder is dilated, and its muscular coat may be thinned and atrophied with an excess of fibrous tissue between the muscle fibres. In cases of stricture of the urethra, and other obstructions which can be overcome by increased force, the bladder is usually contracted, and its muscular wall greatly hypertrophied and thickened. The hypertrophied fasciculi of muscular tissue form ridges beneath the mucous membrane, having irregular depressions

between them, so as to cause the interior of the bladder to resemble somewhat the inside of one of the cavities of the heart, with its projecting columnæ carneæ. The hypertrophy is usually dependent on the same cause that has given rise to the chronic inflammation, but in some cases cystitis alone may cause the hypertrophy. It would, then, seem to be due to the obstruction caused by the thick ropy mucus, which requires greater force for its expulsion than healthy urine, and it is consequently only an indirect effect of the inflammation. Sacculi are commonly found projecting at the posterior and lateral parts. These are of two kinds, both of which are formed by projections between the fasciculi of the wall of the bladder. In the first and less common kind, the muscular as well as the mucous coat is pushed outwards; in the second form, the mucous coat alone forms a kind of hernial protrusion (Fig. 900). In the sacculi thus formed accumulations of various kinds may take place; mucus, pus, phosphatic deposits, and even calculous concretions, not unfrequently being met with. The urine, mixed with mucus

Fig. 900.—Sacculus in the Wall of the Bladder.

and pus, retained in these pouches, readily undergoes decomposition, and the difficulty in cleaning such a sacculated bladder by injections is great. Sometimes ulceration of a sacculus takes place as a consequence of the irritation of the fetid accumulation, and perforation may occur, followed by peritonitis and death. Ulcerations of the mucous membrane and abscesses in the submucous tissue are occasionally met with in bladders which have suffered from chronic cystitis, but they are usually the result of the exacerbation that

often sets in before death. The effect of chronic cystitis in causing disease of the kidney has already been described (p. 992).

The **Symptoms** of chronic cystitis closely resemble those of the acute form, differing only in degree. The bladder is unable to bear more than a slight degree of distension without pain, consequently there is a frequent desire to pass water, and the urgency is such that the slightest delay gives rise to considerable suffering. This *pain before micturition* is always one of the most prominent symptoms. The fluid is generally ejected forcibly or even spasmodically, and in small quantities at a time. Its passage may be attended with some pain, but seldom enough to be termed strangury. If the cystitis is not complicated by stone there is distinct relief after micturition. The urine is turbid, and always contains an excess of mucus. In slight cases this is small in amount, but more commonly it becomes abundant and viscid, requiring some force and straining for its expulsion, forming the condition known as *Catarrh of the Bladder*. The urine then, unless special means are taken to prevent it, becomes ammoniacal and fetid, and is often mixed with much pus. The urine, on standing, separates into two parts, the upper being clear, but the lower consisting of a thick, viscid, slimy, or gummy mucus, often semi-opaque and purulent in appearance; it sticks tenaciously to the bottom of the vessel, and when poured out hangs from the edge in long stringy masses. It often contains triple phosphate crystals in large numbers. The alkaline condition of the urine in vesical catarrh is due to the formation of ammonium carbonate from decomposition of the urea. The cause of this change is a question of great importance, as the irritation of the ammoniacal urine in the bladder is one of the most important causes of the persistence of vesical

**catarrh.** It is generally recognized that it takes place by a process of fermentation, but the exact nature of the ferment has been a matter of dispute. All urine undergoing ammoniacal fermentation is found to contain microscopic organisms, often of various kinds. The most constant is a small micrococcus, but with this, rod-shaped organisms showing active movements are almost invariably present. These organisms are very generally regarded as the actual ferment, and they are supposed to be carried into the bladder in most cases by instruments used in the treatment of the various conditions upon which the cystitis is dependent. The evidence in favour of this view cannot be fully discussed here, but it may be stated briefly that experiments by Lister and others have shown that healthy urine drawn from the bladder, with proper precautions against the admission of organisms from the air, into vessels which have previously been heated or exposed to the flame of a spirit lamp, shows no tendency to undergo spontaneous decomposition, and may be preserved for months in contact with filtered air without becoming ammoniacal. It is not uncommon, moreover, in practice, to meet with cases in which the patient has been unable to empty his bladder completely for many months in consequence of prostatic disease, and yet the urine has remained acid and free from decomposition throughout; at last a catheter is passed, and within three days the urine is decomposing and strongly ammoniacal. Cases are, however, not unfrequently met with in which the urine is foul, and yet no instrument has ever been passed. In these the explanation suggested is that the mucus secreted as the result of cystitis hangs in the urethra, which is not washed clean at every act of micturition, and constantly forms a channel of communication between the external air and the bladder by means of which decomposition may extend into the bladder. Urine which is mixed with a considerable proportion of alkaline mucus decomposes far more readily than the healthy secretion.

The constitutional symptoms of chronic cystitis are chiefly due to the disturbance at night and want of rest, unless the urine is allowed to become foul. If this happen, the ordinary symptoms of chronic septic poisoning usually manifest themselves—irregular febrile disturbance, loss of appetite, foul tongue, and progressive emaciation.

Chronic cystitis is not unfrequently fatal, death resulting in most cases from septicaemia, or from extension of decomposition to the urine in the ureters and pelves of the kidneys with suppurative nephritis. These conditions are accompanied by the symptoms already described. Occasionally, in old patients, the constant disturbance may cause death by exhaustion.

The **Treatment** of chronic cystitis must always have reference to its cause. If it be due to stone or stricture no permanent improvement can be obtained till these causes are removed, but before undertaking this, if the symptoms are verging on those of the acute form, hot hip-baths, fomentations, mucilaginous drinks, hyoscyamus with alkalies, and especially potash, will be found most useful. The bowels must be kept regular by enemata or castor oil. If there should be strangury, morphia or belladonna suppositories will give most relief. By these means the disease may be prevented from assuming the form of chronic vesical catarrh; but in order to ensure this it is most important that decomposition of the urine should be prevented, or if it have already commenced that it should be arrested. For the prevention of the decomposition all instruments should be washed in carbolic acid lotion (1 in 40) before being

used, and then greased with "Lund's oil," composed of absolute phenol, 1 part, castor oil, 4 parts, and olive oil, 15 parts; or with the following, which has the advantage of not crystallizing in winter: absolute phenol, 1 part; castor oil, 7 parts; and almond oil, 8 parts. The penis should also be washed with boric acid or carbolic acid lotion after micturition and covered with lint soaked in glycerine of carbolic acid or a piece of salicylic wool. If the urine has once become foul it becomes necessary to adopt local means to correct it. No good can be expected from medicines so long as the bladder is full of putrid mucus and urine. The bladder must therefore be washed out with some antiseptic solution, once, or, if necessary, twice daily. This is done as follows: a soft catheter is passed and the urine drawn off; about two ounces of fluid are then thrown in from an india-rubber bottle fitted with a brass nozzle and stop-cock. The fluid is then allowed to run out again, and this is repeated till that which comes back is quite clean. Nothing is gained by injecting larger quantities, which only cause needless pain and irritation. There is another method of washing out the bladder which will often be found useful. It consists in attaching an india-rubber tube, about three feet long, to the catheter. At the other end of the tube is a glass funnel. By raising the funnel about two feet above the patient's body and pouring the fluid into it, sufficient force will be obtained to fill the bladder. When sufficient fluid has entered, the funnel may be allowed to hang over the side of the bed over a vessel, when the fluid will be withdrawn from the bladder, the tube acting as a siphon. Amongst the most useful of all antiseptic injections is permanganate of potash; the solution may be injected repeatedly till it comes back purple. Its effect is, however, very temporary, and it is well after the bladder has been cleaned by Condy's fluid and water to throw in a small quantity of some more powerful antiseptic. Perhaps the best of these is quinine, in the strength of two to three grains to the ounce of water, with a minim of dilute sulphuric acid added for each grain; of this about one drachm may be left in after the catheter is withdrawn. Other antiseptics are also useful, as boric acid (a concentrated solution); perchloride of mercury (gr.  $\frac{1}{2}$  to  $\frac{3}{4}$ ); a concentrated solution of thymol; dilute nitric acid (m. ij. to  $\frac{3}{4}$ ), &c. One of the most efficient of all antiseptics I have found to be iodoform, in the proportion of from two to four grains to the ounce of water, with a little mucilage to suspend it.

Various drugs may be administered internally with the object of arresting the decomposition of the urine. The best known of these is benzoic acid, which is discharged with the urine in the form of hippuric acid; it may be given in ten-grain doses three or four times a day, either in a pill or in a mixture containing mucilage to suspend it.

Betol, the salicylate of  $\beta$  naphthol ether, may be given in three to eight-grain doses in cachets or pills. Saccharin in one-grain doses has also been found useful, if the urine is foul. Salol is somewhat extensively used, although Mansel Sympton has pointed out that the drug is dangerous if there is advanced kidney disease; five grains may be given three times a day or oftener, either in pills or suspended with mucilage. Boric acid is sometimes useful; ten grains should be given three times a day.

When by these means the urine has been brought into a tolerably healthy condition, so far as putrefaction is concerned, there still may continue a considerable excess of mucus which renders it prone to decompose, and unless constant care is exercised the patient may speedily relapse. To check this

various astringent injections are sometimes of use, such as tannin (gr. j to 3j); acetate of lead (gr.  $\frac{1}{4}$  to 3j); or nitrate of silver (gr.  $\frac{1}{4}$  to 3j).

Simultaneously with antiseptic or astringent injections, medical treatment may also be carried out. The greatest benefit will be derived from stimulating and balsamic diuretics such as buchu, uva ursi, and triticum repens; but these remedies are useless, unless taken in quantities of a pint or a pint and a half in the day. The best of these is buchu. The infusion should be made freshly every day by putting half an ounce of the leaves in a tea-pot and pouring a pint of boiling water on them. It should be taken cold, and the whole pint consumed in the 24 hours. When the disease is very chronic no remedy appears to me to possess so much influence over the mere ropy mucoid discharge as the balsam of copaiba. Turpentine, cubeba, and tincture of the sesquichloride of iron, will be found useful. It is often difficult to say beforehand which diuretic will suit best, and I can lay down no precise rules to guide the practitioner in this respect. But they may often be tried or alternated with advantage. In many cases great relief is obtained from each new remedy, but it is not maintained.

The diet must be very carefully attended to; no hot or spiced food should be allowed, and little or no salt. Alcoholic stimulants are better entirely avoided, but should any be required weak gin, or Hollands and water, or whisky and water are the best. Coffee must be strictly forbidden, but weak tea may be taken. Much benefit may often be derived from a pure milk diet for some weeks if the patient can bear it; if it prove too rich the cream may be taken off. A course of one of the alkaline mineral waters may sometimes prove of service, especially in gouty subjects. The body must be warmly clothed and all exposure to cold avoided.

#### IRRITABILITY OF THE BLADDER.

**Irritability of the Bladder** is not a disease; it is merely a symptom. It is of very frequent occurrence and is met with at all ages, and arises from a great variety of causes. It consists in a frequent desire to pass water, not dependent on an increase in the quantity of the secretion. The desire is usually so urgent as to amount to actual pain, and in extreme cases it is impossible to delay the act by any voluntary effort. The urine is generally ejected forcibly, or even spasmodically, and in small quantities at a time. It may or may not be attended with strangury, according to the cause and the part affected. Strangury is most marked in those cases in which it is due to disease of the prostate or neck of the bladder. In some persons frequency of micturition may be merely a habit. It then occurs in the day only. If a patient is disturbed more than once at night to pass water true irritability exists.

The **Causes** of irritability of the bladder differ somewhat as the affection occurs in men, in women, or in children. In *men* they may be arranged under the following heads:—

1. *Morbid Conditions of the Urine.*—If this secretion be preternaturally acid and loaded with urates or uric acid, it is especially apt to occasion an irritation of the bladder, attended with pain and a frequent desire to micturate. Urine containing oxalates in large quantity is sometimes, though more rarely, a source of irritability of the bladder, which in these cases is perhaps increased by the morbidly sensitive state of the nervous system sometimes co-existing

with these conditions of the urine. Amorphous phosphates passed at the end of micturition may cause severe pain, with a constant desire to pass water, lasting for an hour or less. It ceases as soon as the "alkaline tide" in the urine has passed (p. 1029).

In *gout*, irritability of the bladder is not unfrequently met with. This may in some cases be owing to the acid character of the urine; in others, to gouty inflammation of the bladder or prostate.

2. *Renal disease*, more particularly the lodgment of a stone in the kidney, will often occasion sympathetic pains in the bladder, with much irritability of that organ, so as closely to simulate vesical disease, or even to lead to a suspicion of the existence of stone in the bladder. Tuberculous pyelitis will give rise to similar symptoms; in fact, in some cases the frequency of micturition may be greater than in almost any other affection of the urinary organs.

3. *Disease of the Bladder itself*, as a chronically inflamed state of its mucous membrane, will give rise to pain and irritation on the accumulation of a small quantity of urine, with a frequent desire for its expulsion. So, also, when the bladder is fasciculated, or sacculated, and more especially if there be a tumour in a state of ulceration, most severe and intractable irritability may be induced.

4. *A Stone in the Bladder* will always, by its mechanical action, by its weight and pressure, by rolling about when the body is in motion, irritate the interior of the organ; and, in fact, the "rational symptoms" of stone in the bladder are simply those of irritability of that organ.

5. *Inflammation, Ulceration, Abscess, Tubercle, or other Diseases of the Prostate*, and inflammation, gonorrhoeal or simple, and abscess or stricture of the deeper portions of the urethra, also not unfrequently occasion irritability of the bladder.

6. *Various Diseases in Neighbouring Organs* will occasion this condition. Amongst the most frequent are fissure and ulcer of the rectum and anus, piles, prolapsus recti, intestinal worms, gall-stones, and varicocele.

The **Diagnosis** of irritability of the bladder is made by the patient himself; but it is often a matter of no little difficulty to the Surgeon to ascertain the precise cause of that irritability. This can of course be done only by a careful exploration of the whole of the urinary organs, and often of the neighbouring parts; no mere inquiry into the nature of the symptoms can do more than establish the fact of the existence of "irritability of the bladder," and afford some evidence of a negative kind as to the absence of certain causes. Nothing short of a careful exploration of the urethra, prostate, and bladder, by means of the catheter, finger, and sound, and cystoscope, can enable the practitioner to state with absolute certainty on what the irritability depends. I have repeatedly seen cases of stone in the bladder, and of prostatic disease, vainly treated for months as cases of simple "irritability of the bladder;" the existence of the real cause of the symptoms having been overlooked altogether, until a proper examination of the urinary organs was instituted. So closely, in fact, do the symptoms of vesical irritation, arising from gout, or sympathetic with kidney disease, simulate those that are occasioned by stone in the bladder, that it is impossible for the most experienced medical practitioner to refer them with certainty to the right cause without exploring this cavity. I have known several patients who had been operated on for stone, and who, some years afterwards, suffered from gouty irritability of the bladder, imagine, but erroneously, that they were labouring under a

recurrence of the calculus, so closely do the two classes of symptoms coincide in character.

Cases, however, will be met with now and then, in which, in spite of the most careful examination and prolonged observation, no tangible cause will be found for the irritability of the bladder.

In the **Treatment** of irritability of the bladder it must be borne in mind that this condition is not a substantive disease, but an assemblage of symptoms resulting from the influence of a great number of very various causes, which must first be removed before the bladder can recover its normal sensibility and tone. When once the occasioning cause has been removed, whether that be a calculus, or gout, or prostatic disease, or a pile, such local vesical irritability as may remain may be removed by alkaline and mucilaginous drinks. Sedatives may be of use ; some in one case, others in another. Opium and belladonna, either by mouth or in suppository, are amongst the best. Hyoscyamus, or Indian hemp, suits some patients ; and chloral is one of the most generally useful remedies. The diet should be carefully regulated, and warm hip-baths used frequently. In cases in which no tangible cause can be found and removed, and which prove hopelessly intractable to every means of treatment, local and constitutional, nothing can be more miserable than the state of the unfortunate victim of an "irritable bladder." Under these circumstances, much relief may be given by temporary drainage of the bladder. This may conveniently be done in the following manner, as practised by Thompson : An ordinary curved median staff is first passed into the bladder, and the patient is tied up in the lithotomy position. The Surgeon then introduces his left forefinger into the rectum and feels for the apex of the prostate. He then takes a long narrow-bladed straight bistoury, and makes an incision about one inch and a quarter long in the middle line of the perinæum, terminating about three-quarters of an inch from the margin of the anus. The knife is then turned with its back to the rectum and entered near the lower end of the superficial incision. Guided by the finger in the rectum, the knife is then pushed steadily on till it enters the groove of the staff near the apex of the prostate. By drawing it forwards in the groove the membranous part of the urethra is opened. The knife may now be withdrawn, cutting slightly forwards in so doing, care being taken not to wound the bulb more than can possibly be avoided. Thompson then introduces a blunt gorget-like director with a beak to run in the groove. An ordinary long steel director, or a long probe, may be used instead if this instrument be not at hand. The staff being withdrawn, the finger is gently pushed along the director into the bladder. The operation is, in fact, nothing more than the ordinary median operation for lithotomy as performed by Allarton. By careful examination of the interior of the bladder with the finger, it may be possible to detect some cause for the symptoms, and to apply appropriate treatment. But even when no cause is detected many patients are greatly relieved or even cured by draining the bladder for a few days with a tube. In some cases of this nature an exploratory suprapubic cystotomy has been performed ; it is a more severe operation, but the opening is more conveniently placed for a thorough exploration of the bladder.

**Irritability of the Bladder in Boys** may, as in adults, arise from a variety of causes. Among the less common is stone, but this should ~~always be~~ excluded, first by careful sounding lest time be lost in useless treatment of

some other supposed cause. A long foreskin, especially with accumulation of smegma beneath it, or a phimosis, may give rise to considerable frequency of micturition and pain in a young boy. If neither stone nor phimosis be present the urine should be examined, and possibly a deposit of uric acid may be found, which is not uncommon in young children who are overfed or exposed to an impure atmosphere in a crowded city. If much mucus be present, or even pus, it may be due to chronic cystitis. This affection appears to be analogous to the strumous inflammations of the mucous membranes of the eyes, nose, and throat, that commonly occur in scrofulous children. In this condition the child passes water with great frequency and with much pain; the urine is offensive, and usually phosphatic; much uneasiness is complained of about the groins and along the penis; in fact, many of the ordinary symptoms of stone are present. On sounding the bladder, it will be found roughened, fasciculated, and often containing sabulous matters mixed with mucus. Occasionally, though rarely, tuberculous disease of the urinary tract is met with in children. It presents the same appearances as in the adult. Irritable bladder in children is very frequently due to thread-worms in the rectum, which should always be sought for in all doubtful cases. More rarely it may arise from the presence of a rectal polypus.

The **Treatment** consists in removal of the cause when this is possible. In the strumous affection of the mucous membrane, if the urine be foul, the bladder must if possible be cleaned out as in the adult, should the child be old enough for this to be done. The bladder may also be washed out from time to time with a weak solution of nitrate of silver. Beyond this the treatment consists in attention to the general improvement of the health, in the removal of intestinal irritation, in the regulation of the digestive functions, and in the administration of copaiba in small doses, either alone or conjoined with a few minims of liquor potassæ.

**Irritability of the Bladder in Women** often simulates stone so closely, that it is only after very careful sounding that the Surgeon is satisfied that no calculus exists. This condition may arise from a variety of causes, similar to those described at p. 1117, as occasioning irritability of the male bladder. There are some conditions, however, in which it occurs, that are peculiar to women: 1. It may be a truly neurotic or hysterical affection. 2. It is most commonly the result of enlargement of the body of the uterus from whatever cause, and is thus very frequent in early pregnancy. 3. Inflammatory affections in the pelvis, such as pelvic peritonitis, frequently occasion painful and frequent micturition. 4. It is often sympathetic; being connected with some local disease of the genito-urinary organs, such as a vascular caruncle of the urethra, which will require to be cured before the bladder can be brought into a healthy state. 5. Tumours of various kinds occupying the cavity of the pelvis may occasion irritability of the bladder by the traction exerted upon it. 6. Prolapse of the anterior wall of the vagina, drawing down the corresponding portion of the bladder, may occasion the condition, especially if the vesical pouch contains stagnant phosphatic urine. It may be relieved by the use of a pessary, or by a plastic operation. 7. In strumous girls it may be due to a congested and irritated state of the vesical mucous membrane, similar to that which is met with in boys (see above). It is commonly associated with a muco-purulent discharge from the vagina. In cases such as these, the patient requires to be put upon a general tonic treatment, and the bladder should be

mopped out with a very strong solution of the nitrate of silver. This is best done by dilating the urethra, passing a silver tube into the bladder, and then through it a small sponge-probang charged with the solution.

## ATONY OF THE BLADDER.

By **Atony of the Bladder** is meant such a degree of weakness of this organ that its power of emptying itself is partially or wholly lost. It is in the great majority of cases a condition of old age, and is not to be confounded with paralysis of the bladder, such as occurs in cases of injury or disease of the spinal cord. In atony the nervous supply is unimpaired; it is the muscular tissue that is at fault. The muscular tissue of the bladder may be impaired from several causes. By far the most common is the chronic strain to which it is exposed in over-distension of the bladder from mechanical obstruction at its neck arising from enlargement of the prostate. In this condition, if the dilated bladder be examined microscopically, its walls will be found to contain a great excess of somewhat dense fibroid tissue, amongst which lie scattered patches of muscular tissue.

In some rare cases atony of the bladder may result from a single prolonged voluntary or involuntary over-distension. The structural changes just described would then of course not be present.

Besides these, there is another variety of atony of the bladder commonly met with in early middle life, though it may occur at any age. In all the cases in which I have seen this form of atony it has been the consequence either of gonorrhoeal cystitis or of cystitis following lithotripsy. It may lead to partial or complete retention. It is often, but not always, associated with vesical catarrh and fetid urine. This condition, when once it has become chronic, is, I believe, incurable. In it structural changes take place in the bladder consequent upon the extension of the chronic inflammatory process from the mucous membrane to the submucous tissue and muscular coat. Its walls become thickened, rugged, and pouched. The bladder is able neither to retain the normal amount of urine, nor completely to empty itself. The retained urine usually undergoes decomposition, and this condition is very apt to end in fatal disease of the kidneys.

Excluding all these conditions, there is yet another form of atony of the bladder which may be regarded as the most typical variety. It is essentially a condition of old age, and appears to be a senile degenerative change analogous to that of the heart and other organs so commonly met with at that time of life. Such a change occurring in a bladder occasions its distension from slight causes of obstruction which could readily be overcome by the healthy organ of a younger man. Thus, we not unfrequently see a dilated atonic bladder occurring as the result of stricture of the urethra in an old man, instead of the contracted hypertrophied organ commonly met with as the result of this disease. A strong bladder may overcome a moderate amount of obstruction to the escape of the urine; an atonic bladder utterly fails to do so. Thus, we see that a condition of atony of the bladder may occur in an otherwise healthy man from the obstruction of prostatic disease, while, on the other hand, a degree of obstruction that would be harmless to a healthy man may cause serious symptoms in one whose bladder is atonic to begin with. It is difficult to determine in most cases which is to be regarded as the primary condition.

The fact that atony of the bladder is rarely met with in women would suggest that in the great majority of cases mechanical obstruction from enlargement of the prostate is to be regarded as the primary factor in the production of the disease.

**Symptoms.**—When this condition comes on slowly as the result of advancing years, the patient usually finds that the urine escapes in a dribbling manner; that there is some difficulty, and at last an impossibility, in emptying the bladder completely; that there is not that forcible ejection of the last drops of urine that is characteristic of a healthy tone in the organ; at the same time, there is not unfrequently a tendency to the dribbling away of a few drops towards the end of micturition, and after its apparent cessation. The patient feels a desire to pass water more frequently than usual. He cannot retain his urine for more than an hour or two; he is often disturbed during the night, and if he does not at once obey the impulse, is apt to wet his clothes. This frequent desire to pass water is due to the bladder never emptying itself, a certain quantity—several ounces—of residual urine being left behind; by the addition of a small quantity the bladder becomes overloaded, and the desire to micturate is felt. Temporary relief is afforded, but as secretion continues the bladder soon fills up again, and so the process goes on. When complete retention occurs, the bladder slowly rises out of the pelvis into the hypogastric region, reaching even as high as the umbilicus. On examining the lower part of the abdomen, the organ will be felt hard, elastic, rounded, and pyriform in shape, projecting above the pubes, and feeling much like an enlarged uterus. In this situation, also, percussion will elicit a dull sound; on exploring the part through the rectum, the bladder will be found to project in this direction also; and on tapping with the fingers above the pubes, fluctuation may be felt through the wall of the gut.

The distension of the bladder is sometimes so very gradual and slow that the over-distended organ has been mistaken for an abdominal tumour. The urine dribbles away, and no pain and but little inconvenience is felt. Oedema of the legs may occur from pressure on the iliac veins.

Atony of the bladder is a sufficient cause for incomplete retention of urine. But it does not appear to be adequate to explain the complete retention with distension of the bladder that is commonly seen. For this to occur there must be some mechanical obstacle, however slight, to the outward flow of the urine—contraction of the neck, or an enlarged prostate. Could complete retention occur from a merely atonic bladder, we should meet with it as frequently in women as in men. It is the mechanical obstacle at the neck of the male bladder which intensifies the effects of its atony and leads to the complete stoppage.

After the bladder has once become distended, the retention may be complete, but it more commonly happens that a quantity of urine continues to dribble out of it; in fact, the amount that escapes in this manner may be very considerable, though the retention continue unrelieved. This *retention with dribbling* is a condition of great practical importance, as the continued escape of urine may lead the patient, and even the Surgeon, to overlook the true state of things; the more so, as in elderly people retention slowly induced often occasions but little inconvenience. I have drawn off nearly a gallon of urine from a patient in whom it had not been suspected that retention existed, in consequence of the continuance of this dribbling. In women

retention is not by any means so common as in men, but the bladder will sometimes attain an enormous size, rising as high as the umbilicus; and such large bladders have been tapped under the supposition that the tumour was an ovarian cyst, or some similar growth. I once witnessed such a case in which the Surgeon, to his surprise, on tapping the tumour, drew off a quantity of clear and healthy urine, instead of ovarian fluid; fortunately no bad effects followed. This retention with dribbling occurs in consequence of the bladder, as it rises out of the pelvis, elongating its neck; and as the body becomes bent forward over the pubes a sharp curve or angle is formed at the junction of the neck and body of the viscus, through which a small stream of urine continues to dribble away, and escapes rather by its own gravity than by any expulsive effort on the part of the patient.

**Diagnosis.**—Retention from *Atony* can easily be distinguished from retention from *Obstruction*. In the former, on introducing the catheter when the patient is lying on his back, the instrument will not only readily enter, but the urine will simply flow out in a slow uniform stream, not being projected in a jet by the contraction of the walls of the organ, but rising and falling in obedience to the respiratory movements, or to the contractions of the abdominal muscles. In retention from obstruction, some difficulty will be experienced in passing the instrument at some one point, either in the urethra or at the prostate; and when once it is introduced into the bladder, the urine will escape in a free and far projected stream.

**Results.**—The habitual retention of a small quantity of urine in an atonic bladder which is incapable of discharging completely the whole of its contents occurs much more frequently than is suspected. The quantity thus retained will vary from an ounce to half a pint—the patient believing that he has emptied his bladder. The existence of this residual urine is readily determined by the introduction of a catheter after the patient thinks he has emptied his bladder. In consequence of the bladder never being completely emptied, there will be frequent, sudden, and almost irresistible calls to pass urine, so as to simulate irritability of the bladder. The retained urine becomes offensive, ammoniacal or fishy in odour, and mixed with mucus or muco-pus. The constituents of the urine become re-absorbed or are not excreted, derange the health, give rise to impaired nutrition, and, being eliminated by the skin, irritate it and occasion intractable forms of skin disease. I have seen chronic eczema of the most inveterate character produced in this way, and yield to treatment only on care being taken to keep the bladder clear and free from residual urine.

The effects of the presence of retained urine and of retention with dribbling are not identical. When retained urine is constantly present the general health suffers, the patient becoming slowly poisoned by the inability to get rid of an excretion. In retention with dribbling the danger is more immediate, and directly dependent on the liability to secondary disease of the bladder and kidneys. Subacute cystitis occurs as the result of the continued over-distension of the bladder. The symptoms are such as are described at p. 1003 as being indicative of urinary fever. The patient suffers from chills or slight rigors followed by depression and low spirits. Fever of a typhoid type comes on, with brown tongue, occasional retchings, mild delirium, and great prostration. This condition occurring in an aged man long suffering from atony of the bladder, with most probably an unsound state of the kidneys secondary to

this, is commonly fatal. It is thus that chronic retention from atony of the bladder destroys life, not by ulceration of the organ or by extravasation of urine, which does not occur in these cases as in other forms of more acute retention.

**Treatment.**—Atony of the bladder, except in the few cases that arise from a single over-distension, is incurable. It is dependent upon senile changes in the viscous of an organic character that may be relieved but cannot be remedied. The great danger in this state arises from the retained urine, even though retention be by no means complete. So long as this residual urine is in small quantity no harm results. Even when it accumulates so as to amount to several ounces, it may give rise to no symptom beyond frequency of micturition. Sooner or later, however, the over-distension causes some irritation of the bladder, and the urine becomes cloudy from excess of mucus. Decomposition of the retained urine then frequently takes place, either from extension of decomposition up the urethra or after the passage of instruments, as already described. It must not be supposed that mere retention of a small quantity of urine after each act of micturition is sufficient in itself to cause decomposition. Nothing is more common than to find patients who have not emptied their bladders for many months, and whose urine is yet perfectly normal in every respect. The statement sometimes made that decomposition never takes place till after an instrument has been passed, is, however, not accurate, although in the great majority of cases the urine becomes ammoniacal only after surgical interference. When this takes place all the symptoms of chronic or subacute cystitis supervene. Febrile disturbance of the type of chronic septic poisoning sets in, and death may follow. This is more especially likely to happen when the kidneys are affected by chronic interstitial nephritis, which, as already pointed out (p. 994), is a common result of prolonged over-distension of the bladder.

The primary object of all treatment in ordinary uncomplicated senile atony of the bladder is to free the patient from the residual urine, which he is no longer able to expel. This can be done only by the use of the catheter, and it is the duty of the Surgeon to teach the patient how to use this instrument for himself, so that at all times he may be the master of his own situation, and relieve himself when necessary.

The commencement of "catheter life," as it has been appropriately termed by Sir Andrew Clark, is an important period in a man's existence. For when once the use of the instrument has been begun, it can rarely be discontinued. Hence it is well not to begin it unnecessarily early. But it is of at least equal importance not to fall into the opposite error of delaying its use too long, lest the residual urine be allowed to accumulate to such an extent as to become a source of discomfort to the patient, of injury to his general health, and of danger by inducing septic cystitis and all its concomitant evils.

The use of the catheter in cases of atony of the bladder for the removal of residual urine is very simple, and, if the kidneys be sound and the most ordinary precautions taken, is unattended with any danger. The safest catheter to use is a soft one. The simple soft red rubber catheter will often pass with ease, and is then by far the best instrument to use. Metallic instruments need not be used by the Surgeon, and should never be employed by the patient himself. The ordinary elbowed prostatic catheter, or the conical one with a bulbous end of medium size, will be found most convenient if the rubber

instrument will not pass. This should be passed whilst the patient is standing up, with every possible care and gentleness. The instrument should be lubricated with an antiseptic oil. After and before use the instrument must be washed in cold carbolized water, so that all chance may be avoided of septic material being carried into the bladder, and thus leading to putrefaction of the urine. At first it may be quite sufficient if the residual urine is drawn off every third or second day. After a time this will be required once or twice daily. Until the patient becomes accustomed to the use of the catheter all unnecessary exertion, fatigue, and, above all, chills, should be most carefully avoided. When once the habit has been established, these precautions may be relaxed, *provided there is no evidence of renal disease*, and the urine continues clear and healthy.

The catheter must not be retained, lest it occasion subacute cystitis. If, as often happens in senile atony, the prostate is somewhat enlarged, care must be taken that the catheter really enters the bladder, and that the dilated prostatic urethra be not alone emptied. The weight of the residual urine causes the fundus of the bladder to pouch behind the prostate. This pouch must be thoroughly emptied by slowly withdrawing the catheter when the body of the bladder has been drained. Should subacute cystitis come on, with decomposition of urine, during the treatment, the bladder must be washed out after being emptied, with antiseptic lotions of the permanganate of potash, quinine, or iodoform.

When once a bladder has become atonic in advanced age, it never completely recovers its contractility, but the regular use of the catheter may do much to restore the normal contractility, in some degree at least. When once fairly established, "catheter life" may continue for many years without discomfort or appreciable danger. The general health must be attended to on ordinary principles; but no medicines are of any special service in these cases.

The treatment of that form of atony of the bladder, which arises in younger subjects, as the effect of gonorrhoeal cystitis or stone in the bladder, consists in the daily use of the catheter. *Nux vomica* may possibly be of use in some cases. Whenever the urine becomes turbid or offensive, antiseptic injections must be used. All this the patient may, in most cases, be readily taught to do for himself. When once he has acquired the art of auto-catheterism, he may pursue the ordinary business of life with comfort and without peril. But he must never relax his care of himself, lest subacute cystitis may come on, or phosphatic deposits form in the bladder.

#### INCONTINENCE OF URINE.

The term "incontinence of urine" is usually applied to all cases in which the urine is passed involuntarily. It occurs in three forms:—1. Passive incontinence, in which the urine dribbles away as fast as it is secreted, the bladder remaining empty. 2. Distension of the bladder with overflow. 3. Active incontinence, in which the bladder is emptied involuntarily at short intervals by its own contraction.

**Passive Incontinence** arises most commonly from paralysis of the neck of the bladder, from disease or injury of the spinal cord. It is occasionally met with in children from causes that are not clearly ascertained. *Civiale* states that it has been known to arise from impaction of a calculus in the

neck of the bladder in such a way as to prevent its closing, and yet to leave sufficient room for the urine to pass. Very rare cases have been recorded occurring in later life in which it was due to enlargement of the lateral lobes of the prostate, with a middle lobe situated between them in such a way as to keep them apart, and yet not to block the passage from the bladder. In tuberculous disease of the prostate, with extensive destruction of the gland, complete incontinence may occur. Passive incontinence is occasionally met with in women, as the result of dilatation of the urethra for the removal of stone.

2. **Distension of the Bladder with Overflow**, as it is termed by Thompson, may be due to atony of the bladder (p. 1121), or to enlargement of the middle lobe of the prostate. The effects of atony in causing overflow of urine have already been described; overflow from prostatic disease will be described subsequently. It is of the utmost importance that this condition should be distinguished from true incontinence.

3. **Active Incontinence** is met with most frequently in children, and is, as a rule, not constant, occurring only at night. It usually occurs in boys. It seems to arise in some cases from the patient losing command over the sphincter during sleep, as soon as a small quantity of urine has accumulated behind it. This troublesome condition may last to adult life, and is a source of great misery and discomfort. In children it is in many cases sympathetic, being dependent on the irritation of a tight foreskin, of worms in the rectum, or of a polypus. In other cases it may be merely a symptom of stone in the bladder. In strumous children, nocturnal incontinence may be produced by the irritation of urine containing uric acid crystals. All these conditions must be carefully sought for in every case, and removed if possible.

**Treatment.**—In true incontinence little can be done beyond providing the patient with a proper india-rubber urinal, which can be worn day and night. The treatment of overflow consists solely in the periodical use of the catheter (p. 1124). In nocturnal incontinence of children, if it be not connected with some evident source of local irritation, which should then be removed, the administration of tonics will be found useful—either quinine or the tincture of perchloride of iron, alone or conjoined with tincture of cantharides. If there be irritation of the mucous membrane of the bladder, the administration of alkalies, in conjunction with a tonic, as the potassio-tartrate of iron, or a little copaiba mixed with honey, will be found very serviceable. The last meal should not be immediately before bed-time, and the amount of fluid taken should be restricted. Cold sponging, light clothing at night, and means calculated to break the habit, such as waking the child at the time at which it generally occurs, changing his position in bed, &c., should not be omitted. Of all remedies for incontinence of urine in children, belladonna is the most successful. Ringer advises it to be given in full doses—from 10 to 20 minims of the tincture three times a day. Sometimes better results are obtained with atropine, which should be given at night in a dose gradually increased from  $\frac{1}{100}$ th to as much as  $\frac{1}{10}$ th of a grain. In obstinate cases the passage of a sound may be useful.

**Hysterical Retention and Incontinence of Urine** not unfrequently occur in nervous girls, and require to be treated by anti-hysterical remedies, amongst which preparations of perchloride of iron, either alone or with valerian, will be found most useful. Cold douches are also of great service.

In cases of hysterical retention, the use of the catheter should, if possible, be avoided, as the patients are apt to get into the habit of having it introduced, and will, with that morbid propensity that characterizes hysteria, continue for a length of time to require its introduction. If left to themselves, though the bladder may become much distended, it will not burst, but will probably empty itself without further trouble, particularly if the patient be put into a bath and well douched over the hips and loins with cold water. In some cases, these morbid conditions in women appear to be connected with some local irritation about the urethra or uterus; and then proper treatment must be directed to these organs before the disease can be removed.

**Painful Conditions of the Bladder.**—The bladder may be the seat of severe pain, either continuous or remittent, without any disease being discoverable in it; the pain being either a kind of neuralgic condition, especially occurring in hysterical or hypochondriacal patients; or else being sympathetic with, and dependent on, disease at a distance, as in the kidneys, uterus, rectum, &c. At the same time it must be borne in mind that the secretion of acid or irritating urine will, in some individuals, be a source of much constant suffering; and that any disease seated about, or coming into contact with, the neck of the bladder, as tumour, stone, &c., is especially apt to give rise to severe suffering, and will, in many cases, be accompanied by frequent desire to micturate, with much spasm about the part.

#### TUBERCLE OF THE BLADDER.

**Tuberculous Disease** of the bladder appears to be rarely primary. It is usually an extension from similar disease of the kidney and ureter, or of the prostate, and is not uncommonly met with as part of a general tuberculous affection of the genito-urinary tract. Even in cases in which all the symptoms during life are referable to the bladder, *post-mortem* examination will usually reveal the existence of tuberculous deposits elsewhere, especially in the prostate. The disease shows a special tendency to affect the parts about the trigone. It is rarely that the disease is seen in its earliest stages, when small granulations are present in the mucous membrane. Ulceration soon occurs, and in addition the signs of chronic cystitis become more or less marked. The ulcers are usually small and rounded or oval; the edges are slightly raised, and the surface is yellow and granular. Occasionally a single ulcer of considerable size is met with. The ulceration is usually superficial, and perforation of the bladder is rare. In the advanced stages of the disease the ulceration often extends to the neck of the bladder and the prostatic portion of the urethra.

**Symptoms.**—Tuberculous disease of the bladder has been met with at all ages, but it is most common in young adult males. The onset is often extremely insidious, and the only symptom in the early stages may be increased frequency of micturition. This may be so marked that care must be taken not to mistake it for incontinence, especially when the disease occurs in children.

Hæmaturia is frequently an early symptom, and thus at this stage the disease may possibly be confounded with stone or tumour of the bladder. Tuffier, writing in the "*Traité de Chirurgie*" of Duplay and Reclus, points out that the hæmorrhage may be distinguished from that due to stone by its

painlessness and the absence of any relation to rest and movement; whilst from the hæmaturia due to a tumour it differs in its small amount and the period of increased frequency of micturition which usually precedes its first occurrence. In the later stages, when ulceration has occurred, the symptoms are those of chronic cystitis. The act of micturition is frequent and the pain severe. The urine contains pus, often in considerable quantity. At this stage the symptoms may closely resemble those of stone, and often the diagnosis is based chiefly upon the coexistence of tuberculous disease elsewhere, more especially in the kidneys, prostate and testes. The bacillus tuberculosis can occasionally be demonstrated in the pus in the urine. Cystoscopic examination may be useful as a means of diagnosis (p. 1110). The gravity of the case and the intensity of the patient's sufferings are much increased if the tuberculous affection become complicated with septic cystitis.

The prognosis is necessarily grave, especially if the affection of the bladder forms only part of a genito-urinary tuberculosis. In some cases, however, the course of the disease is very slow, and cure may undoubtedly occur as the result of local and constitutional treatment.

**Treatment.**—When the existence of early tuberculous disease of the bladder is suspected the general treatment should be carried out on the lines indicated in Vol. I., p. 1099. Guyon recommends, even in the early stages before symptoms of ulceration are present, instillations of perchloride of mercury. The solutions employed vary in strength from 1 in 200 to 1 in 1,000, and the amount injected from 10 to 40 drops. The bladder is emptied with a catheter and the injection made with a small syringe; it may be repeated every few days.

In the later stages of the disease much may be done to relieve the pain and irritation by washing out the bladder; and by the use of iodoform considerable improvement may sometimes be produced. Boric acid lotion will be found one of the most useful injections, and iodoform can best be introduced in the form of an emulsion. Berkeley Hill advised the following:—Iodoform 2 parts, mucilage 4 parts, glycerine 2 parts, water 20 parts; two drachms to be injected once or twice a day. If the passage of the catheter and the washing out of the bladder cause much pain, a drachm of 5 per cent. solution of cocaine may be first injected. Cystotomy may be required in cases in which the simpler methods of treatment have failed, and in which the pain and irritability of the bladder are seriously affecting the patient's health. Not only does the drainage relieve the patient's symptoms, but by putting the bladder at rest the operation favours the healing of the ulcers, and also enables the Surgeon to treat the diseased surface directly. Median cystotomy is the simplest method, and this is probably the best treatment when the operation is undertaken merely as a palliative in advanced cases. In favourable cases, however, supra-pubic cystotomy should be preferred, as it allows a more thorough examination; and, if necessary, the ulcerated surface can be scraped and treated with iodoform. In a few cases this has been done with considerable success. In the female, direct treatment of the ulcers can be carried out after simple dilatation of the urethra, or by the use of Kelly's cystoscope.

## SACCU LI OF THE BLADDER.

Sacculi have already been mentioned at pp. 992, 1041, and 1114, as arising in connexion with over-distension of the bladder or obstruction to the escape of urine from it. These are of small size, not usually exceeding a pigeon's egg. They arise, as already described, in the bladders of elderly men who have suffered from severe mechanical obstacle to the passage of the urine, in the shape of stricture or enlarged prostate; they are associated with a generally thickened fasciculated state of the organ, and appear to be the result of pressure on the contained urine during efforts at expulsion, causing extrusion of the mucous and serous coats, and perhaps of the thinned muscular coat at some points of least resistance.

Sacs connected with the bladder are, however, occasionally met with, the origin of which can hardly be explained in this way. These may be single or multiple, and may attain an enormous size. The largest I have seen occurred in a man 35 years of age, otherwise perfectly healthy. There was a tense elastic tumour, smooth and rounded, occupying the whole abdomen and extending into the pelvis, so as to be felt through the rectum. Had it occurred in a woman, the disease would probably have been pronounced to be ovarian. The tumour had existed for six months, had gradually increased, but occasioned no uneasiness except by its pressure-effects. There had been no difficulty in passing urine or in defæcation. The tumour was aspirated at its most prominent part, and seven pints of clear urine were drawn off. The patient suddenly became faint, and died of syncope. On examination after death, two enormous sacs were found connected with the bladder, one on each side, by a rounded opening that would admit the little finger. These orifices were equidistant from the mesial line, and about an inch and a half above each ureter. The sacs were thin-walled, composed chiefly of mucous membrane and peritoneum, possibly having scattered muscular fibres in their composition; both were emptied through the bladder by the one puncture. The ureter on each side was adherent to the wall of the sacculus and considerably pressed upon, and as the result of this the pelves of the kidneys were dilated; the pyramidal portion of the kidney was absorbed and the cortex greatly thickened and indurated by chronic interstitial inflammation. The bladder was greatly dilated and hypertrophied, its mucous membrane was opaque and white, and showed no signs of old or recent cystitis. The prostate and urethra were healthy, and no source of mechanical obstruction was detected. The cause of the condition is extremely obscure. There is a similar specimen, but somewhat less marked, in the museum of University College; the sacculus springs from the same spot, which indeed, from comparison with other specimens, seems to be the common point of origin of all sacculi of the bladder which reach any considerable size.

## TUMOURS OF THE BLADDER.

**SIMPLE TUMOURS.**—The most common simple growth is the **Villous Tumour** or **Papilloma**. It consists of delicate branched processes, which, when the growth is immersed in water, float out, so that it somewhat resembles a sea anemone. These may spring from a narrow base forming a peduncle.

lated mass, or spread over a considerable area of the bladder wall. The base from which they arise may be almost level with the surface of the bladder, or may form a fleshy mass of some thickness. Microscopic examination shows that each papilla is composed of a fine capillary loop, surrounded by an extremely delicate connective tissue, in some parts almost homogeneous, with numerous rounded or spindle-shaped cells scattered through it. The surface is covered with epithelium of the same character as that of the bladder, but more delicate. The cells are often oval or fusiform, and are arranged in several layers. This delicate epithelium separates almost immediately if the growth is put in water, and is consequently often lost in microscopic specimens. The base is composed of loose and highly vascular connective tissue. These tumours almost invariably spring from the neighbourhood of the trigone, although rarely from the trigone itself. Hurry

Fenwick found that in 43 per cent. the growth is attached to the orifice of the right ureter, in 26 per cent. to that of the left, and in 10 per cent. to the interureteral region. They are usually single, but occasionally two or more are found. Thompson states that only about one in six or seven is distinctly pedunculated, the great majority being more or less sessile. When pedunculated, the pedicle may, in rare cases, be of considerable length, sometimes an inch or more.

Fig. 601.—Villous Tumour of Bladder.

Other simple tumours are occasionally met with. Thus in children **simple mucous polypi** have been observed. They are smooth or nearly smooth on the surface, and composed chiefly of myxomatous tissue, similar to that seen in the simple polypus of the nose. In others the connective tissue basis of the tumour was so firm and the papillation on the surface so imperfect

that the growth has been described as a **fibroma**. Probably all these growths are closely related to each other, consisting essentially of an outgrowth from the submucous tissue of the bladder. **Myomata** also, or tumours containing non-striated muscular fibre, have been met with springing from the wall of the bladder.

**Symptoms.**—Simple tumours of the bladder occur usually in youth or early middle age. The earliest symptom in all forms of simple tumour is painless hæmorrhage. At first it is small in amount and intermittent, but as the disease progresses it becomes more abundant and almost constant. The characteristic sign of hæmorrhage from a villous tumour is that the blood is not uniformly mixed with the urine, but comes chiefly towards the end of micturition, sometimes dropping away almost pure after the urine has ceased to flow. The quantity may be very large, and clots are often passed. As the disease advances frequency of micturition and the general signs of irritability of the bladder may make their appearance, but hæmaturia may form the only symptom for many months or even years. I have known abundant hæmaturia to continue for many years—for twelve or fourteen—probably from a papilloma, without deranging the general health to so great an extent as might be

expected from so continuous and copious a loss of blood. The most important sign, and one which should always be persistently sought for, is the passage of recognizable fragments of the growth in the urine. But little information is gained by sounding; occasionally some irregularity may be felt, but its nature and outline cannot be determined. A hollow sound may, however, return with some of the growth in its eye, and thus determine the nature of the case. Profuse hæmorrhage, after sounding, commonly occurs, but is not sufficient to found a diagnosis upon. Examination of the trigone from the rectum never gives any information unless the tumour be very large, when it might possibly be recognized by pressing firmly above the pubes at the same time. Careful examination of the bladder by means of a small flat-bladed lithotrite may detect the presence of the tumour, as in the first case recorded by Thompson.

These tumours occasionally become encrusted with *phosphatic* matter, deposited upon them by the urine, and then they will resemble still more closely a calculus when the bladder is sounded; from it, however, they may be distinguished by their fixed character, and by the impossibility of passing a sound around them.

If the disease be left unrelieved it terminates fatally sooner or later, sometimes by exhaustion from constant loss of blood, but more often by disease of the kidneys induced by the obstruction to the orifices of the ureters by the growth, or by septic inflammation extending to the pelvis of the kidney.

The **Diagnosis** can usually be made by attention to the above points, but it must be remembered that certain other affections may cause symptoms closely resembling those of a benign tumour. Among these Hurry Fenwick, who has made a special study of this subject, enumerates:—1, Certain forms of prostatic congestion occurring in young men; 2, Certain forms of renal hæmorrhage, such as that due to granular kidney (p. 1008) and early carcinoma; 3, Urethral caruncle in the female; and 4, Stone in the bladder, especially in elderly men, if the bladder be insensitive, or the stone lodged behind the prostate. In practised hands the employment of the electric cystoscope has proved of the greatest value in the detection of simple tumours of the bladder, and as a means of distinguishing between this disease and other causes of painless hæmaturia (p. 1135). Not only may the presence of the tumour be ascertained, but valuable information may be gained as to its size and situation.

In the cases in which the Surgeon is unable to make a certain diagnosis by other methods, he may proceed to explore the bladder digitally through an opening, which will also serve for the removal of the growth, if such be found to exist. This exploration may be carried out through a perineal incision, similar to that recommended by Thompson in some cases of irritable bladder; but, as a general rule, suprapubic cystotomy allows a more thorough examination, and is far more convenient for the removal of the tumour. Should there be no papilloma, the method of examination will determine the condition of the interior of the bladder, the presence or not of malignant disease, or of encysted calculus, and if none of these are present, will serve as an opening through which drainage may be maintained, in the hope of relieving the irritability or chronic inflammation from which the patient is suffering.

In females the bladder is easily explored by dilatation of the urethra and

introduction of the forefinger, a proceeding which, as a rule, is not even followed by incontinence of urine.

The **Treatment** of simple tumours of the bladder was up to a recent period of the most unsatisfactory character, Surgeons usually contenting themselves with attempting to restrain the hæmorrhage by means of gallic acid and similar astringents. Operative means were seldom employed. It is true that Civiale removed a small growth situated near the neck of the bladder by seizing and twisting it off with a lithotrite. Warner removed a tumour of this kind the size of an egg from the bladder of a woman after dilating the urethra. Billroth removed a tumour from the bladder of a boy which proved to be in parts a myo-sarcoma, in others a myo-carcinoma. It was as large as a man's fist, and had a pedicle which appeared to be connected with the muscular coat. The operation consisted of cystotomy by the ordinary lateral operation. But as the tumour was too large to be got away through the perinæum, the bladder was opened above the pubes by a free transverse cut. The tumour was then torn away by the finger, and the pedicle cut across with a knife guarded by the finger. The patient did well. Humphry in 1877 operated on a boy who had a tumour in the bladder causing dysuria and hæmorrhage. He opened the bladder by lateral cystotomy through the perinæum, and removed the tumour with forceps and the finger-nail. It proved to be a fibro-sarcoma. The patient made a good recovery. Volkmann and Marcacci both performed suprapubic cystotomy for the removal of vesical myomata, but with fatal results. In 1881 Ransohoff of Ohio removed a tumour as large as a small peach growing from the posterior wall of the bladder. The operation he practised was lateral cystotomy; the tumour was then scraped away by means of one of Volkmann's sharp spoons. The patient recovered after a tedious convalescence.

To Thompson is due the merit of having placed the operation on a more definite basis. His earlier operations were all performed through the perinæal incision, described at p. 1119. The finger was introduced into the bladder through the opening in the membranous urethra, and the position of the tumour ascertained; it was then crushed or torn away from the mucous membrane by means of specially-constructed forceps. Increasing experience showed that this method was only adapted to simple pedunculated growths of very moderate size. For large growths, therefore, Thompson found it necessary to proceed to suprapubic cystotomy, pushing up the bladder with a large sound passed through the perinæal wound.

More recently, however, Thompson has practised suprapubic cystotomy both for exploration and removal of the growth. Even for small pedunculated growths this operation is probably safer, especially for those Surgeons whose experience is limited, as in it the forceps can be guided by sight and touch, whereas, by the perinæal method, it is more or less a scratch in the dark. Among others who have especially advocated the high operation are S. Jones, Bennett May, and Hurry Fenwick in this country, and Von Bergmann, Guyon, Dittel, and others on the Continent.

**Operation.**—The bladder is opened in the same way as in the high operation for stone (p. 1043). Each side of the incision in the bladder must be held well up by a stitch passed through the coats. The cavity must then be gently cleaned, either with a small piece of sponge, or by running a stream of boric lotion through it. Great gentleness must be used in doing this, as if

the tumour be made to bleed it is practically impossible to see anything. If, however, the bladder can be cleaned without hæmorrhage, its cavity may be illuminated by means of a lamp and mirror, or, better still, by a small incandescent electric lamp passed into it. Often, however, the blood obscures everything, and the Surgeon must be guided by feeling the growth.

Hurry Fenwick employs a specially-constructed expanding speculum, which is introduced into the opening and passed down to the growth; the water is then sucked out of it, and thus, by means of a strong light, the removal of the growth can be safely carried out. Fergusson's specula, of different sizes, may be used for the same purpose.

The growth is removed with Thompson's forceps, but sometimes, if it is sessile and widely-diffused, it may be scraped away with a sharp spoon. If the bleeding is severe, it may be arrested by sponge pressure, or by cold or hot water, or the galvano-cautery may be applied to the bleeding surface. Strong chemical styptics should be avoided, as they may cause serious cystitis. The after-treatment is the same as in suprapubic lithotomy.

In the female, dilatation of the urethra is so simple a proceeding that it should always be done before any further operation is undertaken.

**MALIGNANT TUMOURS.**—**Sarcoma** of the bladder is much less common than either papilloma or carcinoma. Roger Williams found that of 30 cases of tumour of the bladder consecutively treated in four London hospitals only 6 were sarcoma, whilst 59 were carcinoma and 23 papilloma. The growth is composed of round cells, or mixed round and spindle cells, and is papillary on the surface. The distinction between this and a papilloma with a thick base which has been inflamed is not easy to make out, and further investigation is required before a clear separation can be made between these tumours; more especially as all new growths in the bladder, whether simple or malignant, tend to assume a papillary form. From a study of fifty cases of sarcoma of the bladder, Fenwick finds that in 20 per cent. the surface of the tumour is villous. Thompson describes tumours which, in his opinion, occupy a place between papilloma and sarcoma, and which he terms "transitional." One tumour removed by him was found to be a chondrifying sarcoma.

Fig. 902.—Carcinoma of Bladder.

**Carcinoma** appears to be the most common form of new growth affecting the bladder primarily, and, in addition, the bladder is often invaded by malignant growths originating in the rectum or uterus. Primary carcinoma of the bladder assumes the squamous-celled form. Scirrhus is said to have been met with, but most probably it commenced in the prostate and not in the bladder itself. Carcinoma of the bladder often commences on the posterior surface, extending secondarily to the trigone. As a rule the tumour invades the wall of the bladder from the first, and rapidly ulcerates; in rarer instances the tumour grows more superficially, and may slowly form a considerable mass of growth with but little tendency to infiltration in the early stages. The ulcerating surface of the tumour occasionally becomes encrusted with phos-

phatic deposit, and sometimes a phosphatic calculus may form in the diseased bladder, and thus add greatly to the intense pain that usually attends this affection.

**Symptoms.**—Sarcoma of the bladder is so rare that in speaking of the symptoms of malignant tumours the remarks will have reference chiefly to carcinoma. Sarcoma has been met with in childhood; it is then usually of rapid growth, and quickly proves fatal. Carcinoma is rarely met with before forty, and is more common in men than in women. The symptoms it gives rise to are intense dysuria, with discharge of blood and viscid mucus, in which fragments of the tumour may be found. No conclusion of any kind can be drawn from single cells; it is only when a distinct group of cells is found, possibly attached to a portion of stroma, that any opinion can be formed as to their source. In a case under the care of Berkeley Hill, the nest-like arrangement of the epithelial cells was recognized in some fragments passed in the urine. Thompson states that the diagnosis of cancer from simple tumours may be made by the age of the patient, and by the fact that pain and frequency of micturition appear early, often before the blood. In simple tumours, blood is the first symptom, preceding pain, often by many months. The rapid progress of the disease, and the intensity of the patient's sufferings, usually differ widely from the slow progress and slight discomfort caused by simple tumours during the early period of their development. The symptoms will, however, be found to differ according to the varying tendency of the tumour to infiltrate the wall of the bladder. Fenwick has shown that in the case of the more superficial slowly-growing varieties of carcinoma the early symptoms may closely resemble those of a papilloma; the bleeding being unaccompanied by pain, but usually being more profuse than that due to a simple growth. Cancer of the bladder frequently causes a tumour which can be felt from the rectum: simple tumours practically never do, and for this reason Thompson lays down the law that if the tumour can be felt from the rectum it is not a case to operate on except for the purpose of relieving suffering by perineal drainage. Death usually occurs from exhaustion and the spread of septic inflammation to the kidneys.

When secondary to rectal cancer, a communication will usually have been established between the two cavities, through which flatus and faeces pass into the bladder, and thus greatly aggravate the patient's sufferings.

The **Treatment** of cancer of the bladder must necessarily be merely palliative in all but exceptional cases. Morphia hypodermically administered, the frequent use of antiseptic injections, possibly drainage of the bladder through a median perineal section, and, in those cases that are secondary to rectal cancer, colotomy, constitute the main elements of the treatment. In some cases of superficial papillary carcinoma long freedom from recurrence has followed operation; the surface of the growth being removed with forceps and the base with scissors or a lance-pointed knife. The possibility of removing a portion of the wall of the bladder has been demonstrated by numerous experiments on animals, and by operations on the human subject. In 1885 Sonnenburg, of Berlin, removed two-thirds of the bladder wall, opening the peritoneum in so doing. He sutured the peritoneum accurately, but was unable to close the walls of the bladder, and yet the woman survived one month, dying of exhaustion. In the same year, Antal, of Buda Pesth, successfully removed about one-third of the bladder without wounding the peritoneum.

which had to be stripped off part of the portion removed. Such proceedings can, however, rarely be possible.

The **Results** of operation in carefully selected cases of tumour of the bladder have been on the whole satisfactory. Hurry Fenwick has recorded the results of his first 40 operations undertaken for the removal of tumours of the bladder diagnosed to be present by means of the cystoscope. In one case no actual tumour was found, and in another no attempt was made to remove it. In 38 cases a tumour was removed. In 3 cases death was directly due to the operation; in 2 cases of carcinoma recurrence occurred within three months and proved fatal, and in 4 cases a second operation was performed for recurrence. The remaining 27 cases were in good health when the report was made, in one case four years having elapsed since the operation.

#### HÆMATURIA.

The admixture of blood with the urine may usually be recognized by the colour which it communicates to this fluid. If the blood be in large quantity, the urine will be dark brown, chocolate, or maroon-coloured, and will stain red the bottom of the utensil or a piece of white blotting-paper. If it be in smaller quantity, the urine will be brown in varying shades—smoky, or having something of the aspect of thin beef-tea; in other cases it will be little discoloured, but will deposit a red or brown sediment on standing. Under the microscope, blood-discs may be detected in large numbers. Heat coagulates the blood into a brownish-grey deposit, leaving a clear supernatant fluid. Microscopic examination should never be neglected in doubtful cases, as by that means small traces of blood may be certainly recognized; and, moreover, it must be remembered that in the condition known as hæmatinuria the urine is darkly stained with blood-pigment, but contains no corpuscles. The patient's word that he has passed blood should never be relied upon too implicitly, as high-coloured urine depositing uric acid or urates is often ignorantly supposed to contain blood.

**Hæmaturia** may arise from a *constitutional* condition or from a *local* cause. When *constitutional*, it may be the consequence of scurvy or purpura. In these cases it will necessarily be associated with other, and probably marked, evidences of the disease. A form of hæmaturia, depending on the presence of a parasite—the *Bilharzia hæmatobia*—is prevalent in Africa, and has been ably investigated by Leuckart, John Harley, Cobbold, and others.

When arising from *local* causes, hæmaturia is a symptom of disease existing in some part of the urinary apparatus, and it often assumes great importance from the loss of blood induced.

**Sources.**—Hæmaturia may arise from, 1, the Kidneys; 2, the Bladder; 3, the Prostate; or 4, the Urethra.

1. **Hæmorrhage from the Kidneys.**—When occurring from the kidneys, the bleeding may be the result of injury, congestion, acute inflammation, or malignant disease of those organs; of acute, tuberculous, or calculous pyelitis; or of passage of a calculus down the ureter. The most certain evidence that the blood comes from the kidney is the presence of blood-casts of the renal tubules. The renal congestion may be inflammatory or passive; in either case the urine will present, after the discharge of blood has ceased, evidences of chronic renal disease in the form of albumen, pus, or casts. When the hæmorrhage arises from renal calculus the symptoms described at p. 1007 will be well

marked. Blood from the kidney does not often appear as clots, and is uniformly mixed with the urine. Blood-casts of the ureter have been seen in cases of very profuse renal hæmorrhage from cancer or injury.

2. **Hæmorrhage from the Bladder.**—If the blood proceed from the bladder, it may be the result of congestion of the mucous membrane, of the irritation of a calculus, of a papilloma or other villous tumour, or of the ulceration of malignant disease. When it depends on vesical congestion, there will be a sensation of weight in the region of the bladder, with frequent desire to pass urine; when it depends on calculus, the special symptoms of the existence of stone will be present. When it occurs from a villous tumour at the neck of the bladder, the quantity of blood lost is usually very great and the hæmorrhage persistent. If it arise from malignant disease, the discharge of pus, and of the *débris* of the ulcerating tumour, may afford evidence of the source of the hæmorrhage. Blood from the bladder usually is most abundant towards the end of micturition, especially in cases of tumour, the first urine that passes, or that is drawn off by a catheter, being pale and less bloody than the last, and at the termination nothing but blood may flow. In stone and cystitis it is more often uniformly mixed with the urine. Irregular masses of clot are often passed when the hæmorrhage has been very abundant.

3. **Hæmorrhage from the Prostate.**—If the prostate be the source of hæmorrhage, the discharge may be occasioned by congestion of that organ, or by its ulceration, simple or malignant. In these cases, exploration by the rectum and urethra will indicate the true cause of the bleeding. The blood usually finds its way back into the bladder rather than towards the penile urethra, and thus may appear towards the end of micturition, or be uniformly mixed with the urine.

4. **Hæmorrhage from the Urethra.**—The bleeding may arise from congestion or inflammation of the mucous membrane, or may follow rupture of the walls of the canal, consequent on injury or on the introduction of instruments. Blood from the urethra usually flows independently of micturition, as in recent injuries, or passes with the first few drops of urine. It may, however, occasionally come with the last drops expelled. This is by no means uncommon in gonorrhœa, or in cases of gleet dependent upon a granular condition of the mucous membrane of the bulbous portion of the urethra. It seems, then, to be due to the contraction of the ejaculatoriæ squeezing a drop or two of blood from the inflamed spot.

**The Treatment** of hæmaturia must necessarily have reference to its cause. When it depends on a morbid constitutional state, as scurvy or malarial poisoning, the treatment of the disease, of which the hæmaturia is merely a symptom or an effect, must be conducted on ordinary medical principles. If it arise from inflammatory congestion of the kidneys, bladder, or prostate, cupping, or the application of leeches over the affected part, demulcents, and saline drinks, will be most efficacious; if from passive congestion, saline purgatives, followed by the use of astringents, will speedily induce a cessation of the hæmorrhage. The astringent that exercises the most marked influence in arresting hæmaturia, when that condition is purely passive, is undoubtedly gallic acid. This may be given in five or ten-grain doses, frequently repeated, in infusion of buchu or uva ursi.

Sometimes the bladder becomes distended by a large soft coagulum, filling up its interior, and causing it to reach to the umbilicus, forming a rounded solid tumour, like the gravid uterus. In such circumstances, the largest catheter

that can be introduced must be passed, and an aspirator or lithotripsy evacuator adapted to it. By this means the blood, even when coagulated into a single large clot filling the whole bladder, may easily be removed. If these instruments be not at hand, the fluid contents of the bladder must be drawn off by a large catheter, and the more solid portions broken down and washed away by the injection of one of the antiseptic solutions recommended for cleaning the bladder in chronic cystitis (p. 1116). Should decomposition occur, the bladder must be washed out frequently with antiseptic fluids.

## CHAPTER LXX.

## DISEASES OF THE PROSTATE.

THE prostate is subject to Acute and Chronic Inflammation, to Hypertrophy, and occasionally to Atrophy, Malignant Disease, Tubercle, and the formation of Calculi.

## PROSTATITIS.

**Acute Inflammation of the Prostate, or Prostatitis**, very rarely occurs as an idiopathic affection. When met with, it is usually the result of gonorrhœa, or of the use of instruments, more especially in middle-aged men.

The **Symptoms** are, deeply-seated dull pain, with heat and weight in the perinæum, a frequent desire to pass urine, and very great and spasmodic pain accompanying the act; in fact, the irritability of the neck of the bladder is perhaps the most distressing feature in the disease. These symptoms are, however, common to various inflammatory affections of the urinary organs, and they can be distinctly referred to the inflamed prostate only by rectal exploration. On introducing the finger into the gut, the prostate will be found much enlarged and exquisitely tender. The patient often suffers considerably from the pressure of the inflamed organ upon the rectum during defæcation.

The **Treatment** should be directed to the prevention of suppuration. The perinæum must be well leeches; warm hip-baths and poppy fomentations assiduously employed; and salines administered. In this way, the formation of abscess within or around the prostate may, in many cases, be prevented. Morphia suppositories may be used to relieve pain.

**Prostatic Abscess** may form as a consequence of acute inflammation, and in this way it is not very unfrequently a complication of gonorrhœa; or it may occur with comparatively little antecedent inflammation—as sometimes happens in pyæmia, or if the organ be accidentally bruised during lithotrity. In these cases, abscess perhaps as frequently forms in the areolar envelope as in the organ itself. Idiopathic suppuration of the prostate, irrespective of any of the above causes, is of rare occurrence; but it may occur in individuals of broken health, the matter then usually accumulating in large quantity, and discharging itself into the bladder.

**Symptoms.**—When inflammation of the prostate terminates in abscess, rigors, with stranguary, and perhaps retention of urine, occur. In many cases the perinæum becomes brawny; in others, tenderness of the gland and deep fluctuation may be felt through the rectum. When left to itself, the abscess most usually gives way into the urethra or neck of the bladder; but it may, especially when occurring in the prostatic capsule, open externally into the perinæum, or even into the rectum. In many cases, the abscess presenting on the urethral surface of the prostate is burst during the introduction of the

catheter, used for the relief of retention of urine caused by the swelling ; the matter escaping along the side of and through the instrument.

**Treatment.**—It not unfrequently happens that the first certain indication afforded to the Surgeon of the formation of a prostatic abscess is the escape of pus by the urethra, or mixed with the urine, so as to give this fluid a thick milky appearance. In such circumstances, the only available treatment is that for the relief of the strangury and local vesical irritation already described. But if, as sometimes happens, the pus come forward into the perinæum, and a hard brawny mass be felt, a deep incision should be made into this. The Surgeon must not wait for fluctuation, but must cut deeply in the direction of the matter, keeping, however, as nearly as possible in the middle line, with the back of the knife towards the rectum. Even if no pus escape at first, it may do so if the part be well fomented for a few hours ; and thus communication with the urethra or rectum may be prevented. It is rarely necessary to open the abscess into the rectum, but this may be unavoidable if the abscess appears to be on the point of bursting through the mucous membrane. The bowels must first be thoroughly opened, and the rectum cleared with an enema. The patient is then anesthetized and placed in the lithotomy position, the pelvis being well raised on a pillow. A duck-bill speculum is next passed, and the fluctuating spot incised with a scalpel ; the opening is then dilated with a pair of polypus-forceps, and a drainage-tube inserted. The tube falls out in a few hours, and need not be replaced, as the cavity usually closes rapidly as soon as the pus is let out. If the incision be limited, and kept as nearly as possible in the middle line, there is no hæmorrhage of any consequence.

**Retention of Urine from Prostatitis** may be due to swelling of the gland, to infiltration of exudation-matter around it, or to the formation of pus in it. If the symptoms are not urgent a morphia suppository should be administered, and the patient should try to pass water in a hot hip-bath. If that fails an instrument must be passed. A soft india-rubber catheter should first be tried. If that fails a soft elbowed catheter not smaller than No. 8 (English scale) should be tried. If soft instruments fail the Surgeon must fall back on silver catheters. In these cases the neck of the bladder may be carried to a considerable distance from the surface, and may then not be reached by an ordinary catheter, which may be buried up to the rings and yet not enter the cavity of that organ. In these circumstances a silver prostatic catheter should be employed ; and this must be carefully introduced, lest, by entering the cavity of an abscess which has already burst *per urethram*, it might be supposed to have entered the bladder itself. In introducing the instrument, care should be taken to keep its point constantly in contact with the upper surface of the urethra, and to hook it round the pube. The upper surface of the urethra is a sure guide to the bladder ; for any abscess, false passage, or irregularity of direction will always first affect the lower aspect of this canal, being surrounded by yielding structures ; whilst the upper part, being firmly supported by bone and ligament, cannot so readily alter its direction.

**Chronic Inflammation of the Prostate** may follow the acute affection, especially when it is gonorrhœal. It may also be induced by masturbation and other forms of erotic excitement. The patient is troubled by a sense of weight and fulness in the perinæum, and there may be an occasional glairy

discharge from the urethra; fine threads of mucus, the so-called "*prostatic threads*," may often be seen floating in the urine, especially in that first passed, and in the last few drops expelled by straining if these be collected separately. The discharge of glairy mucus from the urethra after micturition or defæcation may be so marked as to constitute a true "*prostatorrhœa*" which is of importance chiefly from its liability to be confounded with spermatorrhœa, and from the depressing effect consequently produced upon the patient's mind. Frequency of micturition and some pain during and after the act may be present. Constipation is almost invariable. Examination by the rectum shows that the prostate is slightly tender, hard, and enlarged, sometimes more on one side than the other. A chronic abscess may slowly form without great increase in the intensity of the symptoms. This complication, which is fortunately rare, is recognized by examination from the rectum. Should the abscess burst into the urethra, the cavity in the indurated gland tissue may be very slow in healing. I have known a case in which, after many years, the prostate remained hard and enlarged, and on pressing firmly on it from the rectum, pus could be made to flow from the urethra. The patient was obliged to draw off his water with a catheter, but suffered very little in his general health.

The **Diagnosis** of this condition from tuberculous disease is often extremely difficult. Its extremely chronic nature, the absence of any disease of the testicles or vesiculæ seminales, the more uniform enlargement of the gland, and the history of the case will usually determine its nature. The distinction between prostatorrhœa and spermatorrhœa may be made by microscopic examination of the discharges.

The **Treatment** consists in attention to the general health. Tonics, especially iron and nux vomica, and aperients are usually required. Moderate exercise, change of air, and sea-bathing may be of use. Locally, the application of cold has proved most useful. The cold sitz bath or perineal douche may be prescribed once or twice a day. Berkeley Hill advised that the bath should be commenced at a temperature of 50° F. and gradually prolonged and lowered in temperature until ten minutes at 35° F. is reached.

Small rectal injections of cold water may also be used. A belladonna suppository sometimes relieves the uncomfortable sensations. Blistering the perineum is a recognized method of treatment, but often fails. In obstinate cases in which simpler means have failed injections of nitrate of silver may be made into the prostatic urethra. Berkeley Hill, who regarded this treatment highly, advised that the injection should be made with a Guyon's catheter and syringe, the strength of the solution at the first application being not more than 5 or 10 grains to the ounce and the amount not more than 10 to 20 minims. Ten minims of a 10 per cent. solution of cocaine should be previously injected, and ten minutes after the silver solution has been used the patient is directed to pass his water. If severe pain follows, it may be relieved by a hot hip-bath and belladonna suppositories. Three or four injections are usually required at intervals of one or two weeks, the strength of the solution being increased to 20 or even 50 grains to the ounce. The subsequent passage of a large steel sound may be useful.

In the rare cases in which suppuration occurs, the abscess must be opened in the perineum.

**A deep-seated and very Chronic Abscess** sometimes forms in the

pelvis, between the bladder and the rectum, behind the prostate, giving rise to a train of obscure symptoms, indicative of irritation about these organs, such as dysuria, strangury, and occasional admixture of pus with the urine. On careful examination of the perinæum and rectum, some slight hardness may perhaps be deeply felt in the mesial line, or towards one side of it. This slowly increases, and a perinæal abscess of an ill-defined character develops. When this has become sufficiently evident, a free incision should be made into it, and on careful exploration of the cavity with a probe, a sinus will probably be found leading into the pelvis, and to the original seat of the abscess. This requires to be opened up by a free incision on one side or other of the perinæum, as if for lateral lithotomy, and a direct exit given to the matter. The cavity must then be allowed to granulate from the bottom.

#### CHRONIC ENLARGEMENT OF THE PROSTATE.

**Chronic Enlargement of the Prostate** may be looked upon as a senile disease, seldom occurring before the age of fifty-five, but commonly met with after this. At that period of life, as Brodie observes, when the hair becomes grey and scanty, when the coats of the arteries begin to become atheromatous, and when the arcus senilis forms on the cornea, the prostate often becomes increased in size; but unless the enlargement interferes with the free escape of the urine, no disease can properly be said to exist. If we look upon the diseased enlargement of the prostate as such an amount of hypertrophy of this organ as interferes seriously with the discharge of the urine, we shall probably not find it so frequent even in old men as is generally supposed. Guthrie states that it is not commonly found in the pensioners at Greenwich Hospital. Thompson found that an enlargement appreciable after death existed in 34 per cent. of men above the age of sixty; but that such a degree of enlargement as to give rise to symptoms during life was met with only in 15 or 16 per cent. of the cases he examined. Though age must be looked upon as the primary cause of hypertrophy of the prostate, there can be little doubt that it may be predisposed to by any continued source of irritation of the urinary organs, such as gonorrhœa, stricture, or hard living.

**Characters.**—Enlargement of the prostate is due to hypertrophy of its normal structures—muscular, fibrous, and glandular. In the early stages the enlargement appears to be due chiefly to overgrowth of the glandular tissue, but in the later stages the fibrous tissue is in great excess; when, however, the size of the gland has been very slowly and not greatly enlarged, there is nearly equal hypertrophy of all the tissues. The enlargement generally occupies the whole of the organ, and may cause its size to increase to that of a hen's egg or a small orange. In most cases, all the lobes are enlarged equally or nearly so, but sometimes there is a disproportionate development of one of the lateral lobes or of the middle portion. More rarely, the lateral lobes or the anterior commissure alone are affected.

The enlarged prostate, in the earlier stages, presents to the naked eye an appearance of rotundity and increased fulness; at a more advanced stage, there may be great irregularity of outline. There is usually no change of colour externally, and the texture of the gland is generally indurated; though sometimes, when the glandular element is chiefly increased, it is found to be <sup>some-</sup> ~~lower~~

and softer than natural. On making a section, the cut surface bulges above the level; and the shades of colour are more strongly marked than in the healthy prostate. Not uncommonly, single gland-lobules are found hypertrophied; and in some cases, spheroidal prominences are seen, which are easily enucleated. In some instances, an abundance of fluid escapes from the cut surface and from the openings of the prostatic ducts; while in other cases this is entirely wanting. Small cavities, due to dilatation of the gland-follicles, are occasionally found; sometimes empty, sometimes containing a yellow fluid resembling pus in appearance, but consisting of the prostatic secretion in a thickened state. The prostate may attain a very large size. The largest that I have seen is one in the Norwich Hospital Museum, taken from a man of eighty; it weighs more than 20 ounces.

**Simple Prostatic Tumours.**—The nature of simple tumours of the prostate has been carefully studied by Thompson; to whose work on the diseases of this organ the student is referred for further information. According to Thompson, tumours of non-malignant character are met with in most cases of hypertrophied prostate, and also occasionally when there is no enlargement of the organ. He divides them into two classes:

"1. Tumours which are generally imbedded in the substance of the prostate, but the structures of which are isolated from those which surround them.

"2. Outgrowths which are continuous in structure with the parts of the prostate whence they spring, but which manifest a tendency to become partially isolated, by assuming a more or less polypoid form, and maintaining attachment to the parent organ through the medium of a pedicle only."

1. The *isolated tumours* in the substance of the prostate may occupy any portion of the organ; but are, perhaps, more numerous in the lateral lobes than elsewhere. They are easily enucleated, having but a loose connexion with the substance of the gland. In diameter they vary from  $\frac{1}{16}$ th to  $\frac{3}{8}$ ths of an inch. They are firmer and mostly paler in colour than the proper prostatic tissue, and are less vascular.

"The basis of the tumours appears to be the fibrous basis or stroma of the prostate itself, an admixture of unstripped, soft, pale muscular fibres, and connective with a little elastic tissue, closely interwoven. Interspersed with this, there are present in most cases small cavities containing flattened polygonal or spheroidal epithelium, like that seen in a pouch at the extremity of a prostatic gland-duct, and sometimes, also, some prismatic epithelium. These cavities are sometimes solitary, sometimes slightly branched, and sometimes of an elongated or tubular form. In a few instances there is very little, or perhaps no such glandular tissue to be found; generally, however, a careful search will discover it. In some of the outlying tumours the glandular structure is more perfectly developed—in some it is quite so—and a duct is furnished which evidently carries secretion to the appointed destination."

2. The part of the prostate which is most usually the seat of *outgrowth* is the middle or urethral portion, which may become greatly enlarged in size, with or without hypertrophy of the lateral lobes. The growth assumes a pyriform shape, and is more or less pedunculated. It is continuous in structure with the prostatic tissues, and has its own duct, which opens into the urethra through the pedicle. Prostatic concretions are commonly found in these outgrowths; never in the isolated tumours.

Though most common in the middle portion of the prostate, outgrowths

may occur from the posterior part of one of the lateral lobes, or from that portion of the gland which lies above or in front of the inner orifice of the urethra.

In rare instances, the verumontanum alone appears to be affected, forming a thickened polypoid outgrowth, which projects in a valvular manner, and interferes materially with the flow of urine.

Thompson points out that, as had been suggested by Velpeau, remarkable analogies exist between these prostatic outgrowths and the fibroid tumours of the uterus. This view is in accordance with the theory that the prostatic utricle is the analogue of the uterus.

**Mechanical Effects of Enlarged Prostate on the Urinary Organs.**—

Enlargements of the prostate are productive of inconvenience with regard to the flow of urine, giving rise either to retention or to incontinence, or to a kind of mixture of both conditions. When the lateral lobes are enlarged, there is a diminution of the lateral or transverse diameter of the urethra, at the same time that the antero-posterior diameter is increased, so that the canal becomes a chink-like passage. The urethra also becomes greatly elongated and tortuous; and is diverted from the natural direction—this varying with the form of enlargement. When the median portion is enlarged, there is a more or less angular curvature of the canal at the prostatic point. When, in addition, there is enlargement of one lateral lobe, the urethra is curved also laterally in the direction of the enlarged lobe. The lateral deviation may occur also when there is enlargement of the middle lobe; but it then affects both sides.

Fig. 903.—Bladder laid open, showing Enlargement of Urethral Portion of Prostate.

The inner orifice of the urethra also undergoes changes. Enlargement of the posterior part of the middle portion of the prostate gives it a crescentic form, with the convexity directed upwards; and, in enlargement of either lateral lobe, the convexity of the crescent lies towards the side opposite the enlarged lobe. Sometimes, when there are two or more irregularly enlarged lobes, the orifice is very much distorted, elongated, and tortuous. In cases of valvular or pedunculated projections from the posterior portions, the orifice may appear to be overlapped altogether. This condition existed in the case from which the accompanying drawing (Fig. 903) was taken; the third, or median lobe forming a pedunculated tumour which acted like a valve and obstructed the exit of the urine from the bladder, though it did not offer any obstacle to the introduction of a catheter.

The elongation and expansion of the prostatic portion of the urethra give rise to an increase in its capacity, so that it sometimes holds two or three ounces of urine; and the elongation will carry the neck of the bladder upwards and behind the pubes, to a considerable distance from its normal position.

While the lateral enlargements cause the urethra to assume a somewhat tortuous course, the middle lobe, if hypertrophied, may readily occasion retention,

by projecting against the entrance to this winding channel, and falling over it like a valve whenever the patient attempts to pass urine, as in Fig. 904. In this condition no urine is passed until by accumulation within the bladder the neck has become so stretched that the valve-like obstruction no longer closes the orifice. Then a small quantity of urine is expelled; the neck of the bladder collapses, and before the cavity is completely emptied, the orifice is blocked by the projecting middle lobe, and the flow ceases. Thus a certain amount of urine is always retained, which is commonly termed the "residual urine,"

Fig. 904. — Results of enlarged Prostate: Bladder enlarged; Ureters dilated; Chronic Disease of Kidneys.

and none escapes till the bladder is in a state of considerable tension. As the middle lobe increases in size, a greater degree of stretching is necessary before urine can escape. Under this constant tension the bladder slowly yields and becomes dilated, its walls are thickened by fibroid tissue, and it gradually becomes completely "atonic," losing all active power of contraction. At last a condition is reached in which urine flows only when the bladder is greatly distended, and the escape of a few drops is sufficient to render the obstruction complete, and thus a condition of almost constant dribbling is established. This forms the most typical variety of prostatic obstruction. Less commonly, the obstacle to the passage of urine is of such a nature that it can be forced by increased pressure, and we then find the muscular coat of the bladder hypertrophied, as in stricture of the urethra. In still more rare cases the middle lobe lies between the enlarged lateral lobes, thus propping the neck of the bladder open, and then true incontinence may occur with constant dribbling of urine.

The effect on the kidney will vary according to circumstances. If the bladder is in a constant state of over-distension, a similar increased tension will occur in the ureters, as it is evident that increased force will be required to drive the urine through their orifices. We consequently find all the signs of increased tension already described (p. 994); dilated ureters and pelvis, absorption of the pyramids, chronic interstitial nephritis, &c. (Fig. 904). Finally, should decomposition occur in the urine retained in the bladder, it may extend through the orifice of the ureter to the kidney; and in this way a large proportion of patients suffering from prostatic disease die of septic suppurative nephritis.

**Moral Effects of Enlarged Prostate.**—The irritation of a congested and enlarged prostate will excite libidinous ideas in the aged, which may lead to the perpetration of acts of indecency—such as exposure of the person, indecent assaults on children, or to a general deterioration of the moral tone.

But not only does the diseased state of this body thus excite a depraved condition of the mind; the converse also will happen. And if the true history of many cases of prostatic congestion and hæmorrhage were told, the diseases would be found to have begun in irregular sexual or erotic excitement by which the genital organs have been over-stimulated.

**Bar at the Neck of the Bladder.**—Under this name has been described a transverse ridge obstructing the internal orifice of the urethra, and causing symptoms exactly analogous to those produced by hypertrophy of the middle portion of the prostate. According to Thompson, the fold is in the great majority of cases actually caused by an outgrowth from the middle portion of the gland. In exceptional cases, however, it may be due to hypertrophy of the muscular fibres at the neck of the bladder, produced by long continued irritation, usually caused by chronic cystitis from stone or stricture. Lastly, in very rare cases, a valve-like fold of mucous membrane may be drawn up by enlargement of the lateral lobes without affection of the median portion of the gland.

The **Symptoms of Enlarged Prostate** arise primarily from the mechanical obstacle offered to the escape of the urine. The first symptoms usually consist in the feeling of a necessity to strain slightly before the urine will flow; and then, after the bladder has apparently been emptied, in the involuntary escape of a small quantity of urine. The patient also finds that he is much longer than usual in emptying the bladder; for though the stream flows freely enough as soon as it has once begun to escape, yet it cannot be properly projected, the bladder having, to a certain extent, lost its tonicity. It commonly happens that the more the patient strains the less readily will the urine come away, whereas when he remains quiet, it will usually flow with more freedom. This is especially the case in pedunculated enlargements of the middle lobe. About this time frequency of micturition usually becomes a marked feature, especially at night. In fact, the great majority of patients apply to the Surgeon, not on account of difficulty in passing water, but because they are called upon to perform the act of micturition too frequently. This condition may gradually increase till it amounts to actual dribbling. The frequent discharge of a small quantity of urine may lead the incautious Surgeon to suppose that the patient is affected with true incontinence of urine or with irritability of the bladder. This error may always be guarded against by careful examination of the pubic region by percussion and palpation. Dulness will often be found extending half-way to the umbilicus, and the tense distended bladder may be readily felt above the pubes. If there is any doubt the patient must be made to pass water, and immediately afterwards a soft catheter must be passed. In this way the presence of residual urine and its quantity are determined.

The symptoms may for a long time remain limited to frequency of micturition with some difficulty in the act. The urine remains acid and normal in every respect, and the patient suffers but little, if at all, in his general health. The condition is, however, always one of considerable danger. The over-distended bladder is always prone to slight attacks of cystitis from exposure to cold or other causes. The urine then becomes cloudy from excess of mucus, and often acquires an offensive fishy smell, while still remaining acid. The mucus accumulates in the pouch behind the enlarged prostate, and ammoniacal decomposition readily takes place. This may occur without the passage of

instruments, but in a considerable proportion of cases it is not noticed before the use of the catheter has been commenced. Should it happen, the cystitis becomes more acute, and the symptoms of septic poisoning—febrile disturbance, great depression, brown tongue, nausea, delirium, &c.—may set in and terminate fatally, when septic inflammation of the kidneys, by extension up the ureter, will usually be found to have been the immediate cause of death.

**Complete Retention of Urine from Enlarged Prostate** is a common complication of the disease. It may arise in a patient who has not been able to empty his bladder for some time, and is little more than an aggravation of his usual condition, or it may occur in an old man whose prostate is considerably enlarged, but who, under ordinary circumstances, gets rid of his urine without difficulty. In the latter case it is due to congestion and swelling of the diseased gland, usually induced by exposure to cold, or by alcoholic or venereal excesses. It is especially apt to occur after drinking the sour bad wines usually provided at public dinners.

**Diagnosis.**—The exact condition of the enlarged prostate can be ascertained only by examination through the rectum and urethra. By rectal exploration with the finger, the degree of enlargement of the lateral lobes can best be ascertained; though, as in many cases the end of the finger cannot reach the further extremity of the gland, it will be impossible to say to what extent the hypertrophy has extended. The urethral exploration must be conducted by means of a long gum-elastic or a silver prostatic catheter, and will afford information that rectal exploration cannot give; by it are ascertained approximately the size of the middle lobe, and the condition of the urethra as to elongation and curve.

The diagnosis of enlarged prostate has to be made from, 1, Stricture of the Urethra; 2, Calculus of the Bladder; 3, Vesical Tumour; 4, Chronic Cystitis; 5, Atony of the Bladder; 6, Paralysis of the Bladder.

1. In *Stricture* the stream of urine is small, but the jet is increased by straining, while in enlarged prostate the stream is dribbling, but not reduced in volume, and straining only makes matters worse. Stricture most commonly occurs before middle life, prostatic disease always after. In stricture the obstruction is within six inches of the meatus; in prostatic disease it is at least seven from the orifice. It is not wise, however, to trust too implicitly to measurements in inches, as the penis varies considerably in length. If the finger be passed into the rectum, it can at once be determined whether the point of obstruction is in front of the apex of the prostate.

2. *Calculus* presents many symptoms in common with enlarged prostate, and its more special symptoms may be absent. In stone the frequency of micturition is greater by day, in prostatic disease it is worse at night. The presence of a small quantity of florid blood in the urine passed after exercise should make the Surgeon strongly suspect the presence of a stone; but the use of the sound will alone lead to an exact diagnosis.

3. *Vesical Tumour* gives rise to more pain and tenderness on the introduction of instruments than prostatic enlargement; and the urine generally contains blood and mucus, often with sabulous matter. Microscopic examination of the contents of the urine may show the presence of the tissues of the tumour. Malignant tumours may often be felt through the rectum; while villous growths give rise to the almost constant presence of blood in the urine.

*Chronic Cystitis*, without complication, the absence of the physical enlarged prostate, as ascertained by examination by the rectum and will establish the diagnosis.

*Atony of the Bladder* is, as before stated, very commonly associated with prostate. Its absence would be shown by the urine flowing from the catheter in a steady stream, not influenced by the respiratory movements, and by an active contraction of the bladder.

*Paralysis* of the bladder, accompanied by a similar affection of the rectum, is recognized by its concomitant conditions, and by the absence of all signs of enlarged prostate, and, as in atony, by the passive nature of the flow of urine through the catheter.

**Prognosis.**—In the treatment of enlarged prostate, little can be done by medical means: though the patient's condition may be somewhat ameliorated by measures calculated to lessen irritation about the urinary organs, and to improve the condition of the urine. If it be very acid, alkalies with hyoscyamine should be given. If the symptoms of chronic cystitis make their appearance, the various remedies recommended in the treatment of that disease should be given. If hæmorrhage occurs, tincture of perchloride of iron, infusion of iron, or gallic acid, will be useful. Counter-irritation, the application

Fig. 905.—Elbowed Catheter.

and other measures intended to promote absorption of the enlarged prostate are not of the slightest service.

In the great majority of cases the sole treatment of enlarged prostate is the regular use of the catheter, in order to draw off retained urine; and once this treatment has been commenced, it must be continued for the remainder of life, the patient being taught to use the instrument for himself.

In almost all cases a Jaques's flexible india-rubber catheter can be introduced into the bladder. Its use is so perfectly painless and free from danger, that it should always be tried before adopting more severe measures. If from any cause it be necessary to retain such an instrument, Hutchinson uses a catheter with rings passed into the orifice of the india-rubber catheter, and fitted with a "styletted plug." The nozzle is about three-quarters of an inch in length and is fitted accurately by the plug. The stylet reaches about two-thirds of the length of the catheter so as to stiffen it. With such an instrument in use, the patient need not be confined to bed. If the soft rubber catheter will not pass, the most convenient instrument in the majority of cases is the soft "elbowed" catheter—the *cathéter à coude*, of the size and shape represented (Fig. 905). The stem is soft and pliable, but the angle and point are made of firm gum-catheter material. By keeping the point of the catheter against the urethra, it will often slip in very easily and smoothly in the enlarged prostate. These catheters are made with their points bent into one or two angles or with double elbows, instead of single, and very often the single will not pass, another of a slightly different form will slip in readily.

The size of the instrument is of some importance. As a rule, No. 8 or 9 passes most easily. Nothing is gained by using a smaller instrument, as the passage through the diseased prostate, although it obstructs the flow of urine, is always larger than that through a healthy gland.

If neither of these instruments will enter the bladder, a common French conical instrument may pass : but this very rarely succeeds when the cond catheter fails.

A common gum-elastic catheter of full size, which may be bent to any angle in hot water and fixed by immersing it in cold, may pass when other instruments fail. Sometimes, if it be bent to a curve like that of a lithotrite, it may slip over the enlarged middle lobe. It must be remembered that the heat of the urethra soon causes the catheter to lose the form impressed upon it, and consequently, if it does not enter at once, prolonged attempts to pass it are useless.

Brodie recommended that a gum-elastic instrument, long and of large size,

Fig. 906. - Enlarged Middle Lobe of Prostate, arresting progress of the Catheter.

on a well-curved stylet so that it might preserve its curve when that is withdrawn, should be kept in readiness for these cases. A manoeuvre mentioned by Brodie will often be of use in surmounting a large middle lobe : viz., after passing the gum-elastic catheter as far as it will go, to withdraw the stylet slightly, so as to tilt up the point of the catheter, which then slips over the obstacle.

If none of the foregoing means succeed, the Surgeon must have recourse to silver instruments. If the prostate be much enlarged it may be necessary, in order to reach and empty the bladder, to use a prostatic catheter. This instrument should be of large size, about No. 12. In order properly to enter the bladder, which is carried away from the surface by the elongated urethra, the prostatic catheter should be about four inches longer than an ordinary one ; and, as the neck of the viscus is usually pushed up high behind the pubes by the projection upwards of the lateral lobes, the curve of the

instrument should be greater and longer than usual. I find the best-shaped prostatic catheter to be one the curve of which is exactly the third of the circumference of a circle five-and-a-half inches in diameter. The eyes should be large and rounded; and I have found it of use to have the lower end of the stylet provided with a piston-plate, so that, by withdrawing this the mucus may be sucked in through the eye of the instrument. In introducing the catheter, care must be taken when the point enters the prostatic urethra to depress the handle well between the thighs, while the instrument is drawn slightly towards the pubes, lest the end hitch against the enlarged middle lobe (Fig 906). If it be simply depressed, without at the same time being held back a little, it will probably tunnel the obstruction. In some cases the ordinary catheter passed in the same way will enter more easily than the prostatic. It is sometimes possible to lift the catheter over the obstruction by pressing on it with the finger in the rectum. In fact, no one curve or one kind of instrument will answer in all cases. If it is necessary to use a rigid instrument, I certainly think a silver instrument is safer and more easily managed than the gum-elastic. It might be supposed that less chance of mischief would result from the gum-elastic than from the metallic catheter, as being the softer and more yielding instrument; but this is erroneous, if the stylet be allowed to remain in, as it is then as rigid at the point, as hard, and as likely to penetrate soft structures as a silver one would be.

The commencement of catheterization in cases of enlarged prostate cannot be regarded as altogether free from risk. The patient is liable to an attack of fever such as may follow the introduction of an instrument for other purposes, and the precautions mentioned at p. 1125 must be carefully observed. Exposure to cold is especially to be avoided after the catheter has been used. Before the instrument is passed, the patient should empty his bladder as completely as possible, in order that the amount of the residual urine may be ascertained. If this be about three or four ounces the bladder should be emptied every morning and evening, whilst if this amount be much exceeded the catheter must be passed three or four times in the twenty-four hours.

The patient should use a soft catheter if possible, and the Surgeon must give careful directions concerning the cleansing of the instrument.

In cases complicated with severe cystitis and great irritability of the bladder which have resisted simpler treatment, drainage of the bladder may be the only means of saving the patient from fatal exhaustion or septic poisoning. This may most readily be done by introducing a tube through an incision into the membranous urethra (p. 1119); or suprapubic cystotomy may be performed, as first practised by Thompson in 1869, the opening being maintained by a gum-elastic catheter fitted with a silver shield, and provided with a rubber bottle to receive the urine. The suprapubic method has the advantage of allowing a thorough investigation of the bladder and prostate, but it is only available if the patient's condition is favourable.

**Operative Treatment of Enlarged Prostate.**—Various operative procedures have been proposed from time to time for the relief of difficult micturition from enlarged prostate or bar at the neck of the bladder. One of the first of these was Mercier's operation of division of the bar at the neck of the bladder by means of an instrument shaped like a lithotrite, the male blade of which was represented by a concealed knife. Mercier also devised another

instrument like a lithotrite by which he could cut a deep groove through the bar. Bottini of Genoa has revived Mercier's operation, but uses a galvano-cautery instead of a knife. Such operations have not, however, been attended with sufficient success to inspire Surgeons in general with any confidence in their utility.

Of the various methods which have been devised for attacking the enlarged prostate from the perinæum, the simplest is that practised by Reginald Harrison. The operation consists in dividing the prostate through the ordinary incision employed in digital exploration of the bladder (p. 1119). The projecting bar is divided partly with a probe-pointed bistoury, and partly by divulsion with the finger. A large gum-elastic tube is then inserted, and through it a soft catheter is passed into the bladder for drainage. The presence of the tube maintains the channel made by division of the prostate. It must be retained for many weeks, until urine can be passed voluntarily by the urethra, or a catheter readily introduced.

By far the most radical operation, however, for enlarged prostate consists in opening the bladder above the pubes and removing the obstructing portion of the gland—**suprapubic prostatectomy**. This operation, which had been performed by Belfield of Chicago, and by Trendelenburg, Socin and others on the Continent was first advocated in this country by McGill of Leeds in 1888, who published three cases in which he had successfully performed it with great benefit to the patient.

The operation is performed in the same way as in suprapubic lithotomy until the bladder is opened (p. 1044). The mucous membrane over the projecting part of the prostate is snipped through with scissors, and the enucleation effected with the finger and forceps. Hæmorrhage is arrested by irrigation with hot water. A drainage tube is inserted into the bladder and retained for two or three days.

This operation has now been performed in a large number of cases with considerable success, and in several instances calculi in the post-prostatic pouch have at the same time been removed. The suprapubic method is generally regarded as preferable to the perinæal in most cases as it allows a more thorough removal of the obstruction. The operation is not however unaccompanied by danger, and if the patient can easily pass a catheter for himself, and is free from any other complication, it seems hardly justifiable to submit him to an operation which may prove fatal. If, however, the patient cannot pass the catheter, or suffers from constant cystitis with great irritability of the bladder, or from frequent hæmorrhage, some operative procedure gives the best chance of relief. Suprapubic drainage has for some time been recognised as the best treatment in cases of prostatic disease which cannot be relieved by catheter, and experience seems to show that it is not only justifiable, but advisable to extend the operation to the removal of the cause of obstruction if possible.

**Castration for Enlarged Prostate.**—The considerations which have recently led to the performance of castration in certain cases of enlargement of the prostate are chiefly, the effect of removal of the ovaries in causing diminution in size of fibroid tumours of the uterus, and the well known fact that removal of the testes in young animals prevents the development of the prostate, and in adult animals causes its atrophy.

In a certain number of cases it has also been observed in man that removal

of the testicles was followed by atrophy of the normal prostate. The suggestion to perform castration with the definite object of causing shrinkage of the hypertrophied gland was prominently brought forward by White of Philadelphia, in 1893, but the operation was first performed by Ramm of Christiania in the same year. The patient, seventy-three years of age, had suffered from symptoms of enlarged prostate for fifteen years, and came under treatment for complete retention. The prostate rapidly diminished in size after castration and the patient recovered good power of micturition.

In this country the operation was first performed by Mansell Moullin, and he has been followed by Fenwick, Heath, and others. In the cases which have so far been recorded, more than twenty in number, the result has been almost uniformly satisfactory. In several instances the diminution in the size of the gland has been appreciable within a few days after the operation, and has gradually continued until, after several weeks, complete atrophy has taken place. Further experience alone can show whether castration is capable of producing this result in all varieties and stages of chronic enlargement, and what amount of impairment of the muscular power of the bladder is capable of recovery.

Sufficient evidence is before us to justify a continued trial of the treatment in cases of enlarged prostate in which the severity of symptoms calls for radical measures. Few men of the age at which the operation is likely to be required will refuse to submit to it if further experience can show results equal to those hitherto obtained.

**Treatment of Complete Retention from Prostatic Enlargement.—**

In these cases the patient must be relieved by an instrument as soon as possible, as elderly people are liable to suffer severely if there is any delay, fever soon setting in, which may be fatal.

It cannot be too strongly insisted on that in these cases there is no actual narrowing of the canal. The enlarged prostate is no doubt swollen, but there is always sufficient space left for the passage of the largest catheter, if only the proper way can be found. Nothing is gained by using small instruments; anything below No. 8 or 9 (English) is likely to wound the swollen mucous membrane, and cause troublesome hæmorrhage. In complete retention the various modes of overcoming the obstacles in the prostate, which have already been described, must first be attempted, beginning with soft instruments, and using silver ones only after these have failed. If the retention is thus relieved, it becomes a question whether the catheter should be left in the bladder or withdrawn after the viscus is emptied. As a general rule, it is certainly far better not to leave the catheter in, for the reasons given at page 1125. The instrument should be introduced twice in the twenty-four hours; and care should be taken, if possible, to empty the pouch behind the prostate by depressing its point. Should the mucus be very viscid and offensive, the bladder may be washed out. After the bladder has been emptied for the first time, it will be found to refill in the course of a very few hours, usually in six or eight, the secretion of the kidneys appearing to be set free on the removal of the pressure.

Should any great difficulty be experienced in introducing the catheter, it may be thought desirable to leave it in the bladder for two or three days, and then a gum-elastic one is always to be preferred, as in these circumstances it presents a great advantage over the silver catheter, becoming soft, accommo-

dating itself to the shape of the parts, and not being so liable to irritate the mucous membrane with its point, which, dipping down into the pouch behind the prostate, acts as a siphon, and empties this part of the bladder far better than a silver catheter could do.

When the bladder has been relieved, the patient must be freely purged. Belladonna suppositories are often of use, but if there be much pain, opium or morphia will be preferable. In a few days the congestion of the prostate passes off, and the patient may again be able to pass water unaided. In many cases, however, the bladder of an old man which has, perhaps, not been completely emptied for some time, becomes permanently atonic after a single attack of retention, and he is never able again to dispense with the catheter.

It becomes an important question what course should be pursued in those rare cases in which the Surgeon *fails to pass any instrument into the bladder*. Aspiration of the bladder above the pubes may perhaps be tried as a first resource, and after some hours, during which the patient has been kept in bed, another attempt made to pass a soft catheter. The hope of such a successful result is small, and aspiration in prostatic retention cannot be regarded with much favour. In these cases three lines of practice may be adopted : *tapping the bladder above the pubes, tapping from the perinæum*, and *suprapubic cystotomy*. Puncture of the bladder through the rectum is not a safe procedure, whilst "tunnelling the prostate," that is to say, pushing a silver catheter forcibly through the obstruction into the bladder, may be regarded as a method of treatment belonging to a past age of Urinary Surgery, ruder than the present.

**Tapping the Bladder above the Pubes** consists in making a small incision about half an inch in length through the integuments, exactly in the mesial line, immediately above the pubes, and then pushing a specially constructed curved trochar, with its concavity downwards and backwards, into the bladder behind that bone, and consequently below the reflection of the peritonæum. After the bladder has been emptied, the cannula or a gum-elastic tube must be left in for the escape of the urine, whilst the continuity of the natural passage is being restored. When the bladder is greatly distended, in consequence of retention from enlargement of the prostate or any other cause, the peritoneal reflection is carried up with it, and a considerable portion of the anterior wall of the organ uncovered by peritonæum is left above the pubes. In a case of unrelieved retention from stricture, in which the patient died suddenly during the administration of chloroform, and which I had an opportunity of dissecting, I found that the summit of the bladder reached to five inches above the symphysis pubis, and was only two inches below the umbilicus; that the line of reflection of the peritonæum was  $3\frac{1}{2}$  inches above the bone; and that the space uncovered by serous membrane was  $2\frac{1}{4}$  inches wide. The bladder contained nearly forty ounces of urine, the retention having lasted forty-eight hours.

**Tapping the Bladder from the Perinæum** has especially been advocated by Reginald Harrison. The patient being fixed in the lithotomy position, the Surgeon passes his left index finger into the rectum to serve as a guide. A straight trochar and cannula is introduced in the middle line of the perinæum three-quarters of an inch in front of the anus, and is pushed straight into the bladder through the middle of the prostate. The trochar is withdrawn and the cannula fixed with tapes. Harrison allows the patient to leave his bed at the end of a week or ten days, a tube passing to an india-rubber

urinal or closed with a clip being attached to the cannula. The drainage is continued until urine again finds its way along the urethra. It is doubtful whether this method of tapping is as free from risk as that performed above the pubes.

**Suprapubic Cystotomy** has been performed in some cases of prostatic retention as a substitute for simple tapping. If the patient's condition is favourable it is probable that this is the best course to pursue in these rare cases. Whatever method of drainage be adopted it is frequently necessary to continue it permanently, and the suprapubic opening allows the prostate to be felt, and possibly the obstructing portion dealt with at a subsequent occasion. A small opening only is necessary in the bladder, and its edges may in some cases be drawn up to the skin wound with sutures.

Hæmorrhage occasionally causes trouble in cases of enlarged prostate, and in those rare instances in which there is retention and distension of the bladder with blood clot, suprapubic cystotomy is especially indicated.

**Atrophy of the Prostate** sometimes occurs. It may be the result of exhausting disease, especially phthisis, of old age, of mechanical pressure from tumours or calculi, or of local disease of the gland itself. Congenital deficiency of the prostate may also occur.

#### PROSTATIC CALCULUS.

**Prostatic Calculus** differs from all other urinary concretions in situation and composition, being formed in the ducts of the prostate gland, and composed principally of phosphate of lime and some animal matter; usually about 85 per cent. of the phosphate, to 15 of the organic ingredients. The concretion is said to consist sometimes of carbonate of lime (p. 1030). It generally occurs in old people, though it may sometimes be met with in young subjects. From a lad of nineteen, whom I cut for vesical calculus, I extracted two prostatic concretions.

**Characters.**—Prostatic calculus is usually of a grey or ashy colour somewhat triangular in outline, smooth and polished (Fig. 907), having facets, being very hard, and seldom much larger than a cherry or plumstone; though it may occasionally attain a considerable bulk, having been met with as large as a hen's egg, and then presenting a branched or irregular appearance. Though usually but one or two exist, which are sometimes deposited in a kind of cyst in the gland, as many as thirty or forty have been met with, the ducts being filled, and its whole tissue being studded with them.

Fig. 907.—Prostatic Calculus.

**Symptoms.**—Calculus in the prostate gives rise to a sense of weight, pain, and irritation in the perinæum, sometimes to retention of urine, and, in fact, to the ordinary symptoms of enlarged and irritated prostate; it often occasions a tolerably free discharge of mucus in the urine. On introducing a sound, this passes over the stone, sometimes rubbing or striking it with a distinct grate or click before its beak enters the bladder. This is increased by the finger in the rectum pushing the organ up, and thus bringing the stone into more direct contact with the sound. In some instances the calculus is deeply imbedded in the prostate, and cannot be touched by the sound. In these cases the stone may usually be felt through the rectum. If there be many

small calculi in a sacculus in the prostate, they may be felt by introducing the finger into the rectum, when a peculiar crackling or grating sensation may be experienced by the rubbing together of the calculi, something like that produced by beads in a bag.

The **Treatment** of prostatic calculus will depend upon the situation, size, and number of the concretions. When they are large, single, or at most two or three in number, readily struck with the sound, and situated on the urethral surface of the organ, the ordinary median operation may advantageously be performed, and the calculus removed with a scoop or forceps. If the calculi be small and very numerous, not to be felt with the sound, but only through the rectum, it will be wiser not to have recourse to operation, which could not remove the whole of the concretions. In such circumstances, a palliative treatment directed to the subdual of the irritation of the prostate, and the use of the catheter to relieve retention, is the only course to pursue. When prostatic and vesical calculi occur together, the same operation will rid the patient of both forms of the disease.

#### TUBERCLE OF THE PROSTATE.

**Tubercle of the Prostate** is not uncommonly met with. It usually forms a part of extensive tuberculous disease of the genito-urinary tract. In fact it is rare to find it sufficiently advanced for a diagnosis to be made without one or both epididymises being similarly affected, and it is often very difficult to tell where the disease originally commenced. The vesiculæ seminales are usually implicated, and the tuberculous infiltration frequently extends to the floor of the bladder. Not uncommonly it is associated with tubercle of the kidney. The *post-mortem* appearances are those of tubercle elsewhere. Softening yellow masses are found usually near the urethral surface. After a time the mucous membrane gives way, and a ragged cavity with yellow walls is left in the floor of the prostatic urethra. Sometimes the tuberculous abscess may open into the rectum, and thus a fistula may be left between the urethra and the bowel. More rarely it causes an abscess pointing forwards in the perinaeum. Tubercle in the lungs is usually present at death. The *Symptoms* vary much, according to the situation of the ulceration. If it is limited to the prostate, it may cause surprisingly little disturbance. In a case which occurred in University College Hospital, the patient died of tuberculous meningitis, some months after castration for tuberculous testicle. At the *post-mortem* examination two cavities were found in the prostate large enough to admit the top of the thumb, but the patient had made no complaint of any urinary trouble. Berkeley Hill pointed out that the disease not uncommonly follows gonorrhoea, and that the only symptoms in the early stages are a chronic gleet and perhaps weight in the perinaeum. When the disease extends to the bladder there may be extreme symptoms of irritable bladder. Digital examination by the rectum shows the prostate to be hard, nodular, and irregularly enlarged. Sometimes a softening patch may be detected in it. The vesiculæ seminales, if they can be reached, are usually found to be enlarged. There may be a purulent discharge from the urethra, and pus in the urine. The detection of the tubercle bacillus would determine the nature of the case. The *Treatment* in the early stages when the diagnosis is doubtful should consist in attention to the general health and

to any existing urethral discharge. If symptoms of cystitis supervene injections of iodoform should be used and in some instances cystotomy may be necessary. A tuberculous abscess in the prostate may require to be opened in the perinæum, scraped and drained.

#### CARCINOMA OF THE PROSTATE.

**Carcinoma** does not commonly attack the prostate, but I have met with several instances of the disease. The form met with is usually the hard glandular carcinoma; one case of colloid has been recorded by Stanley Boyd. I have seen the disease in a man about seventy years old; he died with secondary growths in the lymphatic glands and liver.

The **Symptoms** in the early stages are obscure pain and irritability about the neck of the bladder, with the occasional passage of blood. As the disease may occur in patients who are already suffering from the effects of simple enlargement of the prostate, the early symptoms may closely resemble those occasioned by a stone in the post-prostatic pouch or an attack of subacute prostatitis. Digital examination by the rectum will probably detect a hard, ill-defined mass, occupying the situation of the prostate, nodular on the surface, and often peculiarly fixed. It is slightly tender on pressure. The rapid increase in size, with obstruction to the passage of urine, and frequent hæmaturia and increasing pain, will reveal the true nature of the disease.

The vague character of the symptoms of carcinoma of the prostate as compared with those of a primary growth in the bladder may be explained by the different nature of the two tumours. Carcinoma of the bladder is of the squamous variety and, as a rule, rapidly ulcerates, whereas the deeply-seated glandular carcinoma of the prostate may reach a considerable size before ulceration occurs.

The **Treatment** is palliative. Morphia suppositories may relieve the pain, and if the symptoms be extreme, drainage of the bladder may be required. Although excision of the prostate for carcinoma has been performed by Billroth and others, the operation can hardly be regarded as a procedure of recognized usefulness.

## CHAPTER LXXI.

## DISEASES OF THE URETHRA.

## URETHRITIS.

**Simple Inflammation of the Urethra** is especially apt to occur in strumous, rheumatic, or gouty individuals, from slight sources of irritation that would not excite it in more healthy constitutions. In strumous children, it may arise from worms in the intestines, or from gastric irritation; and in gouty or rheumatic subjects, it appears often to occur in connexion with an acid state of the urine. Excessive beer drinking may cause a slight discharge from the urethra—the “Biertripper” of the German students. In other cases, the irritation of a stricture, the passage of instruments, or ordinary sexual intercourse, may occasion the disease, without there being anything of a specific character about it. Contact with women who are out of health, pregnant, or suffering from leucorrhœa, often gives rise to local irritation of this kind. Urethritis, especially when arising from sexual intercourse, is frequently mistaken for gonorrhœa. From this it may, as a rule, be distinguished by the less intense degree of inflammation, and by the absence of the secondary consequences that frequently follow true gonorrhœa; yet, in many instances, the diagnosis is extremely difficult, especially from the subacute forms of gonorrhœa that are common in London. Increasing experience seems to show that the decision as to the gonorrhœal or simple character of a urethritis is best determined by the presence or absence of the gonococcus in the discharges.

**Symptoms.**—Urethritis is characterized by heat, pricking, and tension about the urethra for a day or two, followed by muco-purulent discharge, often rather profuse, and accompanied by some ardor urinæ. The symptoms are not severe, and the disease usually subsides at the end of a week or ten days; but sometimes it becomes chronic, especially if conjoined with stricture, and is then extremely troublesome, particularly in gouty individuals.

In the **Treatment** of urethritis the bowels should be kept open, and salines freely administered; in cases in which there is reason to believe that the affection is of gouty origin, small doses of colchicum, in combination with alkalies, will be found of especial service. The use of emollient or slightly astringent injections, such as opiate lotions, or a very weak solution of acetate of lead, with belladonna, will be found serviceable as the disease is on the decline, but not until then; and when the affection has reached a chronic stage, small doses of copaiba may advantageously be administered. The diet in all cases should be of the blandest character, stimulants of all kinds being interdicted.

If the disease be conjoined with slight stricture, it may not unfrequently give rise to temporary retention of urine. This may, however, most commonly

be readily relieved by leeches to the perinæum, the warm hip-bath, and salines, with, perhaps, opiate suppositories, and plenty of demulcent drinks. The catheter should not be used, if it be possible to give relief without it.

## GONORRHOEA.

**Gonorrhœa** is a specific disease, accompanied by inflammation and an abundant muco-purulent discharge; affecting the urethra most commonly, but also the other mucous membranes of the genital organs, as of the prepuce and the glans in the male, and of the vulva and vagina in the female.

The urethra is the usual seat of gonorrhœa in the male; and the disease may be looked on as an infective urethritis. Its seat of greatest intensity is usually the fossa navicularis; but it may extend over a much greater surface, affecting the entire length of the canal, and even the whole mucous lining of the bladder. In the female it commonly spreads over the extensive mucous surface of the external organs of generation, and sometimes invades the uterus and Fallopian tubes.

**Cause.**—Gonorrhœa has its origin in the female, and is possibly developed in prostitutes without infection from the male. It is a highly infective inflammation of the mucous membrane of the vagina, predisposed to by the decomposition of retained semen and of foul discharges, the result of repeated acts of indiscriminate intercourse without proper attention to cleanliness. It is impossible to say clinically where urethritis or vaginitis ends, and infective gonorrhœa begins. In the male, gonorrhœa arises in all cases from communication of the specific poison from the female by sexual intercourse.

The poison of gonorrhœa differs entirely from those of the venereal diseases described in Chapter XXXVI., as has been fully proved by inoculation; these diseases not being capable of reproducing one another in any circumstances. The pus of gonorrhœal urethritis always contains a specific organism—the *gonococcus* of Neisser, which is undoubtedly the cause of the disease. It can readily be demonstrated by drying a thin layer of the pus on a cover-glass and staining it for a few minutes in an alcoholic solution of methyl-violet. The *gonococcus* occurs in pairs or groups, and is met with in the interior of the epithelium and pus cells. The organism has been cultivated outside the body in fluid media and on blood-serum and gelatine; and inoculations of pure cultivations into the normal urethra have reproduced the disease. Bokai inoculated six students with the organism, which had been cultivated in suitable fluids, and in three gonorrhœa followed. Bockhart successfully inoculated the organism in the urethra of a man after it had been cultivated to four generations on prepared gelatine; and Bumm produced typical gonorrhœa by the introduction into the healthy female urethra of the organism cultivated to the twentieth generation on blood-serum.

It is important to remember that the *gonococcus* is not distinguishable by its form alone from other varieties of diplococcus, such as one which Lustgarten and Mannaberg found constantly in the normal urethra. Roux has, however, shown that the *gonococcus* can be distinguished by the fact that it does not stain by Gram's method, whereas the others do. Lustgarten and Mannaberg also found in the normal urethra an organism like the *staphylococcus bacillus*, which showed the same staining reactions as the *bacillus tuberculosis*, and he *staphylococcus pyogenes aureus*. Recent observations tend to show that the

chief complications of gonorrhœa, such as suppurating bubo, are due to the associated organisms of suppuration and not to the gonococcus itself.

The suppurative inflammation of gonorrhœa has these peculiarities : 1. It has a distinct and lengthened period of incubation ; 2. It rapidly propagates itself along the mucous tracts that it affects ; 3. It is contagious in the highest degree not only when the pus is applied to, and, as it were, rubbed into the mucous surfaces of the generative organs during coitus, but when it simply touches other mucous surfaces ; and, 4. It is sometimes attended with remote constitutional phenomena partaking of a pyæmic character.

**Character.**—Gonorrhœa is usually looked upon as a purely local affection of the genital organs ; but although in the early stages it is doubtless a strictly local affection, yet it is occasionally followed by a train of very characteristic phenomena, that can scarcely be looked upon in any other light than as the result of constitutional infection ; the more so, as some individuals never have gonorrhœa without the disease being followed by these sequences, whilst others are altogether exempt from them. The parts that are secondarily affected are chiefly the fibrous tissues, and the mucous and cutaneous surfaces. The affections of the *fibrous tissues* give rise to so-called rheumatism and to peculiar forms of inflammation of the testicle and of the sclerotic. The affection of the *mucous membranes* displays itself in specific inflammation of the eyes. The occurrence of these various affections, assuming as they do a specific type so distinctly marked that they can at once be characterized as gonorrhœal, certainly tends to show that the disease impresses the constitution in some peculiar manner, somewhat analogous to syphilis or pyæmia ; though in a far minor degree, and with much less certainty, than these diseases.

The **Symptoms** of gonorrhœa in the male may be divided into three stages :—1. The Incubative Stage, or the period of Irritation ; 2. The Acute Inflammatory Stage ; and 3. The Chronic Stage.

1. **Incubative Stage.**—The first stage, that of irritation, usually comes on from two to three days after connexion, when the patient begins to experience some degree of heat, itching, and general irritation about the penis. The lips of the urethra are somewhat red and swollen ; its orifice gapes ; and, on squeezing it, some mucus exudes. This stage usually continues for three or four days from the time of infection, but sometimes for six or eight, when it terminates in the second, which is one of active inflammation.

2. **Acute or Inflammatory Stage.**—The discharge now becomes abundant, thick, and of a greenish-yellow colour ; there is great pain in making water, with considerable heat and smarting, and the urine, which flows in a diminished stream, is passed with increased frequency. The urethra is swollen, firm, and cord-like to the touch ; the whole penis, indeed, looks red and turgid. As the disease advances, and the bulbous portion of the urethra becomes affected, weight and tension in the perinæum will be complained of. If the prostatic portion be the seat of disease, there will be heat and weight about the anus, with frequency of micturition and some stranguary. During the whole of this period there is generally a good deal of constitutional disturbance, restlessness, and fever.

One of the most troublesome symptoms in this stage is the occurrence of **Chordee**, which consists in painful erections at night, with a twist in the body of the penis, which is usually curved downwards.

3. **Chronic Stage.**—The acute symptoms usually continue for about a fort-

night, when the third stage, that of subacute or chronic inflammation, sets in. During this period of the affection the inflammatory symptoms gradually subside, but a thin muco-purulent discharge continues, with some degree of heat and irritation about the urethra, and occasional smarting in passing urine. Under proper treatment, this usually subsides in the course of another fortnight or three weeks; but, if neglected, or in certain constitutions, it may last for many months, or even years, then degenerating into a *Gleet*. In proportion to the continuance of the affection the inflammatory symptoms subside, though the specific and contagious character does not disappear, and the infection may continue so long as the discharge keeps up. Hunter mentions the case of a girl who had been two years in the Magdalen Hospital, and who infected a person with whom she had connexion immediately after she left that institution. The persistence of the contagion of gleet is, it is true, more marked in women than in men. The long persistence of contagion is in accord with the fact that gonococci have been found in the urethral discharge many months or even several years after the commencement of the disease. The presence of the gonococcus may be taken as proof that the discharge is still infectious, but, on the other hand, failure to demonstrate the organism can hardly justify the Surgeon in pronouncing the patient free from any risk of causing infection. So long, indeed, as any discharge continues from the male urethra, though it be but a daily drop, the patient must be looked upon as infectious. The importance of this subject is obvious, and it seems certain that many inflammatory affections of the pelvic organs occurring in newly-married women are due to infection by an apparently insignificant urethral discharge in the husband.

The severity and the continuance of gonorrhœa are often opposed to one another. Thus the disease is most severe in young and plethoric persons, and in first attacks; but it is most difficult of cure in strumous constitutions, more especially if there be a gouty or rheumatic tendency co-existing, and it is very troublesome to remove after repeated attacks. I have observed repeatedly that it is very apt to degenerate into a gleet in people who are subject to chronic eczema.

There is a form of chronic gleet which continues very persistently after an attack of gonorrhœal epididymitis. In these cases the discharge is not so much urethral as testicular. It appears to proceed from the increased exudation from the mucous membrane of the secretory and efferent structures of the testis, during the process of resolution of the inflammation.

The length of time that the infection of gleet will continue in both sexes, but especially in the female, makes it somewhat difficult to say whether the poison of gonorrhœa can be generated *de novo*, as it is not improbable that many individuals communicate the disease, believing themselves to be perfectly cured, though still suffering from slight gleet.

**Gleet.**—The term *gleet* is applied to any mucous or muco-purulent discharge, which is very small in amount and persists for an indefinite time unaccompanied by any other obvious symptoms. This condition is one which gives rise to great mental uneasiness in many patients, and some varieties are, moreover, liable to terminate in stricture if unrelieved. The correct diagnosis of its nature and source is, therefore, of extreme importance. In the first place, it is necessary to remember that in young men a somewhat copious flow of mucus is apt to accompany an erection of the penis. When, as is frequently the case,

an erection occurs just before waking in the morning, the mucus may be found glueing the lips of the urethra together, and may be mistaken by the patient for a gleet. Again, true gonorrhœal gleet must not be confounded with prostaticorrhœa (see p. 1140). Desormeaux has shown that a true gonorrhœal gleet is due to the presence of chronically inflamed patches of mucous membrane in the urethra. These patches are purplish or dark red in colour, whereas the normal urethra is a pale pink. Sometimes the surface of the mucous membrane is covered with small granulations, like those seen on the conjunctiva in granular lids. This condition Desormeaux calls "*granular urethritis*." The patches may be multiple, but more often there is only one situated in the bulbous portion of the urethra. The *symptoms* of such a condition are the following: A slight, sometimes almost colourless, sometimes yellowish, discharge will be found glueing the lips of the urethra together in the morning. This discharge is little affected by diet or stimulants, but is usually greatly aggravated by connexion. If during micturition the first few drops of urine be passed into a separate vessel, flocculi of mucus and pus are seen floating in it. There is no pain or discomfort in micturition, but the stream may be slightly narrowed, and a few drops of urine may be retained in the urethra, and dribble away afterwards, as in a slight stricture.

In a large number of cases of gleet the chronic inflammatory patches in the mucous membrane are sufficient to cause actual narrowing, or rather diminished extensibility of the urethra; so constantly indeed is this the case that the presence of a chronic gleet may almost be said to indicate the existence of a stricture. In other cases the gleet may be due to a chronic inflammatory discharge from the glands and follicles of the urethra. Hill states that it occasionally arises from small vegetations or warts situated immediately inside the meatus; he also drew special attention to the important part played by a contracted meatus in causing the continuance of a chronic gleet.

In examining the urethra in a case of gleet, some information as to the condition of the canal may be obtained by the passage of an olive-headed bougie, meatotomy being, if necessary, performed to allow its introduction (p. 1198). If an inflamed spot be present, a slight feeling of resistance will be felt, and the patient will complain of pain as the bougie passes over it. On withdrawing the instrument a drop of blood may be found on its bulb.

In these cases the most reliable information is obtained by the use of the **Endoscope**. In its simplest form this consists of a metal tube about the size of a No. 12 or 14 catheter, down which light may be thrown with a mirror or by an electric lamp. The most convenient instrument is that made by Leiter of Vienna. It consists of a straight metal tube which is provided with an ebony obturator to facilitate its introduction into the urethra. The expanded ocular end of the instrument, which accurately fits into the tube, contains a small electric lamp the light of which is directed down the tube by means of a mirror. Before introducing the endoscope, 10 minims of a 10 per cent. solution of cocaine should be injected into the urethra with an Ultzmann's syringe. The endoscope is then passed downwards as far as the bulb, where the diseased condition which causes a chronic gleet is most commonly situated. Granular patches and other abnormal conditions of the mucous membrane are readily recognized by an experienced observer, and, moreover, local treatment can be carried out more accurately through the tube than in any other way.

Antal and Hurry Fenwick have found that distension of the penile urethra by the injection of air facilitates endoscopic examination. A special modification of Leiter's instrument has been constructed for this purpose.

The **Treatment of Gonorrhœa** must be conducted with reference to the stage of the disease, but especially with regard to the acuteness of the inflammation accompanying it.

It has been proposed to adopt what has been termed the *abortive* treatment, during the earliest stages of gonorrhœa ; indeed, during the *incubative* period. This method consists either in the injection of a very strong solution of the nitrate of silver into the urethra, or in the application to the inflamed mucous membrane of a strong ointment of that salt by means of a bougie smeared with it ; other Surgeons, again, have recommended the administration of very large doses of copaiba at this period. These various plans have, however, deservedly fallen into disrepute. I have on several occasions seen most intense inflammation produced by this mode of treatment, and never, in any case, any good result. Independently of this, it is impossible to know whether the case, in the earliest stage, will prove to be one of simple urethritis or a specific gonorrhœa.

In the *acute inflammatory stage*, attended by heat, swelling of the organ, great ardor urinæ, and abundant muco-purulent discharge, the activity of the treatment must be proportioned to the intensity of the inflammation. If this be severe, warm hip-baths, poppy fomentations, or the envelopment of the penis in warm water-dressing, will be of essential service. At the same time the urine must be diluted, and its acidity lessened, by the patient drinking large quantities of alkaline diluents—barley-water or linseed-tea containing carbonate of potassium in solution ; and the bowels may be kept in action by the administration of saline aperients. Twenty to thirty grains of carbonate of potassium or a drachm of citrate of potassium with twenty or thirty minims of tincture of hyoscyamus in an ounce of camphor water should be given every four or six hours. All alcoholic stimulants, spices, salt food, and coffee must be avoided, the diet being restricted to light slops, and perfect rest enjoined. By such means as these, the activity of the inflammation will be gradually lessened, the discharge becoming thinner, the smarting in micturition less severe, and the erections less painful. The patient should also be desired to pass his urine frequently, so as to wash the urethra clean.

During the acute inflammatory stage the application of local remedies to the urethra has, as a general rule, been found harmful, but since the nature of the virus has been recognized, the use of germicide injections and bougies has been tried with some degree of success. Watson Cheyne recommends the use of iodoform and eucalyptus bougies. These are composed of iodoform, 5 gr. ; oil of eucalyptus, 10 m ; oil of theobroma, 35 gr. This is sufficient to make one bougie 4 inches long. It is thus used : the patient first passes water to clean the urethra ; he then dips the bougie in carbolic oil (1 in 20) and passes it quickly into the urethra before it becomes softened by the heat of his fingers. It must be pushed in with a pencil, or some convenient instrument, till it completely disappears. An absorbent pad of iodoform or salicylic wool is then placed over the end of the penis, and covered with oiled-silk or gutta-percha tissue secured by a strip of plaster. The patient then refrains from making water as long as possible. (One bougie may be used daily for two or three days, and in the interval some simple injection, such as

chloride of zinc (gr.  $\frac{1}{6}$  to  $\frac{1}{3}$ ), or sulpho-carbolate of zinc (gr. ij. to  $\frac{1}{3}$  j.) may be used. Cheyne states that by these means the inflammation is often cut short and a cure effected in a week or ten days or sooner. If it fails it does no harm. One-twentieth of a grain of perchloride of mercury added to each bougie is said to increase the certainty of their action. In this stage also the use of strong injections of nitrate of silver has in some instances been followed by a rapid cure. Cotes, who gave this method of treatment a thorough trial at the Lock Hospital, proceeded as follows: An endoscope was introduced as far as the inflammation of the mucous membrane extended, this being often as much as four inches by the third day. The mucous membrane was then dried with wool mops. A wool mop soaked in a 10 grains to the ounce solution of silver nitrate was then passed down the tube with a stylet until it projected beyond the end. By withdrawing the endoscope and the stylet together, the nitrate of silver was brought into contact with the whole of the inflamed mucous membrane. A hot bath was given at night, and the patient kept in bed during the following day. A saline aperient and an alkaline mixture were prescribed, and a simple injection, such as weak Condyl's fluid, directed to be used several times daily. Cotes treated 42 cases in this way. In 40 in which the disease was of many days' duration, the average duration of the cure was twelve days; whilst 2 cases of only two days' duration were cured in two days.

During the second, or in fact in all stages of gonorrhœa, much harm is often done by applying lint to the penis. This does not absorb the discharge, but rather shuts it in. It is better to put the penis in a macintosh gonorrhœa-bag, at the bottom of which a good-sized piece of salicylic wool may be placed to absorb the discharge.

When the *third stage* of the disease has been reached, specific treatment may be employed with great advantage; while, if recourse were had to it at an earlier period, it would certainly increase the inflammation and give the patient much distress. Even in this stage the specific remedies, such as copaiba and cubebs, must be cautiously given; the Surgeon feeling his way with them, and being prepared to discontinue them if he find that they increase the irritation. Should the disease, however, from the commencement, have assumed a subacute character, the specific treatment may with safety be adopted at a much earlier period.

Copaiba and cubebs are extensively used in this stage of gonorrhœa. Of these, copaiba is the less irritating, and consequently more generally to be preferred. It may be administered in a variety of ways: in capsule, pill, draught, or extract. The capsule is generally to be preferred, on account of the nauseous taste being thus more completely disguised; but in many cases it acts with more certainty, and with better effect, if given in either of the other forms. When the capsules are given, the patient may take from six to eight or ten in the day, and should at the same time have an alkaline mixture, which increases materially the effect of the drug. A very excellent mode of administering copaiba is to rub it down into a mass with burnt magnesia, and to let the patient take about a drachm of this paste three times a day, in a bolus wrapped in wafer-paper; or, if the taste be not much objected to, he may take it most advantageously in mucilage, with liquor potassæ and tincture of hyoscyamus.

In some relaxed constitutions, and more particularly after frequent claps,

cubebæ will be found to cure the patient more readily than copaiba, or rather more successfully if given in combination with it. An excellent plan is to put about half an ounce of powdered cubebæ into a mortar, and to rub it up with as much copaiba as will form a stiff paste, of which the patient should take a drachm as a bolus thrice daily. The effects of this electuary are often most striking ; but it can be used only in the constitutions indicated, and after the more active inflammatory symptoms have subsided. Copaiba in many subjects brings out a red, raised rash, most marked on the backs of the hands and feet, but sometimes extending over the whole body. It is accompanied by considerable itching and often by some rise of temperature. Hill states that a similar eruption, but more papular in character, may follow the administration of cubebæ. Hæmaturia has occasionally been observed as the result of large doses of copaiba. Oil of yellow sandal wood may sometimes be employed with advantage, though its action is somewhat uncertain. It may be given in capsules in doses not exceeding twenty minims three times a day, or the following formula will be found useful : oil of sandal wood, ʒij., tragacanth in powder ʒss., water to ʒviij. ; one ounce to be taken three times a day.

It is during the third stage of gonorrhœa that **Injections** may advantageously be used. Much and very unfounded prejudice exists against their use in the minds of many ; but surely it is as safe to apply proper local applications to an inflamed urethra as it is to an inflamed conjunctiva ; and the bad consequences, such as stricture and inflamed testicle, which have sometimes been referred to their use, have either been due rather to the long continuance and to the severity of the disease itself than to the remedies employed, or to their application at too early a stage or of too great a strength. It is in long-standing cases of gonorrhœa, in which the discharge continues for months or years, that stricture follows, not in cases of ordinary duration ; and it is the result of the chronic inflammatory thickening of the mucous membrane, and has no more to do with the injections than with the copaiba or salines which the patient may have taken. As the ardor urinæ subsides, emollient and slightly astringent injections may be used. Perhaps the best is permanganate of zinc in the strength of one, or rarely two, grains to eight ounces of distilled water. Berkeley Hill found this injection very free from irritating properties, and most useful except in very chronic cases ; of 70 cases in which he used it, 10 were cured and 54 much improved, in 4 it had no effect, and in 2 it increased the discharge. Chloride of zinc (gr.  $\frac{1}{2}$  to the ʒi.) and sulpho-carbolate of zinc (gr. ij. to the ʒi.) are often useful. Extract of opium or extract of belladonna is frequently added to urethral injections to allay the irritation which they are apt to cause. The permanganate should, however, always be used alone, as it forms an almost explosive mixture with some vegetable extracts. As the disease subsides, a stronger astringent is required, and then one or two grains of the acetate of zinc may be added to each ounce of the injection ; or a weak solution of the sulphate may be employed, gr. ij. to each ounce of water. In the later stages Hill found the sulphates of zinc, alumina, copper, and iron very useful. He frequently prescribed them together, thus : sulphate of zinc 30 to 40 grains, alum 30 to 40 grains, sulphate of iron 20 grains, and sulphate of copper 2 grains, in eight ounces of water. During the whole of this stage, the diet and habits of life must be carefully regulated, and all stimulants interdicted. The injections should be discontinued as soon as the discharge has ceased ; unless this be done, they may re-induce it.

The mode of injection is of importance. A glass syringe should always be used, with a smooth rounded nozzle. The patient sitting on the edge of the chair and holding up the penis, should carefully insert the end of the syringe between the lips of the urethra, and then slowly throw in the injection as far as it will go. Although the inflammation is usually at first confined to the anterior portion of the urethra, yet it in most cases extends to the bulb, and the injection should be applied to the whole length of the inflamed mucous membrane. If any enter the bladder this is of no consequence, as it will immediately be decomposed by the salts and mucus of the urine.

Instead of the ordinary glass syringe, the injector (Fig. 908) may advantageously be used. By it, the injection is thrown from behind forwards, so that when passed beyond the inflamed part it washes out the discharge, instead of forcing it further on.

Fig. 908.—Treevan's injector.

**Treatment of Gleet.**—In gleet, much difficulty will often be experienced in curing the patient of his discharge. Here much depends not only on the administration of proper remedies, but on care being taken to regulate his habits of life. It will constantly be found that, after the disease has apparently been cured, excesses at table, and more especially the drinking of beer, or of effervescing or acid wines, will bring back the discharge. It will return also after connexion, though it have previously ceased entirely. This is especially the case in strumous, gouty, or rheumatic subjects, in whom all urethral inflammations are with difficulty removed. In these cases, then, abstinence from alcoholic liquids and dietetic stimulants, and a continent life must be strictly enjoined; but the local treatment requires careful attention.

In the early stages of gleet an attempt may be made to cure it by injections. For this purpose somewhat stronger solutions are required than in the more acute period of the disease. Sulphate of copper will often be found useful, commencing with half a grain to the ounce, and gradually increasing it to one or even two grains.

Tannic acid in the strength of from two to four grains to the ounce will sometimes check the discharge. Soluble bougies, similar to those already described, but containing tannic acid, sulphate of zinc, or acetate of lead, are often of great service. These, combined with the internal administration of copaiba and cubeba, or the perchloride of iron, may effect a cure. If these do not succeed, the occasional passage of a full-sized bougie is of the greatest use. If the orifice of the urethra be small meatotomy should be the first step in the treatment. The meatus must also be examined for warty growths, which may keep up the discharge.

When the disease has become very chronic, and has assumed the form of granular urethritis, it is difficult of cure; for, as Desormeaux pointed out, an injection, which the healthy portion of the urethra is capable of bearing, will have much effect upon the inflamed patch. He therefore recommended the application of a strong solution of nitrate of silver through the endoscope.

This treatment has proved most satisfactory. The granular patches are dried with small wool mops and are then touched with a mop soaked in a solution of nitrate of silver, 10 to 20 grains to the ounce, according to the amount of congestion. In the absence of the endoscope the solution may be applied by means of Guyon's injector (Fig. 909). This consists of a hollow bulbous sound perforated in the bulb, and fitted with a small syringe. The bulbous sound having been passed down the urethra till the exact situation of the inflamed spot is found by the tenderness and slight cling before mentioned, the perforated head is held fixed at the diseased spot, and a few drops of a solution of nitrate of silver (ten to twenty grains to the ounce of water) are injected. The patient should pass urine immediately before the injection, and not again for some hours if possible. Berkeley Hill, who had great experience of this mode of treatment, states that, if the patient keep quiet for some time after, no complications are likely to follow ; but neglect of these precautions may be followed by swelled testicle or even perinæal abscess. After the operation a mixture containing citrate of potassium and hyoscyamus should be prescribed and a weak astringent injection should be used between the different sittings, of which several may be required. The passage of bougies for a short time is usually necessary to complete the cure. Otis, of New York, is of opinion that every prolonged gleet is the result of a

Fig. 909.—Guyon's Injector. The Smaller Figure represents the Nozzle.

narrowing of the canal, and he recommends internal urethrotomy as a cure—cutting the urethra up to its normal size by the method described under the treatment of stricture of the urethra. The operation is somewhat severe, and should never be resorted to till all other means have failed.

The treatment of gleet may therefore be summed up as follows : The patient must be carefully examined, in order to detect, if possible, some constitutional condition, such as struma, gout, or rheumatism, which may serve as a guide to general treatment, diet, and use of stimulants. Change of air and sea-bathing are often of essential service. The orifice of the urethra must be enlarged, if necessary. Warty growths or suppurating follicles at the orifice may be touched with nitrate of silver. If they are not found, the electuary of cubebs and copaiba, or one composed of cubebs and the sesquioxide of iron, may be administered with advantage, and the injections recommended for the chronic stage of gonorrhœa may be persevered with. Should these fail, and should the olive-headed sound give distinct evidence of a tender spot, and perhaps a slight narrowing of the urethra, the passage of a full-sized metallic bougie every second or third day should be tried. If, after a fair trial, this also fail, the application of nitrate of silver, by means of the endoscope, or with Guyon's injector, must next be had recourse to, followed by mild injections and the passage of bougies ; and, lastly, if everything else have failed, and a distinct narrowing of the canal be present, internal urethrotomy may be tried as a last resource.

**Complications of Gonorrhœa.**—Gonorrhœa, when acute or virulent, seldom runs its course without local complications of some kind, the result of the propagation of the inflammation to neighbouring parts, often of considerable severity, and occasionally even hazardous to life :—such as chordee, phimosis, sympathetic bubo, perineal abscess, irritability of the bladder, retention of urine, hæmorrhage from the urethra, &c. Many of these complications present no special features, but require to be treated on general principles, without reference to their specific cause. Others demand more special management, and these we may briefly consider here.

**Inflammation of the Lymphatics of the Penis** may occur, stretching along the sides and dorsum of the penis in the form of hard threadlike lines, with much redness and œdema of the integuments, and general swelling of the organ, the glans in these cases often assuming a turgid aspect and a dull brick-red colour. This condition is a very serious one, as it may lead to one of two consequences, or both may ensue, viz., inflammation and suppuration of the inguinal glands, or blood-poisoning. It is the latter result that gives rise to the most serious constitutional effects in gonorrhœa, closely resembling the less severe forms of pyæmia.

**Chordee**, or painful erection of the penis, with twist of the organ, coming on at night, is often a most distressing and troublesome symptom. It is usually best relieved by the application of cold to the part, and the administration at bedtime of a pill composed of gr. j. of opium with gr. v. of camphor. Ricord recommends a suppository of camphor and opium, gr. x. of camphor and gr. j. of the watery extract of opium, to be introduced into the rectum an hour before bedtime, as the best means of removing the tendency to chordee. Full doses of bromide of potassium are sometimes of use.

**Acute Prostatitis**, presenting all the symptoms described on p. 1138, and in rare cases terminating in abscess, is an occasional complication. It must be treated as there described.

**Chronic Prostatitis** is rather a sequel of gonorrhœa than a complication. Its symptoms and treatment have already been described (p. 1139).

**Inflammation of the Neck of the Bladder with Strangury and Dysuria** is not an uncommon complication. It arises from exposure to cold or wet during a clap, and occasionally from the use of too strong injections. The discharge may become less when the symptoms of the deeper inflammation set in. When the neck of the bladder only is inflamed, the urine remains acid, and contains but a slight excess of mucus. Frequency of micturition, often excessive, and accompanied by the most severe pain, forms the most prominent symptom. Pus and blood may escape with the last few drops of urine. It is distinguished from acute prostatitis by rectal examination, when absence of prostatic swelling and tenderness will be recognized. The inflammation in many cases is less acute, especially when it comes on in the third or fourth week of the clap. In the acute form leeches to the perineum, hot baths and fomentations, and full doses of Dover's powder, or of hyoscyamus and potash, will afford much relief. If the pain is very severe, a morphia suppository must be inserted into the rectum. In more chronic cases the administration of the perchloride of iron, with belladonna suppositories, will be beneficial.

**Cystitis**, of an acute character, may occur by the extension of the urethral inflammation. The urethral discharge diminishes as the symptoms of cystitis come on, or ceases, as in epididymitis; the patient is seized with intolerable

and frequent dysuria, strangury, and general febrile disturbance. The urine becomes loaded with muco-pus, and may be fetid and alkaline. The condition is perilous. There is danger to life if the constitution be broken, and there is always danger of prolonged or possibly intractable subacute cystitis. Indeed, I believe that many of the cases of chronic cystitis, with muco-pus in the urine, and perhaps atony of the bladder occurring in middle-aged men, may be traced back to the influence of a gonorrhœa contracted in early life. The *Treatment* of this condition consists in the employment of belladonna or opiate suppositories; the frequent use of warm hip-baths; the application of fomentations to the perinæum and hot poultices to the pubic region. The free administration of opium is often of great use, and an occasional dose of calomel should be given to relieve the bowels. As the cystitis subsides, the urethral discharge reappears.

**Pyelitis** and **Nephritis** are very rare complications of gonorrhœa. Murchison has recorded two cases in which death rapidly followed extension to the kidney, with coma and delirium. In a case lately in University College Hospital, a slight urethral discharge was followed by pain in the course of the ureter, and the symptoms of pyelitis. The disease assumed a chronic form, the pus in the urine being very abundant. Gonorrhœal rheumatism of a severe form set in at the same time. After about two years the patient partially regained health, the amount of pus becoming very small. In another case, a large renal abscess formed some time after an attack of gonorrhœa, to which it seemed to be directly attributable. The abscess was aspirated twice, and the patient recovered, but at his death some years after, the kidney was found to be shrivelled to a small mass of fibrous tissue.

**Retention of Urine from Gonorrhœa** may set in at any period of the acute stage. The obstruction is usually dependent on congestion and inflammation of the mucous membrane of the urethra. Leeches to the perinæum, the warm hip-bath, and opiate suppositories, will probably afford relief. It is always desirable to avoid using the catheter, as it is apt to lacerate the inflamed mucous membrane, and thus to occasion troublesome bleeding; and it will always produce much pain, and increased irritation of the canal. Should, however, the retention not give way to the means above indicated, it will be necessary very carefully to introduce a full-sized instrument, which will enter the bladder as easily as a smaller one and with less risk of injury to the tender walls of the canal. If an old stricture complicates the acute gonorrhœa the difficulty in passing a catheter may be very great. When the catheter has been introduced, it is often somewhat difficult to determine whether it should be left in or taken out. If it be left in, inflammation is increased; if it be taken out, the Surgeon may not be able easily to introduce it again. If, therefore, it have been introduced without much difficulty, it is better to withdraw it after the bladder has been emptied; but if, on the other hand, the catheter have been passed with great difficulty, and be firmly grasped by spasm, it should be left in.

It must be remembered that the retention may be due to more serious conditions: to prostatitis, to abscess in the prostate or the perinæum, or to inflammatory exudation in the tissues about the neck of the bladder. In these circumstances, active measures will be required, with the use of the catheter twice in the twenty-four hours, and probably free incisions into the perinæum, and if there be pus or urine extravasated into that region.

**Hæmorrhage from the Urethra** may occur either as the result of chordee,

and consequent rupture of some blood-vessels of the corpus spongiosum, as the consequence of attempts at passing the catheter, or as a simple oozing from the inflamed mucous membrane. Most commonly it may be arrested by the application of ice. If it be apparently due to intense inflammatory hyperæmia, leeches may be applied externally followed by hot fomentations. Should it be abundant, the introduction of a large gum-elastic catheter, and pressure by means of a bandage to the penis or perinæum, will arrest it.

**Urethral or Peri-Urethral Abscess** occasionally forms in gonorrhœa. It is supposed to result from inflammation culminating in suppuration, taking place in one of the lacunæ or glands of the mucous membrane. An abscess may form at any part of the urethra, but the two most common situations are near the end of the penis and in the region of the bulb. It is possible that in many cases the pus may be discharged into the urethra without being recognized; but if the collection of pus reaches any size it points towards the surface. In the neighbourhood of the glans it forms a rounded swelling, usually projecting under or to one side of the frænum. It is tender on pressure, and the parts round are swollen and œdematous. It should be opened as early as possible lest it burst into the urethra, after which, as the aperture is usually insufficient to drain the cavity, a second opening will form on the surface, leaving a fistula, which is very troublesome to heal.

When the abscess is situated in the region of the bulb, it forms a hard, tender swelling in the perinæum, constituting one of the varieties of *perineal abscess*. In this situation, also, if opened early by a free incision in the middle line, it will be found to have no communication with the urethra, and will quickly heal without leaving a fistula. If it be not opened in time, it may burrow widely beneath the accelerator urinæ, and the expansion from it covering the penis. Under these circumstances it may be felt both at the root of the penis and in the perinæum, and there may be considerable swelling of the scrotum. The incision in such a case should be made behind the scrotum only. If left too long, a communication with the urethra may have taken place, but provided the incision is made in the perinæum only, it will heal without difficulty.

**Sequences of Gonorrhœa.**—The sequences, or more remote complications of gonorrhœa, are partly local and partly constitutional. Amongst the local we find more particularly **Warts** about the prepuce and glans or within the urethral orifice, which require to be treated by excision or cantharsis; and **Stricture**, the management of which is fully described elsewhere. In some cases, also, in consequence of extravasation of blood, or inflammatory exudation into the corpus spongiosum or the corpora cavernosa, limited and localized **Induration and Thickening of the Penis** may result, attended by chordee, painful erections, and a permanent twist in the organ. In such conditions as these, an attempt may be made to produce absorption of the effused mass, by the administration of small doses of perchloride of mercury, with the inunction of iodide of lead ointment.

After the cure of a clap that has been of long continuance, the generative organs are often left in a *weak and irritable state*; the penis, scrotum, and spermatic cords being lax and elongated, often with painful and dragging sensations about the cords and groins.

Besides the strictly local complications of gonorrhœa, certain sequences, to which some constitutions are especially liable, occasionally occur as the result

of this disease; viz., inflammation of the testes and of the eyes, and rheumatism. Some of these, as the affections of the eyes and testes, may be either local or constitutional; the others are clearly constitutional. The constitutional effects of gonorrhœa offer characters that have some analogy to those presented by the chronic and subacute forms of pyæmia. This is more especially the case in monarthritic inflammation of the knee or wrist, leading to disorganization or permanent ankylosis of the joint.

**Gonorrhœal Epididymitis** is certainly the most common of these sequences. It almost invariably affects only one testis, and commences in the epididymis, whence it extends to the body of the organ. It usually occurs in individuals who have a lax and long scrotum, with very pendulous testes. It seldom sets in before the third week after the occurrence of gonorrhœa, but may occur at any period during the continuance of the discharge, though it is more frequent between the fifth and sixth weeks than at any other time. In cases of gleet, also, it not uncommonly occurs at a later period. In many instances it is referred to some slight injury—a blow, or squeeze, received during the continuance of the gonorrhœa; but in some cases it would appear to arise from extension of the inflammation along the ejaculatory duct. It was formerly believed to arise in some cases from so-called metastasis of inflammation from the urethra to the testis. That the disease commences in the epididymis, may be advanced in support of the first opinion; whilst the fact that the discharge usually ceases when the inflammation of the testicle comes on, and returns as it subsides, has been adduced in support of the doctrine of its metastatic origin. Curling was of opinion that the diminution of discharge is due to counter-irritation, as he had seen a case in which the urethral discharge ceased, although the orchitis had been occasioned by a blow. As the symptoms and treatment of gonorrhœal inflammation of the testicle present nothing peculiar, I shall reserve their consideration until I come to speak of diseases of this organ. Gonorrhœal epididymitis is apt to be followed by long-continued gleet, consequent on the exudation from the lining membranes of the vas deferens, and the secretory apparatus of the testes.

**Gonorrhœal Inflammation of the Vesiculæ Seminales** is probably more common than is generally supposed, for as Jordan Lloyd, who has drawn special attention to this complication, has pointed out, its symptoms closely resemble those of prostatitis. These are painful and frequent micturition, painful defæcation, with occasionally painful emissions and priapism. On rectal examination the vesiculæ are felt as elongated swellings above the prostate. The inflammation of these bodies is no doubt due to direct extension from the urethra. The *Treatment* is the same as for acute prostatitis.

**Gonorrhœal Inflammation of the Eyes** is fortunately not of very common occurrence. It may affect either the conjunctiva or the sclerotic.

**Gonorrhœal Conjunctivitis** is one of the most destructive forms of purulent ophthalmia, giving rise not unfrequently, in the course of forty-eight hours, to the most intense chemosis, with opacity and softening of the cornea, followed by staphyloma and escape of the aqueous humour. It results from direct infection of the conjunctival sac with the gonorrhœal discharge. In the majority of instances only one eye is affected; but, in some, both are involved to an equal extent. The disease commences with the ordinary symptoms of conjunctival inflammation; itching and swelling of the eyelids, velvety redness of the conjunctiva, muco-purulent discharge, with much

lachrymation. The chemosis sets in early, and is very severe; and, unless treatment afford speedy relief, the consequences are most disastrous to vision.

*Treatment.*—The prevention of purulent ophthalmia in new-born children as the result of infection by the vaginal discharges of the mother, should consist in the use of a vaginal douche of 1 in 2000 perchloride of mercury. As soon as possible after birth the child's eyes should be washed with weak boric lotion, and a few drops of a 2 per cent. solution of nitrate of silver introduced into the conjunctival sac, as recommended by Cr  d  . For the relief of gonorrh  al ophthalmia active measures are required. The patient must be confined to a dark room, the bowels must be kept regular, and a moderate diet allowed; much relief may be given by the extraction of a small amount of blood from the temple by leeches. The most useful topical agent that we possess is the nitrate of silver. This should be freely applied with a camel's-hair pencil in the strength of 15 or 20 grains to the ounce of distilled water, and the eye then washed out with weak salt solution. The conjunctiva may be rendered insensible by cocaine before the application. The lids should be kept covered by compresses dipped in weak alum lotion, and the purulent discharge, as it accumulates, carefully washed away by tepid alum injections. Instead of alum, boric acid may be used with great effect, and lately, a very weak solution of perchloride of mercury (1 in 5000) has been tried with considerable success. In doing this, great care must be taken that none of the discharge come into contact with the eyes of the Surgeon or nurses, as it is highly contagious, and will almost to a certainty produce the disease; instances are recorded in which, in this way, the attendant's vision has been destroyed. If the chemosis be considerable, the swelling must be incised; and, as the inflammation subsides, belladonna lotions may be employed with advantage, and the use of the nitrate of silver and other lotions gradually discontinued.

Great care must be taken to prevent infection of the other eye when only one is affected. It may be covered with a compress, or a watch-glass may be placed over it and secured by plaster or collodion.

**Gonorrh  al Scleritis** is by no means of such frequent occurrence as the conjunctival inflammation; when it happens, it will be found to be associated with gonorrh  al rheumatism, and not unfrequently with inflammation of the testicle, occurring apparently in individuals in whom there is a tendency to affection of the fibrous tissues. This disease is evidently of constitutional origin, as it cannot possibly arise from local contagion; it is attended with the ordinary signs of sclerotic inflammation, and is usually accompanied by some degree of iritis.

The constitutional *Treatment* is that for gonorrh  al rheumatism. Locally the eye must be protected from light, and a few drops of atropine solution put in occasionally. If there is much pain, blood may be taken from the temple by cupping or leeches.

**Gonorrh  al Inflammation of the Nose**, attended with profuse suppuration, the result of direct infection, is a complication that I have more than once had occasion to observe. The swelling of the organ is considerable, the tenderness great, and the discharge abundant; a condition, indeed, of the Schneiderian membrane that seems analogous to the inflammation of the conjunctiva just described. The *Treatment* that I have found to succeed best, consists in fomentations, followed by astringent lotions or injections.

**Gonorrhœal Inflammation of the Rectum** has already been described at p. 952.

**Gonorrhœal Rheumatism** principally occurs in young and otherwise healthy persons. The exact nature of the disease is very uncertain. It is supposed by many to be a form of blood-poisoning analogous to pyæmia. Kammerer is said to have found the gonococcus in the fluid of a knee-joint affected with gonorrhœal rheumatism, but this observation has not been confirmed by others. Berkeley Hill states that his observations led him to believe that the disease is met with chiefly in gouty or rheumatic subjects. If the patient have not previously suffered from these affections, a family history indicating a tendency to them will usually be found. In patients who are distinctly rheumatic or gouty, Hutchinson states that any urethral discharge, whether specific or not, may give rise to symptoms identical with those of gonorrhœal rheumatism. The affection is more common in men than in women, and seldom sets in till the third week after the commencement of the discharge, though it may occur as late as the second month. The disease may assume various forms. It may commence insidiously with pain in the joints, quickly followed by considerable effusion. Several joints may be affected, but the knee is attacked with far greater frequency than any other articulation. The febrile disturbance may be slight. The pain and swelling last usually for some weeks, and gradually subside; but relapses are common. In other cases the course of the affection more closely resembles that of acute arthritis; the pain is intense, and the ligaments are early affected. The swelling assumes an oval form, effusion into the articular cavity being slight, or even wanting. The constitutional disturbance is severe. This variety most commonly ends in ankylosis. In another form occasionally met with, pain forms the chief symptom, without swelling or interference with movement. Other structures beside the joints may be affected, as the fasciæ, the sheaths of tendons, bursæ, and occasionally the nerves. Gonorrhœal scleritis, as already mentioned, is always connected with rheumatism, and orbitis may arise from the same cause. Gonorrhœal may be distinguished from simple acute rheumatism by the attack being less severe, by the affection usually being limited to two or three joints, and often to the knee only, and by the absence of the profuse sweating and the creamy-white tongue. The prognosis is, as a rule, good. Suppuration may occasionally take place, and the disease then merges into that immediately to be described, gonorrhœal pyæmia. Ankylosis is, however, very common, especially in the arthritic form. This arises not so much from destruction of the cartilages, as from shortening and contraction of the inflamed capsule of the joint when recovery takes place. This form of ankylosis is practically incurable.

*Treatment.*—The first essential point of treatment is to check the urethral discharge as quickly as possible by the means already described. Iodide of potassium, with alkaline tonics, are sometimes of use. Salicylate of sodium in large doses has been tried with varying effect. Quinine may be given if the temperature is elevated, and in the later stages perchloride of iron is often of material service. The local joint-affection must be treated by absolute rest on splints, blistering, and strapping over mercurial ointment in the later stages. If ankylosis occurs, it must be treated as described on p. 363.

**Gonorrhœal Pyæmia.**—It is not easy to draw a clear distinction between gonorrhœal rheumatism and pyæmia. The term "pyæmia" is applied to those aggravated cases, fortunately of very rare occurrence, in which the joint-affec-

tion terminates in suppuration, with complete destruction of the articulation. In these cases abscesses are not uncommonly met with in other parts of the body, especially in the subcutaneous tissue. Visceral abscesses are of very rare occurrence. The symptoms are those of chronic pyæmia (Vol. I., p. 285).

**Cutaneous Eruptions**, chiefly consisting of roseola, with slight pityriasis, and perhaps a few patches of psoriasis, have been described as occurring occasionally in severe cases of gonorrhœa. The description given by Travers of these eruptions makes them correspond so closely to the early manifestations of syphilis that it is probable that they really resulted from an intra-urethral chancre, mistaken for gonorrhœa. If these cases and those in which the rash arises from copaiba or cubeba be excluded, it is doubtful if any true gonorrhœal skin eruptions exist.

**Gonorrhœa in the Female** differs from the same affection in the male in being less severe in its initial manifestations but usually more extensive, of longer duration, and more apt to be followed by dangerous or even fatal sequelæ. The severity is less, on account of the shortness of the female urethra preventing the occurrence of the retention of urine as in the male, and also from the absence of such parts as the prostate, testes, &c., the implication of which constitutes the principal source of difficulty in men. Gonorrhœa in the female may affect the parts to very different degrees: thus, the vulva alone may be implicated, or, as most commonly happens, the inflammation may spread to the whole of the mucous membrane of the vagina. Bartholin's glands are frequently affected and may suppurate. The urethra is less commonly the seat of disease, though occasionally implicated with other parts; and, lastly, the interior of the uterus may become affected by the specific inflammation. In some cases it will even spread along the Fallopian tubes to the ovaries; and ovaritis, purulent salpingitis, and fatal peritonitis may thus be induced. In other cases dilatation of the tube and the formation of a pyosalpinx may occur; this is attended with the danger of rupture and the production of peritonitis.

The **Symptoms** of gonorrhœa in women are sufficiently well marked in the early stages, when there is an abundant muco-purulent discharge from the parts affected, with a good deal of inflammatory irritation, accompanied by pain in micturition, and a frequent desire to pass urine. As the disease becomes chronic, however, it is more difficult to determine its true character: it being apt to be confounded with some of those accidental and leucorrhœal discharges to which females of all ages are subject.

**Diagnosis.**—In the majority of cases, gonorrhœa may be distinguished from all other *muco-purulent discharges* of the female organs, by the presence of inflammation about the external parts, and the mucous membrane of the vagina and urethra. In these cases it will be found, on introducing a speculum (which, however, occasions considerable pain, and is firmly grasped by the contraction of the vagina), that the discharge comes from the vaginal wall, and that the uterine orifice is free from it, or nearly so; whereas in leucorrhœa the discharge proceeds in a great measure from the interior of the uterus, the os and cervix of which will probably also present signs of disease. It must, however, be borne in mind that the discharge in gonorrhœa may occasionally be in a great degree uterine; and that that of leucorrhœa may be an exudation from the mucous membrane of the vagina. In such circumstances, when the disease is chronic, it is almost impossible to arrive at a correct conclusion as to the nature of the case from simple inspection; and in these cases

of doubt the Surgeon had better give a very guarded opinion, lest he be led into the error of inculpating an innocent woman. The difficulty is increased, and a good deal of obscurity thrown over the case, by the fact that leucorrhœal discharges will occasionally give rise to urethritis closely simulating gonorrhœa in the male. Female *Children* also are occasionally subject to an acute inflammation of the vagina and nymphæ as the result of simple irritation, of constitutional disturbance, or of teething; these cases require to be recognized, as they have frequently been the basis of unfounded accusations.

The **Treatment** of gonorrhœa in the female must vary, according as the disease is acute or chronic. In the acute stage salines, low diet, rest in bed, and emollient sedative fomentations, are the chief means to be adopted. As the disease subsides into a chronic condition, astringent injections must be employed; a weak solution of acetate of lead or alum being especially useful. These injections should be employed three or four times a day and in large quantity. After they have been thrown up, a piece of lint well soaked in the lotion should be introduced between the opposed mucous surfaces, so as to prevent their coming into apposition, the discharge being in a great measure kept up by their friction against one another. In order that the injection may be properly given, the woman should lie flat on her back, and introduce the fluid with a syringe or irrigator. In the treatment of gonorrhœa in women, specifics are of no use unless the urethra be affected, when copaiiba may very rarely be required. The disease is apt to degenerate into a chronic gleet condition, leaving a thin muco-puriform discharge, which will continue to be infectious for a great length of time. It is, therefore, most important not to relinquish the treatment until this is entirely cured, and the condition of Bartholin's glands must particularly be observed, as the discharge from these may continue to be infectious after other parts are cured.

#### STRICTURE OF THE URETHRA.

The existence of muscular tissue in the wall of the urethra is an anatomical fact which has an important bearing upon certain phenomena presented by some forms of stricture of the canal. The arrangement of the muscular tissue was shown by Hancock to be as follows:—The fibres of the inner layer of the muscular coat of the bladder pass forwards underneath the mucous membrane of the prostatic portion of the urethra, and those from the outer layer of the muscular coat of the bladder outside the prostate. These two layers join at the membranous portion of the urethra, forming the muscular covering of this portion of the canal. At the bulb, these two layers divide again: the inner lying underneath the mucous membrane, separated from it merely by areolar tissue; the external lying outside the corpus spongiosum, between it and its fibrous investment. At the anterior extremity of the urethra they unite again and form its lips. Thus the urethra is surrounded through its whole length by muscular fibres, a double layer of which invests it at the membranous portion, and again at the external meatus. The prostate and corpus spongiosum are included between planes of these fibres. The vesicles and ducts of the prostate are surrounded by layers of involuntary fibres; those of the ejaculatory ducts coming from the non-striated layer of the vas deferens. These fibres are totally distinct from the common muscular apparatus of the perinæum; and their existence proves the urethra to be a musculo-membranous canal.

By **Stricture of the Urethra** is meant a narrowing of the canal at one or more points. These may proceed from three distinct conditions: 1, Spasmodic Action of the involuntary Muscular Fibres situated outside the mucous membrane; 2, Congestion of the Mucous Membrane of the canal; or, 3, Organic Changes in the Mucous and Submucous Tissues, consisting of thickening, induration, or the deposit of plastic matter within them. According as the disease arises from one or other of these causes, it is termed a *Spasmodic*, a *Congestive*, or an *Organic* stricture. These different forms of stricture, which in practice are often associated, present so much variety in their symptoms, in the treatment they require, and the constitutions in which they occur, as to require separate description.

**SPASMODIC STRICTURE.**—The possession of muscular contractility by the urethra is obvious from the fact that a bougie may occasionally be introduced with sufficient ease, but that the Surgeon, on attempting to withdraw it, will find it tightly grasped; so, also, occasionally, on introducing the instrument, he will feel it meet with an obstruction, which on steady pressure will yield with that species of quivering which is peculiar to muscular spasm. Again, the fact that a patient will at one time pass his urine with the most perfect freedom, whilst, if it be rendered acrid or acid by drinking spirits, effervescent wines, or other similar beverages, almost complete obstruction will ensue, tends to prove the existence of an occasional spasmodic constriction of the canal. The effect of anæsthetics in facilitating the passage of a catheter must also be attributed to relaxation of spasm.

The **Causes** of spasmodic stricture are generally such conditions as occasion an irritable state of system, as long residence in hot climates, especially if conjoined with habitual excesses in drinking, high living and sexual indulgences. The more immediate causes are usually any circumstances that occasion irritation of the urethral mucous membrane, and thus give rise to spasm of the smooth muscular fibres beneath it. The most usual of these are those conditions of the system in which the urates are largely eliminated: as exposure to cold and wet, by which the action of the skin is suspended; or too free an indulgence in spirituous and acid liquors—such as red or effervescent wines, beer, or punch.

**Symptoms.**—In spasmodic stricture we find evidence of narrowing of the urethra, and consequent impediment to the free flow of urine, rapidly supervening under the influence of certain causes, and as speedily subsiding. A patient, for instance, in his ordinary health and passing urine freely, if he take such food or drink as will give rise to a very acid condition of this fluid, if he be exposed to cold, or get out of health in any way, suddenly finds himself able to pass his urine only in a small stream by drops with much straining, or may even be seized with complete retention. Under appropriate treatment these symptoms rapidly subside; recurring, however, on the application of any exciting cause. At the time of the occurrence of this spasm there is a sensation of weight and uneasiness in the perinæum, with evident irritation of the urethral mucous membrane, as shown by reddening of the lips of the orifice: in fact, spasm alone without congestion or the presence of some organic narrowing will never cause actual retention.

**Treatment.**—If the patient be suffering from spasmodic difficulty in passing urine, an injection, consisting of half a drachm of laudanum in a little starch, should be thrown up the rectum, a morphia suppository given, or a full dose of Dover's powder administered, and the warm hip-bath used.

As the opium begins to take effect, the urine will usually be passed without much difficulty. The bowels should then be made to act, when the patient will usually be relieved. If the spasm continue, as it often does, for some days or weeks after this, a full-sized soft bougie should be introduced every second or third day, in order to lessen the irritability of the urethra. In some cases this is more effectually done by the use of a steel bougie well warmed and oiled. Whatever instrument is used should be of large size, from No. 8 to 10. A small bougie will often be arrested, and will create much irritation, when a large one will pass readily. If the use of the instrument cause irritation and increase the spasm, it is better to omit it entirely, and to trust to constitutional treatment. But the Surgeon must not be discouraged, if the first few introductions of the bougie appear to increase the irritation; as the urethra becomes accustomed to the use of the instrument, relaxation of the spasm will take place. At the same time, the patient's general health should be carefully attended to; the bowels must be kept open, and the diet regulated; all acids, stimulants, and sweets being carefully avoided. During the time that the bougie is being used, he should take citrate of potash well diluted.

As a *preventive treatment* of these attacks, a careful regulation of the diet, warm clothing with the use of flannel, and keeping the skin in action by means of horsehair-gloves and tepid baths, will be found serviceable.

**CONGESTIVE STRICTURE.**—There can be no doubt that the two conditions of congestion and spasm are frequently associated in the urethra, in the relation of cause and effect; and this is the most frequent condition in which spasmodic strictures are found. Indeed, congestion plays an important part in all forms of stricture; it may, as we have just seen, be connected with the spasmodic variety; it may occur alone; or it may be associated with organic stricture. Some parts of the urethra appear to be more subject to congestion than others: thus, for instance, the membranous and prostatic portions, especially the folds of mucous membrane constituting the verumontanum, are peculiarly liable to become congested.

**Causes.**—Congestive stricture frequently occurs as the result of chronic and long-continued inflammation of the urethra, or of the passage of concentrated urine containing an undue proportion of urates. It is especially in gouty or rheumatic subjects who suffer from irritability of the skin and mucous membranes that this condition occurs. In these cases there is no permanent obstruction; but the disease is transitory, and due solely to a swollen state of the membrane of the part. In the majority of cases, however, it complicates and seriously aggravates spasmodic and slight organic strictures.

**Symptoms.**—In congestive stricture we not only find the common symptoms occasioned by an impediment to the free passage of the urine, but some swelling of the lips of the urethra, with reddening and eversion of them. There is also slight gleet exudation, and not unfrequently an abundant puriform discharge—in fact, urethritis of a marked kind, with a sense of weight or fulness in the perineum, pain in micturition, and sometimes uneasiness in defecation. This state of things constitutes a very troublesome affection, intimately connected with the various forms of urethritis, and exceedingly apt to relapse from apparently trivial circumstances, slight errors of diet, dyspeptic derangements, or any local sources of irritation.

The **Treatment** in these cases should consist in careful regulation of the diet and habits of life, and especially in the administration of citrate of

potash, and the saline aperient mineral waters, as those of Carlsbad or Friedrichshall. If there be much tenderness or weight about the perinæum, the application of leeches, together with the use of the warm hip-bath, will be serviceable.

Congestive stricture, though more influenced by constitutional than by local means in many cases, yet is often greatly relieved by the occasional introduction of bougies. In some instances a soft instrument, in others a steel one, will be found to answer best. Whatever is used, care should be taken to introduce it slowly and with every possible gentleness. With all care, some hæmorrhage usually follows the passage of the instrument; not from deep laceration, but simply as the result of compression of the mucous membrane; and the discharge of blood appears to be beneficial rather than otherwise.

**ORGANIC STRICTURE.**—This, the true form of stricture, is the result of the formation of dense fibroid tissue in the mucous membrane and submucous tissue of a portion of the urethra, in many cases extending to the neighbouring spongy tissue, or even further. This is produced as the result of chronic inflammation or of the healing of ulcers or wounds, and differs in no respect from the cicatricial fibroid tissue formed in other parts under similar circumstances. In its development it shows the tendency to contraction which forms the characteristic feature of all fibrous tissue produced as a consequence of inflammation, and thus leads to a narrowing of the canal it surrounds. The *causes of organic stricture* are: 1. Chronic inflammation of the mucous membrane, resulting from gonorrhœa. Repeated claps and long-continued gleet are by far the most fertile causes of this disease. The long continuance of the inflammation is more to be dreaded than its intensity in occasioning this mischief; hence it is of great importance not to allow gleet to run on indefinitely, as they will almost to a certainty be followed by constriction of some portion of the urethra. 2. The healing of an intra-urethral chancre always gives rise to a stricture. This is met with within an inch of the orifice, and is a comparatively rare form of the disease. 3. The most inveterate form of stricture arises from transverse laceration of the urethra from blows or kicks in the perinæum healing by a contracted scar. Severe contusions of other parts of the canal may in the same way cause narrowing of its calibre. A more rare cause is the injury done to the urethra of a child by the lodgment of a calculus, or in the effort to extract it. 4. S. Gross states that it may be caused by habitual masturbation.

**Age.**—Stricture of the urethra may be met with at any age after puberty. The causes that usually give rise to it seldom come into operation, however, before the adult age; hence strictures are not very common before 25 years of age. Between that period and the age of 40 they most commonly originate, and may then continue for an indefinite period. The earliest age at which I have seen true organic stricture of the urethra has been in a boy 14 years old, when it had already existed for more than 12 months; it was situated one and a half inch from the meatus, and was so tight as only to admit of No. 1 catheter. It had given rise to a perineal fistula, through which the greater part of the urine escaped. The boy could give no explanation of its occurrence, but it was probably traumatic. His attention was first directed to it by a sudden attack of retention. The stricture was hard and gristly, about half an inch long, and required urethrotomy for its relief. There was no calculus.

**Seat.**—The seat of organic stricture varies considerably; indeed, any

portion of the urethra may be affected by it, except the prostatic. It was at one time believed that the membranous portion of the canal was the most frequently affected by this disease. This, however, there can be little doubt, is an erroneous opinion. H. Smith examined 98 specimens of stricture contained in the different London museums: of these he found only 21 seated in the membranous portion of the urethra, whilst 77 were anterior to the triangular ligament; the majority of these being either in the bulbous portion, or a little in advance of this. Thompson, in his work on *Stricture*, states that, in an examination of 320 strictures, he found 215 at the junction of the spongy and membranous portions of the urethra; 51 in the spongy portion, from an inch in front of its commencement to within two inches and a half of the external meatus; and 54 at the external orifice, or within two inches and a half of it. The part most frequently affected is the first inch of the spongy portion; in the membranous portion, stricture is extremely rare, being almost invariably of traumatic origin when situated in this part. Thompson says: "I may confidently assert that there is not a single case of stricture in the prostatic portion of the urethra to be found in any one of the public museums of London, Edinburgh, or Paris." Occasionally strictures are multiple, two frequently occurring, and sometimes as many as four or five.

**Pathological Appearances.**—In describing the appearances commonly met with in a well-marked case of organic stricture, it will be most convenient to suppose that the whole canal has been laid open along its roof, and to consider the parts in the following order: 1. The part of the urethra anterior to the stricture. 2. The stricture. 3. The urethra behind the stricture. 4. The bladder. 5. The ureters and kidneys.

1. The **Urethra anterior to the Stricture** is perfectly healthy, unless it has been injured by instruments. If the cut edge of the mucous membrane be taken in a pair of forceps, it will be found to show a considerable degree of elasticity. Its colour is pink, and it is semi-transparent. The spaces of the spongy tissue beneath are empty and open, or filled with blood.

2. The **Stricture**.—At the narrowed part the surface of the mucous membrane is of an opaque white colour, marked by longitudinal ridges, and often parchment-like in appearance. If its edge be seized in the forceps it will be found to possess but little, if any, elasticity, and to be firmly fixed to the parts beneath. The submucous tissue, instead of forming a delicate areolar layer, is represented by tough rigid fibrous tissue firmly adherent on one side to the mucous membrane, and blending on the other with the cavernous tissue of the corpus spongiosum. The spaces of the spongy tissue are, in all more advanced specimens, obliterated for a greater or less extent near the stricture, so that the corpus spongiosum at this spot is converted into a dense solid mass. In very extreme cases the chronic inflammatory induration extends even to the areolar tissue beyond. The character of the stricture varies greatly. In some cases it is annular, encircling the whole canal equally for some little distance. When it is elongated, there is usually marked consolidation of the corpus spongiosum, as in Fig. 910. In other cases, again, annular strictures may be narrow and sharp-edged, and are then called "pack-thread" or "bridle" strictures; consisting of bands stretching across the urethra (Fig. 911). Sometimes there are several of these in close proximity to one another, leaving merely narrow passages between or under them. These bands occasionally stretch directly across the canal, but more commonly they take a somewhat oblique direction

(Fig. 911). It is not very clear how these bridles stretching across the urethra are formed. It can scarcely be by inflammatory exudation; it is more probable that they are occasioned by perforation of an annular narrow of the mucous membrane by the point of an instrument. These various kinds of organic stricture are hard and elastic; sometimes, when old, almost cartilaginous in their density, feeling gristly and rough to the instrument that passes over them.

The *Amount of Constriction* varies greatly in organic stricture, from slight narrowing of the channel to almost complete obstruction of it. A question has arisen whether the canal of the urethra is ever rendered completely impermeable by a stricture. In answering this, it is necessary to be agreed on the meaning of the term "impermeable." If by it be meant impenetrable to the passage of a catheter, there can be no doubt that such strictures

Fig. 910.—Stricture from Consolidation of Corpus Spongiosum.

Fig. 911.—Bridle-Stricture.

Fig. 912.—Stricture at the Anterior part of the Urethra.

occasionally, though very rarely, occur; the channel being so narrow, oblique or tortuous, that the instrument cannot be passed through it. Strictures of this description, however, may usually be ultimately made permeable to instruments by proper and careful treatment. If by "impermeable" is meant generally impervious to the passage of urine, there can be no doubt that such a condition does not exist. It would clearly be incompatible with life, unless a fistulous opening existed behind the stricture, through which the urine might pass out; and even with such an aperture existing, I have never seen a case in which no urine whatever escaped by the meatus, unless the consequence of injury or disease, a portion of the whole calibre of the urethra had sloughed away.

3. The **Urethra behind the Stricture** is dilated, often so as to form a considerable pouch, in which in rare cases phosphatic concretions may form. The mucous membrane is more opaque than natural, and its loss of elasticity is indicated by its being thrown into longitudinal folds; it is usually of

grey colour, indicating that it has suffered from chronic congestion or inflammation. The orifices of the lacunæ, and of the small glands opening on it, are dilated, often to a considerable size. This is also very marked in the floor of the prostatic urethra. These small pits and hollows often cause considerable embarrassment in treatment, the instrument lodging in them after having safely passed the stricture. The cause of these changes is the extreme tension to which this part of the urethra is exposed during micturition, owing to the obstruction in front and the powerful hypertrophied bladder behind.

4. The **Bladder** in all well-marked cases of stricture shows evidence of chronic cystitis. Its mucous membrane is thickened, rigid, and of an ashy-grey colour. If from any cause the condition has been aggravated before death, dark-red and purple patches will be found upon it. As a rule the cavity of the bladder is diminished, and its muscular coat greatly hypertrophied, giving rise to marked fasciculation of its inner surface. In exceptional cases, especially in old men, it may be dilated as well as thickened; sacculi are very common.

5. The **Ureters** are often more or less dilated. This is not, as was formerly supposed, due to regurgitation of urine, but to obstruction to the orifice of the ureter by the chronic inflammation of the mucous membrane, and the hypertrophy of the muscular coat of the bladder; the force that dilates the ureter being the force of secretion from the kidney. The further changes that occur in the pelvis and in the kidneys are fully described in Chapter LXV.

**Symptoms.**—The amount of constitutional disturbance set up by a stricture will vary greatly in different cases. In most instances, it is not very great. The extent to which the constitution is influenced will generally be in proportion to the tightness and duration of the stricture; but it is surprising how much constitutional irritation is set up in some cases by a stricture, even though it be not very tight. The interference with the free flow of urine ultimately causes secondary mischief in the kidneys, the nature and the symptoms of which have been described in Chapter LXV., to which I must refer the reader. In some cases the constitutional symptoms are rather of a nervous character; the patient suffering not only great pain in micturition, but being seized with rigors, followed by prostration, each time the urine flows over the tender and irritable surface.

The **Local Signs** of stricture are always well marked, and are dependent simply on the mechanical obstacle presented by the contracted urethra to the escape of the urine. The disease usually commences with the retention in the urethra of a few drops of urine after evacuation of the contents of the bladder; these escape and wet the clothes. The patient finds that he has to void urine more frequently than usual, both by night and by day; there is some burning, perhaps a slight gleet discharge, and a feeling of weakness about the genital organs. The stream of urine becomes gradually smaller, as the part of the urethra anterior to the stricture is not distended as is normally the case during the act of micturition. Alterations in the shape of the stream, such as forking, twisting, and scattering, are often mentioned as symptoms of stricture, but are rarely observed; indeed, it seems hardly conceivable that a stricture in the bulbous portion of the urethra can determine the shape of the stream which flows from the meatus. As the disease advances, these signs

(Fig. 911). It is not very clear how these bridles stretching across the urethra are formed. It can scarcely be by inflammatory exudation; it is more probable that they are occasioned by perforation of an annular narrowing of the mucous membrane by the point of an instrument. These various kinds of organic stricture are hard and elastic; sometimes, when old, almost cartilaginous in their density, feeling gristly and rough to the instrument that passes over them.

The *Amount of Constriction* varies greatly in organic stricture, from slight narrowing of the channel to almost complete obstruction of it. A question has arisen whether the canal of the urethra is ever rendered completely impermeable by a stricture. In answering this, it is necessary to be agreed upon the meaning of the term "impermeable." If by it be meant impenetrable to the passage of a catheter, there can be no doubt that such strictures are

Fig. 910.—Stricture from Consolidation of Corpus Spongiosum.

Fig. 911.—Bridle-Stricture.

Fig. 912.—Stricture at the Anterior part of the Urethra.

occasionally, though very rarely, occur; the channel being so narrow, oblique or tortuous, that the instrument cannot be passed through it. Strictures of this description, however, may usually be ultimately made permeable to instruments by proper and careful treatment. If by "impermeable" is meant generally impervious to the passage of urine, there can be no doubt that such a condition does not exist. It would clearly be incompatible with life, unless a fistulous opening existed behind the stricture, through which the urine might pass out; and even with such an aperture existing, I have never seen a case in which no urine whatever escaped by the meatus, unless in consequence of injury or disease, a portion of the whole calibre of the urethra had sloughed away.

3. The **Urethra behind the Stricture** is dilated, often so as to form a considerable pouch, in which in rare cases phosphatic concretions may form. The mucous membrane is more opaque than natural, and its loss of elasticity is indicated by its being thrown into longitudinal folds; it is usually of a

ash-grey colour, indicating that it has suffered from chronic congestion or inflammation. The orifices of the lacunæ, and of the small glands opening upon it, are dilated, often to a considerable size. This is also very marked in the floor of the prostatic urethra. These small pits and hollows often cause considerable embarrassment in treatment, the instrument lodging in them after having safely passed the stricture. The cause of these changes is the extreme tension to which this part of the urethra is exposed during micturition, owing to the obstruction in front and the powerful hypertrophied bladder behind.

4. The **Bladder** in all well-marked cases of stricture shows evidence of chronic cystitis. Its mucous membrane is thickened, rigid, and of an ash-grey colour. If from any cause the condition has been aggravated before death, dark-red and purple patches will be found upon it. As a rule the cavity of the bladder is diminished, and its muscular coat greatly hypertrophied, giving rise to marked fasciculation of its inner surface. In exceptional cases, especially in old men, it may be dilated as well as thickened; sacculi are very common.

5. The **Ureters** are often more or less dilated. This is not, as was formerly supposed, due to regurgitation of urine, but to obstruction to the orifice of the ureter by the chronic inflammation of the mucous membrane, and the hypertrophy of the muscular coat of the bladder; the force that dilates the ureter being the force of secretion from the kidney. The further changes that occur in the pelvis and in the kidneys are fully described in chapter LXV.

**Symptoms.**—The amount of constitutional disturbance set up by a stricture will vary greatly in different cases. In most instances, it is not very great. The extent to which the constitution is influenced will generally be in proportion to the tightness and duration of the stricture; it is surprising how much constitutional irritation is set up in some cases by a stricture, even though it be not very tight. The interference with the free flow of urine ultimately causes secondary mischief in the kidneys, the nature and the symptoms of which have been described in chapter LXV., to which I must refer the reader. In some cases the constitutional symptoms are rather of a nervous character; the patient suffering not only great pain in micturition, but being seized with rigors, followed by prostration, each time the urine flows over the tender and irritable surface.

The **Local Signs** of stricture are always well marked, and are dependent simply on the mechanical obstacle presented by the contracted urethra to the escape of the urine. The disease usually commences with the retention of the urethra of a few drops of urine after evacuation of the contents of the bladder; these escape and wet the clothes. The patient finds that he has to pass urine more frequently than usual, both by night and by day; there is some burning, perhaps a slight gleet discharge, and a feeling of weakness about the genital organs. The stream of urine becomes gradually smaller, as the part of the urethra anterior to the stricture is not distended as is normally the case during the act of micturition. Alterations in the shape of the stream, such as forking, twisting, and scattering, are often mentioned as symptoms of stricture, but are rarely observed; indeed, it seems hardly conceivable that a constriction in the bulbous portion of the urethra can determine the shape of the stream which flows from the meatus. As the disease advances, these signs

(Fig. 911). It is not very clear how these bridles stretching across the urethra are formed. It can scarcely be by inflammatory exudation; it is more probable that they are occasioned by perforation of an annular narrowing of the mucous membrane by the point of an instrument. These various kinds of organic stricture are hard and elastic; sometimes, when old, almost cartilaginous in their density, feeling gristly and rough to the instrument that passes over them.

The *Amount of Constriction* varies greatly in organic stricture, from slight narrowing of the channel to almost complete obstruction of it. A question has arisen whether the canal of the urethra is ever rendered completely impermeable by a stricture. In answering this, it is necessary to be agreed upon the meaning of the term "impermeable." If by it be meant impenetrable to the passage of a catheter, there can be no doubt that such strictures may

occasionally, though very rarely, occur; the channel being so narrow, oblique, or tortuous, that the instrument cannot be passed through it. Strictures of this description, however, may usually be ultimately made permeable to instruments by proper and careful treatment. If by "impermeable" is meant generally impervious to the passage of urine, there can be no doubt that such a condition does not exist. It would clearly be incompatible with life, unless a fistulous opening existed behind the stricture, through which the urine might pass out; and even with such an aperture existing, I have never seen a case in which no urine whatever escaped by the meatus, unless, in consequence of injury or disease, a portion of the whole calibre of the urethra had sloughed away.

3. The **Urethra behind the Stricture** is dilated, often so as to form a considerable pouch, in which in rare cases phosphatic concretions may form. The mucous membrane is more opaque than natural, and its loss of elasticity is indicated by its being thrown into longitudinal folds; it is usually of an

ash-grey colour, indicating that it has suffered from chronic congestion or inflammation. The orifices of the lacunæ, and of the small glands opening upon it, are dilated, often to a considerable size. This is also very marked in the floor of the prostatic urethra. These small pits and hollows often cause considerable embarrassment in treatment, the instrument lodging in them after having safely passed the stricture. The cause of these changes is the extreme tension to which this part of the urethra is exposed during micturition, owing to the obstruction in front and the powerful hypertrophied bladder behind.

4. The **Bladder** in all well-marked cases of stricture shows evidence of chronic cystitis. Its mucous membrane is thickened, rigid, and of an ash-grey colour. If from any cause the condition has been aggravated before death, dark-red and purple patches will be found upon it. As a rule the cavity of the bladder is diminished, and its muscular coat greatly hypertrophied, giving rise to marked fasciculation of its inner surface. In exceptional cases, especially in old men, it may be dilated as well as thickened; sacculi are very common.

5. The **Ureters** are often more or less dilated. This is not, as was formerly supposed, due to regurgitation of urine, but to obstruction to the orifice of the ureter by the chronic inflammation of the mucous membrane, and the hypertrophy of the muscular coat of the bladder; the force that dilates the ureter being the force of secretion from the kidney. The further changes that occur in the pelvis and in the kidneys are fully described in Chapter LXV.

**Symptoms.**—The amount of **constitutional disturbance** set up by a stricture will vary greatly in different cases. In most instances, it is not very great. The extent to which the constitution is influenced will generally be in proportion to the tightness and duration of the stricture; but it is surprising how much constitutional irritation is set up in some systems by a stricture, even though it be not very tight. The interference with the free flow of urine ultimately causes secondary mischief in the kidneys, the nature and the symptoms of which have been described in Chapter LXV., to which I must refer the reader. In some cases the constitutional symptoms are rather of a nervous character; the patient suffering not only great pain in micturition, but being seized with rigors, followed by prostration, each time the urine flows over the tender and irritable surface.

The **Local Signs** of stricture are always well marked, and are dependent simply on the mechanical obstacle presented by the contracted urethra to the free escape of the urine. The disease usually commences with the retention in the urethra of a few drops of urine after evacuation of the contents of the bladder; these escape and wet the clothes. The patient finds that he has to pass urine more frequently than usual, both by night and by day; there is some straining, perhaps a slight gleet discharge, and a feeling of weakness about the genital organs. The stream of urine becomes gradually smaller, as the part of the urethra anterior to the stricture is not distended as is normally the case during the act of micturition. Alterations in the shape of the stream, such as forking, twisting, and scattering, are often mentioned as symptoms of stricture, but are rarely observed; indeed, it seems hardly conceivable that a constriction in the bulbous portion of the urethra can determine the shape of the stream which flows from the meatus. As the disease advances, these signs

necessarily become more marked, until they may terminate in complete retention; they often come on in a very insidious manner, however, and when the patient seeks advice he is found to be already the subject of a very tight and intractable stricture; indeed, in some cases, the first circumstance that directs the attention of the patient to his complaint is the sudden occurrence of retention of urine.

**Examination of the Patient for Stricture.**—In all cases of suspected stricture, the Surgeon should, if possible, see the patient pass water before using an instrument. He will thus be able to judge of the actual amount of obstruction. It sometimes happens that the canal, though not greatly narrowed, is tortuous and indurated, so that an instrument enters with great difficulty, although the patient passes a fair stream of urine. Such a case might readily be mistaken for a very tight stricture if the examination were commenced by attempting to pass an instrument. The existence of a stricture can however be determined with certainty only by the introduction of an instrument. In exploring the canal in a suspected case, two points have to be ascertained—the existence of a stricture, and its degree of tightness.

The *Existence of a Stricture* is best determined by passing a soft conical French bougie about No. 8 (English scale). It must be slightly warmed and well oiled. This will pass readily, unless the canal be distinctly constricted, when it will be arrested at the narrow point. In this exploration, too small an instrument must not be used, lest it hitch in the fossæ of the urethra or against the verumontanum, and this accidental arrest be mistaken for the obstruction produced by a stricture; or it may pass through the stricture, and thus mislead the Surgeon. The existence of a stricture having been ascertained, the next point is to determine its *degree of tightness*. This is best done by withdrawing the instrument previously used, and then introducing a smaller one about the size of the stream of urine that the patient passes. If this fail to enter the stricture, a still smaller one must be used, until that size is reached which can

Fig. 913.—  
Conical-headed  
Sound.

Fig. 914.—  
Olive-headed  
Sound.

be introduced with but a moderate degree of force. In this way the existence, the seat, and degree of tightness of the stricture, are ascertained.

A soft instrument should always be used by preference for this preliminary examination, as it causes less pain, and with the most ordinary skill and care it is impossible to do the patient any injury with it. There is no doubt that information as to the length, degree of induration, and form of the narrowing, may be gained by the experienced Surgeon by means of a metal bougie; but the knowledge thus gained is not sufficient to counterbalance the greater ease and safety of a soft instrument.

The slighter narrowings of the urethra are not easily recognized by the means just described. For this purpose the conical or olive-headed bougie (Figs. 913 and 914) will be found most useful. The conical shape of this instrument enables it to pass readily towards the bladder, but on withdrawing it the

shoulder hitches on any narrow part. The instrument should be graduated in inches, so that the exact distance of the stricture from the orifice can be readily determined. If it be desired to determine more accurately the seat of the stricture, the distance of the orifice of the bladder from the meatus externus must first be determined by carefully passing a graduated "catheter à boule," and noting the exact moment at which the urine commences to flow. The graduated olive-headed sound is then introduced for the same distance, and slowly withdrawn. If the hitch be felt between one inch and one and three-quarters, the stricture is in the membranous part; if between one and three-quarters and three inches, it is in the bulbous portion. For the purpose of measuring slight strictures, Otis, of New York, invented an instrument which he calls the "urethrometer" (Fig. 915). It consists of a straight tube, the end of which can be dilated into a sort of fenestrated sphere, and the size to which it is dilated is registered on a small dial on the handle. The instrument can be readily introduced into the bladder, if necessary, but there is no advantage in so doing. When in the urethra, behind the stricture, the bulb is gradually expanded till it is just held, but not tightly grasped. It is then drawn steadily forward, and when it is stopped the bulb is gradually diminished till it passes the stricture. The exact size of each part is thus registered on the dial.

The **Treatment** of organic stricture of the urethra may be conducted by

Fig. 915.—Otis's Urethrometer. A, Open; B, End closed.

the following methods:—1, Gradual Mechanical Dilatation; 2, Continuous Dilatation; 3, Electrolysis; 4, Forcible Expansion or Rupture; 5, Internal Urethrotomy; 6, External Urethrotomy or Perinæal Section; 7, Excision. Whatever plan of treatment be adopted, the Surgeon must bear in mind that his operations have to be conducted upon a tender canal endowed with exquisite sensibility, in which improper violence may set up a degree of irritation that will readily extend to neighbouring structures, and thus endanger the life of the patient. But, though it is necessary to recollect this, he must not run into the opposite and equally dangerous extreme of adopting inefficient measures for the removal of the obstruction. A bad stricture is one of the most serious diseases to which the human frame is liable, and will almost inevitably, if left to itself, terminate fatally by the induction of renal disease, or of serious local complications. We must therefore not hesitate to adopt sufficiently energetic measures for its removal; and if these be properly conducted, there is scarcely any affection in which the Surgeon can afford his patient greater relief. At the same time, however, that local means are being used, constitutional treatment should not be neglected. Organic stricture is often more or less associated with a spasmodic or congestive condition of the urethra, and requires the same constitutional treatment, modified according to circumstances, that is necessary in these affections—proper regulation of diet, avoidance of all articles of food that generate

urates, and care not to allow the urine to become too concentrated. Attention to the maintenance of the healthy action of the liver and skin will also tend much to increase the patient's comfort, and to ward off the more serious consequences of stricture.

In all except the slightest cases of stricture it is advisable, before beginning mechanical treatment, to subject the patient to constitutional remedies to diminish as far as possible the congestion and spasm which may be present. If any serious difficulty be anticipated, and if the circumstances of the patient permit it, he should be confined to bed for a day or more. The bowels should be freely opened, and he should sit for some time in a hot hip-bath, morning and evening. A morphia suppository may be administered at night, and if the signs of congestion be well marked, a few leeches may be applied to the perinæum. Occasionally blisters over the seat of stricture, when it can be felt clearly from without, may be of service. By these means alone, a stricture which at first seemed almost impermeable may be so far relieved as to take a No. 4 or 5 catheter.

1. **Gradual Mechanical Dilatation**, as it is erroneously termed, is the usual and certainly the most successful mode of treating ordinary strictures :

Fig. 916.—Conical Bulbous Bougie.

but it is not the mere stretching or forcible dilatation of the stricture that cures it. The means employed to produce dilatation tend to promote the absorption of chronic inflammatory products in and underneath the mucous membrane, which especially constitute the stricture.

The instruments that are used for dilatation are either metallic, such as

Fig. 917.—Conical Bulbous Catheter.

silver catheters, steel sounds, or plated bougies ; or made of some soft and yielding material, as gum-elastic catheters, and catgut, whalebone, or elastic bougies. Though each Surgeon will mostly prefer one kind of instrument to another, it is well not to be too exclusive in the use of any one ; for it will be found that in particular cases it is advantageous to depart from the ordinary practice, and that the Surgeon may modify with great benefit to his patient the mechanical means that he adopts. As a general rule, if the stricture can be treated from the first by soft instruments, so much the better. They cause less pain and irritation, and the danger of making false passage is avoided. When the stricture is tight, cartilaginous and of old standing, it is, however, frequently impossible to pass any soft instrument through it, and then a well-made steel bougie or a silver catheter must be used. When once dilatation has been carried to a certain point, for instance to the introduction of a No. 5 catheter, then soft instruments can always be employed if preferred ; but at this stage of the treatment, when the risk of making a false

is very small, conical steel bougies will in many cases be found not so efficient but quite as comfortable to the patient.

Best soft instruments are the conical bougies and catheters with *bulbous* (Figs. 916 and 917). Their introduction excites far less irritation and has much less likelihood of bleeding than that of metallic instruments.

In cases of ordinary stricture they will be found to be the safest and most reliable instruments to use. They will often glide through a tight stricture, when all other instruments, especially metallic ones, fail.

A *form bougie* made of whalebone, gum-elastic or catgut, may sometimes glide through a very narrow stricture, when every other instrument fails.

The ordinary English gum-elastic catheter is of little use in the treatment of stricture by simple dilatation. A conical instrument the point of which is small enough to pass readily through the stricture, can easily be pushed on so as to exert a considerable dilating force with its thickest part. An ordinary gum-elastic catheter which is the same size throughout is not got into the stricture at all so as to exert any dilating effect. It is not stiff enough to be forced into it. If a stylet is used to stiffen it, it becomes as capable of making a false passage as a steel bougie, and is not under the same control.

If the stricture be not only very tight, but twisted, the plan recommended by Brodie may advantageously be employed. It consists in taking a fine catgut bougie, and bending it, as shown in Fig. 918, about an inch from the point, so as to follow the track of the stricture. In this way, strictures that are otherwise inoperable may be rendered pervious with comparative ease.

Metallic instruments are used the most efficient are Lister's *conical steel* bougies (Fig. 919). There should be a difference of three sizes between the thinnest and the thickest parts of the straight portion of the instrument when the dilatation is performed. The point should be well rounded,

Fig. 918. — Catgut Bougie bent to shape of Stricture.

Fig. 919.—Lister's Conical Steel Bougie.

The instrument passes more readily if there is a slight constriction distally beyond it. The instrument should be made of nickel-plated steel and be highly polished. It should have a broad metallic handle, which transmits any sensation communicated to the point more readily than a wooden one. That this instrument will pass much more easily than a catheter is evident, and the latter should be used only when it is intended to tie it. A catheter should be used it should be made very solid and stiff. The rings should be large, so as to serve for a handle, and the eyes well rounded off and somewhat depressed, so that they may not scrape the urethra. These

instruments should be used with every possible care and gentleness, but it is useless to think of passing a catheter through a tight stricture without the employment of some degree of force. The catheter will not "find its own way" here as it does in a healthy urethra, but it must be guided by the hand of the Surgeon; and there is scarcely an operation in surgery that requires more delicacy of manipulation than that of passing an instrument through a tight stricture. Some force must be used, but the skill is shown in proportioning this to the amount of resistance, and in using it in a proper direction. The appearance of force is indeed often greater than the reality; for, though the point of the catheter have passed a tight stricture, it may still require considerable pressure to push the rest of the instrument through it. With a conical steel bougie less force is required than with the catheter, as the stretching is not done with the point, which should pass easily through the stricture, but with the expanded part beyond, which from its conical form passes without much difficulty.

**Introduction.**—Catheters and sounds are best introduced by laying the patient flat upon his back, with the pelvis somewhat raised, and the head and shoulders low. The Surgeon, standing on the left side, inserts the instrument, well warmed and oiled with "Lund's oil" (p. 1116) or vaseline, into the urethra, with its concavity turned towards the left groin, and passes it down the canal, at the same time drawing the penis upwards with his left hand, so as to put the mucous membrane on the stretch. As the instrument approaches the triangular ligament, the handle is carried to the mesial line, and at the same time raised perpendicularly; and, as its point passes under the pubes, it should be kept well against the upper surface of the urethra, and made to enter the bladder by depressing the handle towards and between the thighs. The surest guide to the bladder is the upper surface of the urethra, which is more fixed than the lower, and less liable to the existence of fistulous openings or false passages. Should difficulty be experienced, the introduction may be facilitated by injecting and slightly distending the urethra with olive oil before passing the instrument. If the meatus is small this must be enlarged by a short incision downwards.

If difficulty is found in introducing the instrument, and if any doubt exist as to its being in the right passage, the finger must be introduced into the rectum and its position felt for. If the point of the instrument has left the urethra this may be recognized by its being too thinly covered and too near the gut, or by its being out of the middle line.

Chloroform or ether need be administered only if the stricture be very tight or the patient irritable. Under the influence of an anæsthetic, however, many strictures may readily be passed with metallic instruments that are not pervious in any other way.

**Results of Introduction of an Instrument.**—The introduction of an instrument usually gives rise to a smarting, painful sensation in the urethra: this is generally most severe as the point approaches the neck of the bladder, and is then sometimes attended with nausea and sudden faintness. As a general rule, the instrument should be passed every second or third day, and when introduced should be left in for about five minutes, or until the spasm of the urethra induced by its introduction has subsided. If, however, the stricture be extremely tight, a very small catheter only having been introduced, the instrument may be left in for twenty-four or forty-eight hours.

when it will be found that, however tightly grasped it had been originally, it has become loosened ; a slight discharge being at the same time set up from the urethra. It may then be readily withdrawn, and, when the irritation has subsided at the end of a couple of days, a considerably larger one may be introduced.

The augmentation of the size of the instrument should be very gradual. It is fully sufficient to increase it by one number at each time of introduction. Many urethræ will not bear even this, and it becomes necessary to pass the same instrument on two or three successive occasions before a larger size can be introduced. The size may be gradually increased until the largest is reached which the urethral orifice readily admits ; but as soon as No. 14 or 16 can be introduced with ease, it should not be passed so frequently as before ; it may be passed every seven or ten days, and gradually with less frequency. But a patient who has once suffered from a tight stricture should pass an instrument at least once a month for the rest of his life.

If the size of the instrument be increased too rapidly, irritation may be set up, and inflammation of the testicles, and abscess in the perinæum or prostate, induced. I have more than once had occasion to regret being in too great haste to increase the size of the instrument ; and by augmenting it by two or three numbers at one sitting, I have seen the patient thrown back for weeks by the supervention of some of the affections just mentioned.

By gradual dilatation, properly carried out, most strictures may be considerably relieved in the course of a few weeks ; and the majority may be brought to the full size by continuing the treatment for a sufficient length of time. Some, however, cannot be cured in this way ; it would appear that the tissue of which they are composed is so rigid that, although they may be expanded up to a certain size—say up to No. 5 or 6—it is impossible to go beyond this. In other cases there is a great tendency to relapse, and to a return of the constriction ; the stricture rapidly becoming tighter as soon as the introduction of the instruments is discontinued, even though it be dilated to the full size of the urethra, up to No. 16, for instance. In some instances the relapse is almost instantaneous, micturition being as difficult as before immediately the catheter is withdrawn. In these cases recourse must be had to other measures, which will be described.

**Accidents attending Catheterism.**—The introduction of instruments occasionally gives rise to certain troublesome and even dangerous sequences. Amongst these, syncope and rigors, hæmorrhage, and inflammatory irritation about the urethra or testes, are the most common.

**Nervous Symptoms, Rigors, and Urethral Fever.**—The subject of urethral fever following the use of instruments on the urinary organs in persons affected with chronic or subacute interstitial nephritis has already been discussed at p. 1003. There is no condition in which this untoward complication is more apt to occur than in the treatment of stricture of the urethra, owing no doubt in a great degree to the frequent occurrence of chronic and possibly unsuspected kidney disease in old-standing cases.

Various degrees of constitutional disturbance may be produced by the passage of an instrument through a stricture. In nervous and sensitive individuals this operation is often attended with a sensation of faintness and chilliness as the instrument enters the bulb or membranous portion of the urethra. This sensation is not due either to pain or to fear. It is purely reflex, and

in most cases soon passes off, being less likely to recur as the urethra gets more accustomed to the use of instruments.

If a person liable to these nervous feelings is exposed to a chill, a severe rigor may come on some hours after the passage of the instrument, or the same thing may happen when there has been no predisposition to it, the rigor coming on suddenly and without warning. This is more apt to occur when the stricture is tight; when metallic instruments have been used—possibly with some degree of force, and, though during a considerable length of time—perhaps in vain attempts to penetrate the stricture. The rigors in these circumstances are very severe, so much so as to resemble an attack of ague. During the rigor the temperature rises considerably, often to  $104^{\circ}$  or  $105^{\circ}$ . The subsidence of the rigor is marked by profuse sweating, and is usually attended with great exhaustion. This occurrence is always very alarming, and, though usually not attended with positive danger, leaves the patient weak and exhausted; and if he be old, of broken constitution, or the subject of chronic kidney disease, a fatal result may rapidly ensue. In these distressing cases, death may occur at different periods and in different ways. The earliest period at which I have seen a fatal termination has been in nine hours; usually it takes place in from 24 to 48 hours after the first rigor. The immediate cause of death may be coma, exhaustion, or cardiac syncope.

The cause of these rigors is exceedingly obscure. Constitutional nervousness or timidity has certainly nothing to do with them. They occur in the strongest and most courageous men, and they very rarely follow the use of the catheter in women. I have only once seen these effects in the female, in the person of a young married lady, strong and healthy, who had a stricture of the orifice of the urethra, which I dilated by a two-bladed dilator. Twenty hours after the operation, she had three most intense rigors followed by profuse sweatings. In men they may occur after dilatation of any part of the urethra, but they are much more frequent when the stricture is seated in the bulb or in the membranous portion of the canal. I have heard of one case, however, in which a fatal rigor followed incision and dilatation of the meatus. I doubt whether severe rigors occur unless there have been some traumatic lesion, such as abrasion or rupture of the mucous membrane of the urethra. Rigors certainly follow the use of metallic instruments more frequently than that of the softer kinds, which are less likely to produce such mischief. Rigors are not prevented by the use of anæsthetics. Some of the worst cases that I have seen have occurred after prolonged instrumentation under anæsthetics.

**Treatment.**—The rigor is best prevented by gentleness in the use of instruments; by the employment of soft, rather than metallic ones; by guarding most carefully against a chill, the patient being kept in a warm room during the whole of the day; and by the administration of a full dose of opium and quinine before the use of the instrument.

When a rigor has set in, the patient should be wrapped up in blankets; a glass of hot spirits and water or tea may be given, to be followed up by quinine and opium. The sweating, which is often so profuse as to wet through pillows and bed-clothes, must be encouraged. When it has ceased, the patient should be rubbed dry and wrapped in dry warm blankets.

**Suppression of Urine** is a rare accident after simple dilatation, being more common after the more severe methods of treatment, such as forcible

dilatation. The symptoms are at first those just described, the patient suffering from a rigor, with rapid elevation of temperature, dry skin, and vomiting. The secretion of urine entirely ceases, or at most a few drops darkly stained with blood escape. The patient usually dies in from two to three days, unless the secretion returns. In these cases the kidneys are usually found more or less extensively affected with chronic interstitial inflammation; but cases have been recorded in which the microscope revealed but little change. They are usually gorged with blood. The condition would seem to arise from reflex nervous disturbance of the kidney, but the pathology of the process is very obscure. The *Treatment* consists in dry cupping over the loins and hot-air baths. Large warm water enemata, with a view of "fomenting the kidneys," have been suggested. The bowels must be freely opened by the compound jalap powder. Possibly in some cases pilocarpine hypodermically in doses of from  $\frac{1}{10}$  to  $\frac{1}{4}$  of a grain might be of use.

**Hæmorrhage**, which is sometimes rather profuse, may follow the introduction of a catheter, especially if the stricture be congestive, and the instrument employed small. It generally ceases of itself; but, if it be troublesome, the application of cold will check it.

The **Inflammation** about the urethra and in the testes that occasionally occurs during the treatment of stricture, is best guarded against by not using too large catheters, and by directing the patient to abstain from much exercise during the time of their introduction.

**False Passages** are occasioned by the instrument passing out of the urethra through its coats into the surrounding tissues. They are especially apt to occur in tight bridle-strictures, when a small instrument is being used, more especially if the direction of the constriction be somewhat oblique, so that the point of the sound is thrown against the side of the canal (Fig. 911). The extent and situation of a false passage necessarily vary according to the position of the stricture; and the danger is usually in proportion to its depth. The false passage usually takes a direction downwards and to one side of the urethra. If the stricture be far forward, it may run in the corpus spongiosum; but if it be in the usual situation, it may perforate the lateral lobe of the prostate, or run between this and the rectum, being unable to extend upwards on account of the rigid nature of the structures in this situation. When the false passage merely perforates the corpus spongiosum, running parallel to the urethra, and opening again into the canal, or when, perforating a portion of the prostate, it enters the bladder, it is not necessarily attended with much danger; but when it enters the areolar tissue between the bladder and the rectum, admitting urine into the recto-vesical space and about the neck of the bladder, then the most serious consequences, such as inflammation and abscess, are apt to ensue, and may prove fatal.

At the moment when a false passage is made during the introduction of an instrument, by the Surgeon using too much force or pressing in the wrong direction, he feels the point make a sudden slip, which the plane of the handle shews to be to one side of the urethra. The patient complains of severe pain, and is often conscious of a laceration; there is a grating or rough sensation communicated by the tissues against which the instrument has passed; and though it have entered deeply, it will be found not to have reached the bladder. On the Surgeon introducing his finger into the rectum, he probably feels the point of the instrument in the areolar tissue between the gut and the bladder.

on withdrawing it, it will be found covered with blood, and there will be free hæmorrhage from the urethra.

The Surgeon knows when he has entered an old false passage by the change that takes place in the direction of the instrument, by its not reaching the bladder and by the rough sensation communicated to it, very different from that afforded by the smooth lining of the urethra. The patient is often conscious of the existence and of the entry of the instrument into the false passage, and will warn the Surgeon of it.

If the Surgeon be aware that he has made a false passage, he should, if possible, at the time of the accident pass a catheter into the bladder, and leave it there for a few days until the laceration has healed. If there be an old false passage he must be careful, by keeping the point of the instrument away from it, not to enter it, lest during the introduction of the catheter he raise with the point of the instrument the valvular angle that intervenes between it and the urethra; every time that this is opened up tends to lessen the chance of closure of the aperture, whilst, overlapping the urethra, it interferes with the onward passage of the instrument into the bladder. By withdrawing the instrument and changing its direction, the false passage may often be avoided, and the bladder reached. Should there have been much difficulty in introducing the catheter, the better plan will be to allow it to remain in for two or three days, when the false canal may possibly close.

It has already been stated that, in certain forms of stricture, gradual dilatation does not succeed in effecting a permanent cure. In these cases, five plans of treatment have been recommended: continuous dilatation, electrolysis, forcible dilatation, division by the knife, and excision. These methods will now be described.

2. **Continuous Dilatation** is merely a modification of the preceding mode of treatment, and is useful only in very tight strictures. A small instrument is passed and tied in. In tying the catheter in, care should be taken that it does not lie too far in the bladder. It should be pushed backwards and forwards until the exact point is found at which the eye is inside sufficiently to allow the water to flow, and be fixed at this point. It is best retained by soft thick silk tied round the corona of the glans, or fixed to the body of the penis by a piece of plaster, care of course being taken not to produce strangulation. In from twelve to twenty-four hours, although it may at first have been tightly grasped, the catheter will be found to be quite loose, and urine will escape beside it. It must now be changed for a larger one. In doing this, the fresh instrument should be ready, so that the moment one is removed the other may be introduced. A neglect of this precaution, especially when false passages are present, may seriously increase the difficulty of passing the fresh catheter. By the second day a slight discharge will be found to have been set up from the urethra. The treatment should be continued till the urethra reaches the size of No. 5 or 6, which it will do in a few days at most, after which it is not necessary. The catheter may be closed with a small wooden plug, so that the patient can draw off his own urine, or, better still, an india-rubber tube may be attached so as to drain the bladder. In cases in which a gum-elastic catheter cannot be passed, a small silver one may be tied in, and replaced by a gum-elastic at the first change. When nothing but a filiform whalebone or catgut bougie has been passed, it may still be tied in, as the urine will usually find its way beside it even when it seems at first to be

tightly grasped ; and in twelve hours or a little longer it may, in most cases, be changed for a fine gum-elastic catheter. This plan of treatment is of great use in cases in which considerable difficulty is found in introducing the instrument, but it has the disadvantage of being extremely apt to set up cystitis. If the treatment be continued beyond three days, the urine will almost always be found to be alkaline ; and this is scarcely to be wondered at when we consider the way in which the bladder is, as it were, opened up to the air. The risk of cystitis is much diminished by draining the bladder, for then no urine is left to decompose, and the mere contact of the soft instrument with the walls of the bladder seems to cause but little irritation by itself. In rare cases, sloughing of the urethra may take place at the seat of stricture, leading to perineal abscess. A case of this kind occurred some years ago in University College Hospital.

3. **Electrolysis.**—The cure of a stricture by destroying the fibroid tissue which narrows the urethra, by electrolysis, was introduced by Mallez and Tripiér, more than twenty years ago, but did not find much favour. Its results were uncertain, and in some cases it was followed by perineal abscess and other complications. It has been revived by Newman of New York, Fort of Paris, and has been practised in this country by Bruce Clarke, Edwards and others. The operation consists in passing the negative electrode, which is like an ordinary soft catheter with a metal tip, down to the stricture, and placing the positive, which must have a large moist pad, on some part of the body, as the back. The strength of the current is accurately measured with a galvanometer and should be from  $2\frac{1}{2}$  to 5 milliampères. The electrode is held gently against the stricture, and after a period varying from a few minutes to half an hour, it will be found to have passed through. The operation should give little or no pain. It requires to be repeated two or three times, a larger electrode being used on each occasion. Fort of Paris, who demonstrated his method in this country in 1889, employs a linear electrolyser resembling a Maisonneuve's urethrotome. It consists of a long bougie 2 millimeters in diameter, terminated by a filiform guide. The current is conveyed by a fine wire in the bougie to a blunt triangular blade of platinum which projects from the instrument and rests against the stricture.

Newman, who strongly advocates this treatment, asserts that he has operated on two hundred cases without an accident and without a relapse. It is asserted that the current used in this way does not actually cauterise, but causes chemical decomposition and absorption of the scar tissue. This method of treatment is again on its trial. That it is not more dangerous than other modes of treatment and that by it the canal may be restored to its normal size, seems to be tolerably clearly proved, but better evidence is wanted than has as yet been furnished that it effects a permanent cure without any tendency to a relapse. If it can do this, it stands alone amongst all methods of treating stricture.

4. **Forcible Expansion or Rupture.**—Forcible and rapid dilatation causing the expansion and rupture of the stricture, is a method that, originally practised by Luxmoor, Arnott, and Buchanan of Glasgow, has been revived, and ingeniously modified in detail, by many Surgeons, amongst whom Reybard, Maisonneuve, Perrève, Wakley, Holt, Thompson, and Hill are the most conspicuous. However varied the means by which strictures are thus

treated, the instruments employed may be arranged in three groups: *a.* Those that act as sliding tubes; *b.* Those that expand by a screw mechanism; and *c.* Those that act on the principle of a wedge. It may also be effected by the passage of the conical steel bongs already described, one after another, while the patient is under an anæsthetic, though this method is perhaps more properly included under simple dilatation.

*a. Sliding Tubes* were first employed in the treatment of stricture by Desault at the close of the last century, subsequently by various French Surgeons, and in later years by Hutton of Dublin, and very extensively and successfully by Wakley. The mode of application of these tubes is as follows. A long conductor is introduced through the stricture into the bladder, and over this a catheter, either of gum-elastic or silver, is passed, which in its turn is made to serve as a conductor to a larger one. In Wakley's instrument the conductor, or "urethral guide," consists of a small silver catheter, which, after being passed through the stricture, has a long steel rod screwed into it. Over this a silver tube is passed, which in its turn is made to serve as a conductor; and thus the stricture may be rapidly dilated by passing one tube over another until a full size is reached. The only difficulty in this very ingenious method—which is, however, common to it and every other plan of treating stricture by dilatation—consists in the first introduction of the "urethral guide;" when that has once passed through the stricture, the tubes

Fig. 920.—Thompson's Stricture-Expander.

must follow as a matter of necessity. They cannot possibly go wrong; and, as no laceration of the stricture is effected by the instrument, it appears to be a safe means of employing rapid dilatation.

*b.* The method of forcibly expanding a stricture by the introduction into it of a small two- or four-bladed instrument, fashioned somewhat like a narrow beaked sound, and which, by **Screw-Mechanism** in the handle, admits of being opened out so as to stretch the stricture to an extent corresponding to the distance at which the blades are screwed apart, has many advocates; and various ingenious contrivances have been invented to effect this object. More than half a century ago, Luxmoor attempted it by the use of a four-bladed instrument. Some years later Civiale invented a stricture-expander; and subsequently two-bladed instruments, having this end in view, were introduced into practice by Perrière, Lyon, and Thompson. The accompanying drawing (Fig. 920) is a representation of the instrument used by the last-named Surgeon; it answers the intended purpose admirably, the expansion of the blades being effected by a screw worked by turning the handle. This should be done very slowly, several seconds being allowed to elapse between each turn of the handle, so that the tissue composing the stricture may be gradually stretched, and the canal of the urethra at the seat of stricture dilated beyond the full size, so as to be over-stretched; the extent of dilatation may be carried up to 16 or 18, and is marked on a scale attached to the handle of the instrument. If this

operation be done slowly, little if any bleeding results, and there is no evidence of deep laceration of the wall of the urethra at the strictured spot. A large gum-elastic catheter may then be passed, and the urine drawn off. It is not usually necessary to leave the catheter in the bladder, though there can be no objection to doing this for forty-eight hours, after which the patient may have one passed occasionally in order to maintain the dilatation.

c. The rupture or splitting of the stricture by an instrument acting on the principle of a **Wedge**, was recommended by Reybard, and very extensively employed by Holt. The instrument used by him is represented in the accompanying figure (Fig. 921). It consists of two grooved metallic blades joined at the extremity. Between these a tube is slipped along a wire, which in its descent separates the blades at a considerable angle, and thus splits up the stricture. In this way the contracted part of the urethra is at once enlarged to its normal diameter, so as to admit a full-sized catheter, by which the urine is then drawn off. The introduction of the catheter should be had recourse to at first on alternate days, and afterwards at longer intervals. Holt believes that the effects of the dilatation are entirely confined to the morbid contraction, the healthy portion of the urethra not being injuriously disturbed by the expansion of the instrument.

Berkeley Hill invented a modification of the dilators previously in use

Fig. 921.—Holt's Instrument for Splitting Strictures.

which presents several advantages. He thus describes it: "The instrument consists of a split sound, which equals in calibre a No. 2 or 3 catheter. The halves of the split sound can be separated by passing between them a wedge fixed on a slender stem. The wedge is prevented, by two dovetail grooves at its hinder part, from leaving the sound which acts as a guide during the passage of the wedge down the urethra." "The advantages claimed for this instrument are: simplicity of construction; the central guide of Holt's instrument is not needed, hence the split sound can be passed through narrower strictures. Next and chiefly, diminution of resistance, and consequently the more immediate application of the rupturing force—the wedge—to the impediment to be overcome. The force needed to push Holt's dilator is sometimes very great, and the attempt has been abandoned, or the instrument has broken, even in skilful hands, from this cause. Much of the force is expended on the continuous friction outside the tube along the split sound, and inside along the guide. In the wedge-dilator the friction-surface is reduced to two dovetail grooves, which together do not exceed half an inch. For this, the force required is so small that one hand suffices to overcome the resistance." The instrument can, if required, be adapted to a conducting sound, such as is described afterwards under Internal Urethrotomy.

Another instrument of the same class has been devised by Bigelow (Fig. 922). It consists of a filiform conducting sound, which is first passed. The guiding rod is then screwed into this and passed into the bladder, pushing the conducting sound before it. The cup-shaped cap at the upper end of the guide rests on the glands, while the Surgeon's left hand grasps the body of the penis.

The stricture is then dilated by forcing down the olive-shaped divulsor, which is deeply grooved to run on the guiding rod. Being olive-shaped it passes more easily, as in Hill's dilator, not being grasped by the whole canal.

Forcible dilatation is doubtless a most efficient mode of treating stricture; by it the urethra is immediately restored to its full diameter, and the result which it may take weeks to accomplish by simple dilatation is at once obtained. It is, however, by no means devoid of danger. The urethra is not dilated, it is split, and a longitudinal rent in the mucous membrane is made corresponding to the length of the stricture. The shock produced by so violent a proceeding is often severe, and suppression of urine has followed in several recorded cases. It has also sometimes been followed by urinary abscess, and more rarely by pyæmia. What it gains in rapidity it loses in safety, and

Fig. 922.—Bigelow's Divulsor.

to adopt it as a universal mode of treating strictures would lead to the loss of many lives that might have been saved by more gentle treatment.

5. **Division of the Stricture** may be practised either from *within* the urethra, or from *without*, through the perinæum.

**Internal Urethrotomy.**—The division *from within* may be performed in two ways: either by cutting through the stricture from before backwards, or by passing an instrument through it, and dividing it from behind forwards. The first method is attended with great danger unless the instrument is provided with a guide which ensures that the urethrotome is really in the stricture. On the other hand, the operation of cutting from behind forwards could not, until recently, be performed unless the stricture was capable of admitting a No. 5 at least. The Surgeons to whom we are most indebted for improvements in the instruments employed, are Van Buren, Gouley, and Otis of New York, Maisonneuve of Paris, and Berkeley Hill of London. The objects in view have been, first, to provide a safe and certain guide for a small cutting instrument, and secondly, so far to diminish the size of the instruments as to make them available for strictures not capable of taking more than a No. 1 catheter. Lastly, as it was found that the great mobility of the urethra rendered it difficult in many cases to divide the stricture, a combination of stretching and cutting was introduced by Otis, which greatly facilitates the operation.

The guide to the bladder may be obtained in two ways. A fine whalebone bougie having been passed through the stricture, the urethrotome may be so constructed, by being tunnelled for a short distance at its point, as to slide over this into the bladder. But a better plan is the employment of Maisonneuve's *sonde conductrice*, or conducting sound. This is a very fine gum-elastic bougie, provided with a male screw at the end (Fig. 923 c). This is first passed on till it is judged to be in the bladder. A small catheter corresponding to a No. 1, having a female screw at its extremity, is then screwed on to it and passed onwards, while the conducting sound coils up in the bladder. If the urine flow, it is then certain that the conducting sound has passed in the proper direction. It is now withdrawn again, the conducting sound being left in position. The catheter is now replaced by the urethrotome, which screws in the same way. Berkeley Hill invented a very ingenious urethrotome for cutting from behind forwards, in which a very fine knife can be protruded from an instrument not larger than a No. 2. Another instrument invented by the same Surgeon for cutting from before backwards is represented in Fig. 923. It combines the principles of several others, and has been found to work most successfully. It is thus employed. The conducting sound having been passed and ascertained to be in the bladder, the female screw *b* is applied to the male screw *a*, and the instrument passed through the stricture. The blades *i* and *h*, when closed about equal a No. 3 catheter in size. The point *b* is about equal to a No. 1. The instrument having been passed, the wedge *e*, which contains a knife *d* concealed in a shield *c*, is now inserted between the blades and passed steadily down. The blades thus separated stretch and steady the urethra; and when the stricture is reached, the shield *c* stops against it and prevents further progress. The small concealed knife *d* is then protruded by pressing the button at the top of the instrument, and as soon as the finger is removed it is withdrawn again by the spring *l*. The wedge can then be passed on a little further, and if it hitch again the knife can be again protruded. By this means the urethra is cut only at

Fig. 923.—Berkeley Hill's Dilator and Urethrotome. *a*, Front View; *b*, Side View; *c*, Conducting sound with small male screw at *a*; *b*, female screw; *c*, sheath for concealed knife; *d*, knife protruded; *e*, wedge for separating the blades *h* and *i*; the knife is on the posterior aspect of the wedge; *f*, rod for carrying back the wedge; *g*, rod for protruding the knife; *h*, screw for regulating the distance to which the knife can be protruded; *i*, spring to draw back the knife and keep it concealed, except when protruded by pressing the button opposite *a* and *b*. (In Fig. *a*, the button should have been represented as depressed.)

the points of stricture, and no more wound is made than is absolutely necessary. The incision is always made downwards towards the floor of the urethra. This instrument may be employed in almost any stricture that will admit the conducting sound.

Maisonneuve's urethrotome consists of a fine steel sound, deeply grooved along its upper surface. If necessary, it is guided into the bladder with a *sonde conductrice*. The stricture is divided by means of a triangular blade with a blunt apex and cutting anterior edge, which is passed along the groove in the sound. Teevan modified this instrument by using a guarded knife similar to that of Hill's urethrotome.

After the operation of internal urethrotomy, a full-sized instrument should immediately be passed, but it is not usually necessary to tie it in. Hill recommended that the patient should pass his water in a hot bath during the first day or two after the operation, and that no instrument should, unless required, be introduced for ten days. A full-sized bougie is then passed daily for a few days, and after that every second or third day for three or four weeks. After that, the patient should be taught to pass it for himself, and continue to do so at least once a month for the rest of his life.

The operation of internal urethrotomy is, of course, required only in exceptional cases. These are chiefly resilient or very irritable, and some very tough strictures. In resilient strictures, dilatation fails because the stricture, though admitting of expansion, immediately relapses. In very irritable strictures, the patient cannot bear the pain of dilatation. In some very tough strictures, simple dilatation fails, and then internal urethrotomy or forcible dilatation is required. In all these cases, the division of the stricture from within removes at once all difficulty in treatment; and I have frequently employed this very simple method with the most marked and permanent success. In fact, in strictures of the scrotal or penile portions of the urethra, one or other of the above conditions — resiliency or irritability — commonly prevails, and I have generally found internal urethrotomy the best mode of treatment.

*Result.*—The risk attending the operation is not great, and diminishes as the stricture approaches the orifice of the urethra. It is not, however, free from danger. The accidents that may happen are, perineal abscess, extravasation of urine, hæmorrhage, and orchitis; and in some rare cases it may be followed by pyæmia. If the kidneys be diseased, it may, like any other operation for stricture, give rise to fatal acute interstitial nephritis. Perineal abscess usually results from cutting too deeply, so that the knife completely divides the corpus spongiosum. Such abscesses most frequently form beneath the accelerator urinæ, and burrow forwards, directed by the expansion of that muscle to the root of the penis. They contain a mixture of urine and pus, but it is rare to find general extravasation into the scrotum. Hæmorrhage also results from cutting too freely. In rare cases, after the operation, a permanently bent condition of the penis remains during erection. In University College Hospital, where the operation has been extensively practised, I find from the Reports of the Surgical Registrar that the results are as follows: In 76 cases operated on during a period of five years, there were 4 deaths, one from tuberculous disease of kidneys, lungs, &c., one from pleurisy, one from septicæmia, and one from suppurative nephritis. Perineal abscess occurred in 8 cases; extravasation of urine in 1, and epididymitis in 4. There was

hæmorrhage in 5, and in 2 the patient was left with permanent chordee during erection.

(For the effects produced on the kidneys by splitting strictures and by internal urethrotomy, see Chap. LXV.)

**External Urethrotomy.**—The division of the stricture *from without*, by incision through the perinæum, may be performed by two distinct operations : the one being applicable only to those strictures that are pervious to an instrument ; the other to those which are impermeable. In the first case a grooved staff is passed through the stricture, and the section is made upon this. In the second case, the Surgeon cuts through the stricture, without any guidance except such as his anatomical knowledge may afford.

**Operation for Permeable Stricture.**—The first of these operations, introduced by Syme as *Urethrotomy*, and commonly called *Perineal Section*, is a comparatively simple procedure. The instruments required for its performance are a staff, a No. 8 silver catheter, a pointed scalpel, and a broad director. The staff should vary in size from No. 1 to No. 6, according to the tightness of the stricture ; it should be grooved along its convexity, either the whole of the way, or better, merely for the lower third (Fig. 924). The stem is smooth, and of full size, and joins the lower grooved part by a distinct shoulder, which, being passed down as far as the stricture, forms by its projection a guide to the part of the urethra requiring division. In those cases in which there are false passages, a hollow staff of the same size and shape may advantageously be used ; the flow of urine through it indicating with certainty its passage into the posterior part of the urethra.

Fig. 924.—Syme's Staff for Perineal Section.

**Performance of Perineal Section.**—The operation is performed as follows : The staff having been passed through the stricture until the shoulder rests against it, the patient is placed in the lithotomy position, and the Surgeon, seating himself in front, pushes the scalpel, with the back of the blade downwards, into the mesial line of the perinæum a little above the rectum, and cuts upwards for an inch or more into the raphé. The dissection is carried on very carefully exactly in the median line until the staff is reached, when the knife must be entered into its groove *behind* the stricture, and carried forwards through this. The staff, having been pushed on to ascertain that all is free, must be withdrawn, and a No. 8 catheter introduced, which is to be kept in for forty-eight hours ; it must then be taken out, and at the end of eight or ten days the urethra must be dilated by the introduction every second day of a full-sized silver catheter. Urine escapes for some little time by the perineal incision ; but, as this heals by granulation, the flow of fluid gradually lessens and at last ceases entirely.

The principal points to be attended to in this operation are :—

1. To see that the staff is fairly through the stricture, and to be especially careful in determining this if false passages exist.
2. To cut carefully in the median line ; where, as Syme has observed, a kind of septum exists even in the deeper structures of the perinæum, and where there can be no danger whatever of dividing any artery of magnitude, which might happen if any lateral deviation of the knife took place. The

only vessel, indeed, which is at all endangered, is the artery of the bulb ; and this will of course be avoided by carefully keeping in the raphé.

3. To enter the point of the knife behind the stricture, and to divide that by cutting forwards in the groove of the staff.

4. Much difficulty has occasionally arisen in the introduction of the catheter into the bladder after the division of the stricture. This may be avoided by passing a broad director, with the groove turned up, into the posterior part of the urethra after the stricture has been cut, but before the staff is withdrawn. As the catheter is passed down the canal, its point will be guided by this onwards into the bladder.

Where there are more strictures than one, the division of the deepest is usually alone necessary ; the others may be dilated.

*Result.*—The result of the perineal section, so far as the life of the patient is concerned, is usually satisfactory ; yet cases have not unfrequently occurred in which a fatal termination has been the consequence, and there is every reason to believe that such cases have been more numerous than the advocates of this operation have been willing to admit. Occasionally, an incurable fistula has been left in the perinæum ; and not unfrequently accidents of a grave though not fatal character, such as inflammatory œdema of the scrotum, perineal abscess, &c., have supervened.

The whole value of urethrotomy will at last depend on the liability of the stricture to return after its division ; and this point has not as yet been by any means satisfactorily determined. The operation is now rarely practised, being reserved for cases complicated by urinary fistula or perineal abscess. Its place has been taken by internal urethrotomy in all ordinary cases. Its advocates formerly maintained that it was a permanent cure, but as in all other operations for stricture, the ultimate result depends upon keeping up dilatation of the urethra for some months after the division of the stricture, a catheter of full size being passed once in a week or ten days. If this precaution be neglected, relapse will certainly occur. Against external urethrotomy it has been argued that, like a wound, the incision into the urethra might occasion a cicatrix which would contract, and thus eventually tend still further to lessen the diameter of the canal. But *post-mortem* examination of patients who have died some years after this operation had been performed has shown that the idea is groundless, the cicatrix being linear and scarcely perceptible. In fact, there is a great difference in the result, between cases in which the urethra has been divided transversely and those in which it has been incised longitudinally. In the former, a dense and contractile cicatricial mass is formed ; in the latter, a linear and scarcely perceptible scar.

6. **Excision.**—Complete or partial excision of the stricture, followed in some instances by suture of the divided ends of the urethra, has been practised with some success by Guyon, Keyes, and others. In a considerable number of the recorded cases the stricture has been traumatic in origin. It can only be in very exceptional cases that such treatment is advisable or even practicable. Excision would be available in a case of traumatic stricture in which other treatment had failed or in which an instrument could not be passed, also in some cases of obstinate perineal fistula. The operation consists in making a median incision in the perinæum exposing the urethra at the seat of constriction. The latter, with the indurated tissue around it, is excised either partially

or completely. A catheter is tied into the bladder, and if possible the continuity of the canal is restored by suture.

**Comparison of Methods of Treatment.**—Gradual dilatation, carried on with patience and gentleness,—if need be, on account of the irritability of the urethra or the sensitiveness of the patient, with the help of anæsthetics,—will suffice for the cure of the vast majority of strictures; and it rarely becomes necessary for a Surgeon who combines patience with skill to have recourse to those more severe methods of treatment which have been somewhat unduly extolled and too often unnecessarily practised. The urethra is indeed frequently treated as if it were an inert tube, to which the various procedures of rupture, splitting, forcible dilatation, or incision, could be applied with impunity, rather than a highly sensitive canal, very apt to resent, locally or constitutionally, undue violence applied to it.

But, whilst we fully recognize this important point, and hold with Liston that whenever a catheter can be got through a stricture its cure by dilatation is all but certain in the hands of a skilful Surgeon, yet it is certain that cases do occasionally occur in which simple dilatation fails to effect a cure; the stricture being highly contractile, and not allowing expansion beyond a certain point, or relapsing whenever the dilating means are removed. In other cases, also, the patient suffers so much pain and irritation whenever an instrument is passed that he cannot bear the repeated introductions that are necessary, more particularly if the stricture be complicated with perinæal fistulæ or false passages, which render its cure by dilatation tedious and almost impracticable. In such cases as these the Surgeon, being unable to benefit his patient materially by dilatation, must choose between the employment of palliative means or more active measures.

It appears to me that there are four classes of cases, in which more energetic means than simple dilatation may not only be advantageously employed, but are absolutely required:—

1. *Very old dense cartilaginous strictures*, often of traumatic origin, which admit an instrument with great difficulty, and cannot be dilated beyond a certain point, owing to the conversion of the urethral structures into a dense, cicatricial tissue, which neither admits of expansion nor of absorption by the pressure of instruments; and in which a considerable extent—half an inch or more—of the urethra is involved.

2. The same kind of stricture, complicated with *fistulæ* in the perinæum or scrotum, with perhaps considerable plastic infiltration of these parts. In both these classes, I think that the perinæal section is to be preferred, though with the improved instruments of the present day some of the first class may be successfully treated by internal urethrotomy.

3. *Very tight strictures*, accompanied by *excessive sensitiveness* of the urethra; in which each introduction of the instrument is attended with intense suffering and rigors, so that the patient cannot be induced to submit to a proper course of bougies.

4. *Very elastic*, though perhaps *narrow strictures*, that can be dilated readily enough, even up to the admission of full-sized instruments; but which, when the treatment is discontinued, immediately begin to contract again, so that the patient is never out of the Surgeon's hands, and sees no prospect of cure.

In these last two classes of cases, I am of opinion that internal urethrotomy, or the forcible expansion or rupture of the stricture, is the best method of

treatment ; the perineal section being too severe and dangerous, whilst simple dilatation is too feeble a means of treatment.

**Stricture of the Meatus** is usually the consequence of destruction of tissue by a chancre. It is apt to be extremely tight, and has a great tendency to relapse. A tight stricture is not uncommonly met with also within an inch of the orifice as the consequence of an intra-urethral chancre, and less commonly of gonorrhœa.

These strictures may be treated by *gradual dilatation* by means of short nail-headed styles of graduated sizes, but this is usually tedious and inefficient. *Division* by Civiale's instrument, introduced shut, and cutting as it is withdrawn (Fig. 925), or in the absence of this, by a common probe-pointed bistoury, will be found the only really advantageous treatment. The incision should be made downwards. It is practically free from danger, as rigors and

Fig. 925.—Civiale's Urethrotome for Stricture of the Orifice, modified.

other constitutional disturbance scarcely ever follow operations on the anterior extremity of the urethra.

**Impermeable Stricture.**—In order to perform the perineal section, the stricture must be pervious to a grooved staff, however small this may be ; and this, it might be supposed, would limit materially the cases in which the operation can be performed. But complete obliteration of the urethra cannot take place except as the result of sloughing, usually from injury ; indeed "impermeable" strictures, though frequently spoken of, are very rarely met with. Syme, indeed, denied their existence, and stated that, if urine can escape through a stricture, a bougie can be introduced. A Surgeon may often be foiled in his first attempts to pass an instrument through a very tight stricture. But I believe that, with patience, by attention to constitutional treatment, so as to lessen urethral irritation, and especially by the administration of an anæsthetic, he will usually at last succeed in making an instrument of some kind pass through the very worst strictures. In the first case in which I performed the perineal section, almost all the urine had for twelve years been discharged through fistulæ in the perinæum and scrotum ; and the principal portion escaped through a large hole on the inside of the left thigh, only a few drops occasionally passing out by the lips of the urethra. No instrument had been passed for four years, though repeated attempts had been made by different Surgeons. Failing to introduce a catheter into the bladder, I kept the patient in the Hospital for two or three weeks, attending carefully to his constitutional condition, but without making any further effort. He was then placed under an anæsthetic, when I succeeded in passing No. 1. The urethra was then dilated up to No. 5, beyond which no instrument could be passed, when the perineal section was performed. The patient made an excellent recovery, the fistulæ closing, and the urine being discharged by the natural channel. In another case, persevering attempts had

been made for five years to make an instrument enter the bladder, but without success, the stricture not only being excessively tight, but the urethra acutely sensitive; under chloroform I succeeded in introducing No.  $\frac{1}{2}$  silver catheter into the bladder, and speedily cured the patient.

The influence of *Anæsthetics* in facilitating the passage of instruments through apparently impermeable strictures is very marked. Shortly after the introduction of ether as an anæsthetic agent, Liston was going to cut through a stricture that had resisted all attempts made by his most dexterous hand at introducing an instrument into the bladder; but no sooner was the patient put on the table and rendered insensible, than the No. 8 silver catheter, which had been passed down as far as the stricture, and the point of which was to serve as a guide to the knife, slipped into the bladder, and thus rendered operation unnecessary.

Yet no Surgeon can doubt that cases do occasionally, though rarely, occur, in which, in consequence of extravasation of urine and old inflammatory mischief, the urethra has become so tortuous and narrow, and the perinæum so thickened and indurated, that an instrument cannot be passed through, even though the urine pass out readily. It must be borne in mind that a stricture may be permeable to urine, but impermeable to a catheter, even in the most dexterous hands. It does not follow necessarily that, because a fluid will trickle out of a narrow and tortuous channel, a catheter or solid sound can be passed into it from without. In a case of extravasation of urine following stricture consequent on injury of the perinæum, in which no catheter had been introduced for eight years, it was found after death that, although the urethra had been converted into a mass of cicatricial tissue at the part injured, it was yet permeated by a narrow tortuous passage, through which the urine had escaped.

Hence cases will occasionally occur, in which the perinæal section is not practicable. In the event, therefore, of a stricture being so tight and tortuous that no instrument will pass through it, or where, a portion of the urethra having sloughed away, its canal is obliterated, neither the cure by dilatation nor urethrotomy can be performed, and it may then be necessary to have recourse to incision of the stricture without a guide.

**Operations for Impermeable Stricture.**—In operating for the relief of impermeable stricture various means have been adopted, the chief of which are, 1, opening the urethra behind the stricture; 2, opening the urethra behind the stricture and cutting forwards through the constriction; 3, opening the urethra in front and dividing the stricture from before backwards.

1. **Opening the Urethra behind the Stricture**, or, as it is often called in this country, "Cock's operation," is thus performed: The patient having been prepared as for lithotomy, the operator introduces his left forefinger into the rectum. He then takes a broad sharp-pointed knife, which Cock advised should be double-edged, and passes it towards the apex of the prostate, guiding its course by the finger in the rectum. The knife must be passed at one thrust to the apex of the prostate, and great care must be taken that it keeps accurately to the middle line. The external wound is then enlarged somewhat by moving the knife up and down, till the lower angle reaches to about half an inch from the anus. The knife is then withdrawn and a large probe-pointed director with a handle is passed through the prostatic urethra from the wound,

and along this a female catheter, or an instrument of that shape fitted with rings by which it can be securely tied in, is guided into the bladder. The essential points of the operation are to keep accurately to the middle line and to open the urethra as it emerges from the prostate gland. Should the prostate itself be notched no harm will result. The instrument having been passed as above described is tied in and retained for some days or weeks as may be required. In a very large proportion of cases after the irritation of the passage of urine through the narrow stricture has been removed, a certain degree of relaxation will take place, and a few days after the operation it frequently happens that a catheter will pass through the stricture which was formerly "impermeable." If this does not take place, an effort may subsequently be made by some further operative procedure to open up a way in the natural line of the urethra, and should this fail the patient may pass his urine permanently through the fistulous opening in the perinæum. This can readily be kept open by the occasional passage of a flexible bougie, which must be left *in situ* for a few hours. Cock records cases in which the patient passed his water in this way for twenty years or more. The opening being well in front of the prostate the control over the escape of urine is perfect, and the patient's mode of micturition is assimilated to that of the other sex.

This operation is best adapted to those cases in which the patient is suffering from actual retention at the time the Surgeon is called upon to operate. The objection to it is that it does nothing to relieve the stricture unless this should happen to yield after the irritation of the passage of urine is cut off.

**2. Opening the Urethra behind the Stricture and cutting forwards.**—This operation may be regarded as an extension of the preceding method. It is thus performed: A No. 8 silver catheter is passed down to the stricture; the patient is then tied up as if for lithotomy; and the Surgeon, sitting in front, pushes a bistoury with the back turned towards the rectum into the raphe of the perinæum as far as the apex of the prostate, so as, if possible, to open the dilated urethra *behind* the stricture. He then cuts *forwards* through the stricture on to the point of the catheter, and, having thus opened a passage, endeavours to pass that instrument on into the bladder. This operation, I have no hesitation in saying, is one of the most troublesome in surgery, and I have more than once seen the most skilful operators foiled in their endeavours to accomplish it. The difficulty consists in finding the posterior part of the urethra. When the tissues of the perinæum are hard and gristly from repeated attacks of inflammation and the presence of fistulae, it is a most difficult matter to dissect through such an altered mass and hit the urethra beyond it, and the difficulty is still further increased by the bleeding, which is often very profuse. Moreover, should the Surgeon find the posterior part of the urethra and cut forwards from it to the catheter in the urethra the chances are that his incision will not follow the line of the urethra, and the fistulous track he establishes between the part of the urethra, in front of the stricture and that behind it will almost to a certainty contract, as the wound heals, to such an extent as to leave the patient little better for the operation.

**3. Opening the Urethra in Front of the Stricture and dividing from behind backwards.**—This operation, though difficult of performance in some cases, gives better results than any other. Wheelhouse has invented some ingenious instruments which greatly facilitate its performance.

The operation is thus performed: The patient having been secured in the

lithotomy position, Wheelhouse's staff is passed down to the stricture. The end of this is about the size of a No. 8 catheter; on one side it is flattened and grooved, and on the other it forms a small blunt hook, with which the upper end of the "button-hole" incision in the urethra may be drawn upwards. The staff being passed and held with the grooved side forwards, the Surgeon cuts down upon it by an incision about  $1\frac{1}{2}$  in. long in the median line and opens the urethra just in front of the stricture. The staff is now pushed out of the wound and turned round, so that the small hook is forwards; it is then drawn upwards so as to catch in the upper angle of the opening, and in this way the urethra is put on the stretch and steadied. If the special staff be not at hand the end of a catheter can be cut down on with almost equal ease. The edges of the slit in the urethra are then seized in artery-forceps and held apart so as to expose the interior of the canal, which can be readily recognized by its smooth shining surface. It will often be found to be convenient to pass a silk suture through each side by which the edges may be held apart, as the forceps are rather apt to get in the way. Oozing having been allowed to cease, the aperture leading to the stricture will usually be found without very great difficulty. The chief trouble in many cases arises from the constant trickling of blood from the upper part of the wound. This may be arrested by plugging it with a small sponge, or by the application of water, at a temperature of about  $140^{\circ}$  F., which is usually more efficient than ice. Another difficulty may arise from the urethra having been opened too far above the stricture, under which circumstances the incision must be prolonged downwards. If a false passage have been opened instead of the urethra it is recognized by the absence of the smooth pink mucous membrane. The orifice of the stricture must be sought for with a fine probe. Wheelhouse used a small probe-pointed director. In some cases the small director used in slitting up the canalculus will be found to pass when other instruments have failed. In seeking the true orifice of the stricture every depression must be carefully explored without force. Pressure above the pubes will often cause a slight escape of urine by which the proper orifice may be recognized. When the opening is found and the probe passed, the stricture must be divided along it with a fine knife or tenotome. A small gorget is then passed through the stricture, and along this a full-sized catheter can easily be guided into the bladder. It must be tied in and retained for a few days. The wound may be wiped out with a strong solution of chloride of zinc and afterwards sprinkled with iodoform and filled with iodoform-wool, which may be left undisturbed till the third day, when healthy granulation will usually be found to have commenced. This operation requires care and patience, but it is easier and safer than any other.

In a few rare instances in which failure has attended every other means of passing an instrument through the stricture, suprapubic cystotomy has been performed and a catheter passed from above.

**General Results of the Treatment of Stricture.**—Whether it is or is not possible permanently to cure a stricture, is a question which has been much debated. The advocates of the various modes of treatment, whether forcible dilatation, internal urethrotomy, external urethrotomy, or electrolysis, have often asserted that by the means they adopt a stricture can be really cured, so that the patient is rid of his disease for ever, and need fear no return. The general opinion, however, of those who have studied this question care-

fully, is that, although a patient can be put into a position in which his stricture need never be a source of danger to him if he occasionally passes an instrument, he cannot be really cured—that is to say, by no means of treatment can a strictured urethra be restored to its normal condition. Every patient, therefore, who has once suffered from a definite organic stricture, should continue for the rest of his life to pass a full-sized instrument not less often than once a month; otherwise, gradual contraction is almost certain to take place, and the whole treatment will have to be commenced again.

#### COMPLICATIONS AND RESULTS OF STRICTURE.

**Retention of Urine** has already been several times described as arising from different causes. Thus, in boys, it arises from the impaction of a calculus in the urethra; in girls it is usually hysterical; in old men it is almost invariably the consequence of atony of the bladder or enlarged prostate, alone or combined. In those of middle age, stricture of the urethra is the cause in the vast majority of cases. Retention of urine has a tendency to occur in all tight strictures from the gradual and progressive contraction of the canal. It most usually, however, takes place in consequence of a congestive and spasmodic condition being superadded to the organic constriction. It commonly happens that a patient having a moderately tight organic stricture commits an excess, or becomes exposed to cold and wet, and thus gets such a congested condition superadded, that the urine will not pass at all, or only in such small quantity, and with so much pain and straining, that the bladder cannot be completely emptied. In these cases the retention always eventually becomes complete: the bladder speedily fills, and rises above the pubes; there is much distress and constitutional disturbance; and, if relief be not afforded, the distended portion of the urethra behind the stricture will ultimately give way, and extravasation of urine ensue. In these circumstances it becomes imperatively necessary to empty the patient's bladder as speedily as possible.

The **Treatment** varies with the severity of the symptoms and irritability of the patient. If the retention have not continued very long, and if the patient be not very irritable, an endeavour may be made at once to give relief by passing a small catheter into the bladder. In this the Surgeon may often succeed more readily than might have been expected, the stricture frequently yielding before an instrument more easily when there is retention, than when this condition does not exist. Even if the catheter do not enter the bladder, its point or that of a catgut bougie merely being introduced well into the stricture, it will generally happen, as Brodie has pointed out, that, on the withdrawal of the instrument, the urine will follow in a full stream; but if a sufficiently small catheter be used (in many cases not larger than No. 1 is admissible), the instrument may usually be made fairly to enter the bladder. If the patient be very irritable it is better, before attempting the introduction of the instrument, to give him an enema of a drachm of laudanum in about two ounces of starch, and to put him in a warm hip-bath, when perhaps he may pass water, but if he does not the introduction of the catheter may be attempted, and will generally succeed. Should it still fail, the effect of an anæsthetic should be tried, when it almost invariably may be made to pass without the employment of any great or dangerous degree of force. There are no cases in surgery in which anæsthesia is of more value than in these:

under its influence it is seldom, indeed, that the catheter will not pass. If a very small catheter only can be introduced, it often happens that the eye is blocked by a clot of blood, and the Surgeon may think he has not entered the bladder. This difficulty is overcome by applying an aspirator to the catheter, which will immediately clear it if it be really in the bladder. It is wiser, therefore, always to have that instrument at hand when attempting to relieve a case of retention of urine. After the catheter has been passed into the bladder it should be left there, being tied in by means of tapes passing from its rings under the patient's thighs, to a bandage that is passed round his waist. A free purge may be administered on the following day, and the patient should be confined to bed. The catheter will be found to be loosened at the end of forty-eight hours, when it should be withdrawn, and the cure by dilatation proceeded with in the usual way.

There are two conditions which in retention of urine may eventually call for operative interference. The first is the necessity for very frequent introduction of the catheter, owing to an irritable state of the bladder. In these cases, it may eventually be thought safer to puncture the bladder and to establish a direct opening either through the perinæum or above the pubes, rather than subject the patient to the constant terror of repeated catheterism, which will end by exhausting him. Every act of catheterism inflicts a certain shock to the system, greater in some, less in others; and if this have to be repeated every three or four hours, less danger will probably result from puncture of the bladder than from the frequent use of the instrument. In these cases the patient cannot allow it to be tied in for the same reason, that of extreme irritability, which necessitates its repeated introduction.

The second condition that calls for operation is a different one, viz. the necessity of relieving retention of urine. For if the Surgeon be unable to introduce a catheter in the ordinary way through the stricture, relief must be given to the over-distended bladder in some other way, lest it or the urethra burst, and extravasation of urine occur. The bladder may be emptied in three ways: 1. By Aspiration; 2. By making an Opening into the Urethra behind and through the Stricture; and, 3. By Puncturing the Bladder above the Pubes.

Forceible catheterism, that is to say, passing a small metal instrument down to the stricture and attempting to drive it on by main force into the bladder, is an unsurgical and dangerous procedure, which should under no circumstances be adopted. Puncture of the bladder through the rectum is also an available method of treatment in these cases which had better be abandoned. It is no doubt easy of performance, but it is attended with obvious inconveniences and not a few dangers. Among the latter may be mentioned septic cystitis, urinary infiltration, pelvic abscess and peritonitis. I also had a case under my care in 1859 in which a widespread emphysematous condition extending to the nates and thighs was produced by the escape of rectal flatus into the areolar tissue after the cannula was removed. The cannula had been in position for five days, and the patient died on the third day after its removal.

1. The use of the **Aspirator** is on the whole the simplest and safest means of affording immediate relief in a case of retention of urine due to stricture of the urethra, in which the Surgeon altogether fails to pass an instrument into the bladder. The perforating trochar of the aspirator should be passed

directly into the bladder above the pubes. The operation is a simple one, and with a little care is perfectly safe. The chief points are not to thrust the needle too deeply, to direct it well behind the pubes, and gently to withdraw it before the whole of the urine has escaped, so as to prevent the emptied bladder from collapsing upon and being wounded by its point (see p. 757, Vol. II.). After relief has thus been afforded the patient should be confined to bed, and means be taken to subdue the congestion and spasm which, complicating the organic stricture, have probably been largely instrumental in causing the attack of retention. A morphia suppository should be introduced into the rectum and a brisk saline aperient given. After a few hours another attempt may be made to pass a catheter; if this fail and the patient be still unable to relieve himself, aspiration may be repeated twice or even three times when the bladder has refilled.

It must be clearly understood that aspiration is undertaken merely with the object of affording temporary relief to the distended bladder, and thus allowing time for further attempts at catheterization. If the latter still prove unsuccessful, even after aspiration has been performed three or four times, the case must be treated as one of impermeable stricture, Wheelhouse's operation being as a rule the best method to adopt (p. 1200).

2. **Tapping the Bladder above the Pubes**, in cases of retention from stricture, is occasionally practised. It differs essentially from aspiration in this respect, that a cannula, or a soft catheter introduced through it, is left in the bladder for drainage, whereas in aspiration the distension of the bladder is relieved and the needle at once removed. This operation, which has been discussed at p. 1152, is undoubtedly easy of performance, and sufficiently safe, though not free from the danger of infiltration of urine into the tissues around the puncture, and of the inconvenience of a fistulous opening being left. The only advantage which this treatment presents is that it is a simple method of giving perfect rest to the urethra, and thus allowing its condition to become more favourable for the passage of an instrument into the bladder. As soon as this can be done the stricture is dilated or divided, and after the introduction of a full-sized catheter *per urethram* the cannula above the pubes is removed and the opening allowed to close.

3. **Opening the Urethra behind the Stricture**.—This operation is rarely required as an immediate treatment in cases of retention from stricture. There is, however, one class of cases in which Cock's operation should certainly be performed—those in which retention is complicated by commencing extravasation of urine or perineal abscess. If there be a urinary tender swelling in the perinæum it may almost certainly be concluded that suppuration has occurred around the urethra behind the stricture or that the extravasation of a few drops of urine has taken place. Under these circumstances the incision into the dilated urethra behind the stricture will not only relieve the patient from the distress and danger of the retention, but will also afford a free exit for any extravasated matters. The mode of performing the operation has already been sufficiently described at p. 1200.

**Extravasation of Urine** is one of the most dangerous and fatal results of unrelieved retention. This accident may occur in consequence of rupture of the dilated portion of the urethra which is immediately behind the stricture. It then takes place suddenly, the patient, while suffering from retention, feeling something give way during a violent effort at micturition, and at the same

time there is a sense of some relief, as if he were emptying the bladder, followed by a hot and burning throbbing pain in the perinæum.

In other cases the process is more gradual, and is preceded by the formation of an abscess in the immediate neighbourhood of the urethra, most probably commencing in one of the lacunæ or glands opening into it. The abscess bursts into the urethra, and its cavity is subsequently distended with urine at each act of micturition; finally its walls give way, and general extravasation takes place. In some cases it is probable that the abscess arises from a very limited extravasation of urine into the tissues in the immediate neighbourhood of the urethra, consequent upon ulceration of the mucous membrane behind the stricture. In these cases the signs of perinæal abscess, presently to be described, precede the extravasation often for some days.

The part of the urethra that gives way is almost invariably the membranous portion of the canal, just between the layers of the triangular ligament, where it is weak, being least supported by surrounding structures, and usually most dilated and attenuated by the pressure to which it has been subjected. The extravasated urine afterwards finds its way through the inferior layer of the triangular ligament, where it is perforated by the urethra, and so beneath the deep layer of the superficial fascia of the perinæum, by which its course is afterwards directed. The fascia is firmly attached across the perinæum to the free border of the triangular ligament and, along each side, to the rami of the ischium and pubes, as far upwards as the pubic spine, from which point its attachments are continued outwards along Poupart's ligament to the crest of the ilium. The extravasated urine, therefore, uniformly takes a course forward into the perinæum and scrotum, and upwards upon the external organs of generation, the groins, and the anterior abdominal wall; so that it ascends contrary to gravity rather than soaks back into the more dependent parts of the body, as it would do, were it not for the particular connexions of the fascia that have just been alluded to. I have, however, known the superficial fascia to give way, and the urine, then gravitating backward, to give rise to extensive sloughing in the ischio-rectal fossæ and about the nates, denuding the rectum.

The **Local Effects of Extravasated Urine** that has become acrid, decomposed, and concentrated by long retention, are most deleterious upon the tissues with which it comes into contact. It acts as a most intense irritant on all that it touches. The vitality of whatever portion of areolar tissue it infiltrates is quickly destroyed; the tissue becoming converted into a kind of putrid stringy slough, intermixed with and soddened by a quantity of fetid dark-coloured acrid pus and urine. The ravages of extravasated urine are often extensive; the urethra giving way suddenly behind the stricture, the fluid is driven with all the force of the over-distended bladder into the perinæum, and thence rapidly finds its way through the scrotum upwards. Rapid swelling and infiltration, partly urinous, partly inflammatory, take place in the scrotum and penis; these parts become enormously distended, red, and oedematous. The skin is speedily affected, becoming of a dusky-red or purple colour, and then falling into a state of gangrene, sometimes with emphysema. In this way the testes may become denuded and the cords exposed. It is remarkable, however, if the patient survive these destructive effects, with what rapidity repair goes on in this region. It is seldom that infiltration extends higher than the

groins, or the anterior portion of the abdominal wall ; but it may reach the costal cartilages before proving fatal.

The **Constitutional Disturbance** is always very great. At first there is high fever, with a rapid full pulse ; but the symptoms speedily assume the form met with in acute septic poisoning. The tongue becomes brown and dry ; there may be vomiting ; the pulse becomes small and very rapid ; muttering delirium sets in, ending in insensibility, and death quickly follows.

The *Treatment* must be active and immediate, and consists in making a free exit for the urine infiltrating the tissues, and preventing further extravasation by establishing free drainage of the bladder. As soon as any pain and throbbing, with diffused swelling, occur in the perinæum, with redness and œdema of the scrotum, a deep median incision should be made so as, if possible, to open the dilated urethra behind the stricture. The patient having been placed in the position for lithotomy, the Surgeon should introduce his left index-finger into the rectum, so that the gut may not be wounded, and then pushing a long sharp-pointed bistoury deeply in the raphe of the perinæum, cut upward to a sufficient extent into the extravasation, and in the direction of the urethra. A catheter should then, if possible, be introduced, secured in the bladder, and left unplugged, with an india-rubber tube attached ; in this way no further extravasation can occur, an outlet will be afforded to matters already effused, and the urine will escape by the aperture thus made. Should the case not be seen until extravasation has spread widely, a free incision should be made not only into the perinæum, extending into the urethra, but also into the scrotum on each side of the septum, into the penis, and wherever else swelling is observed. The sole chance of safety for the patient is in making these free incisions, through which the parts may, to a certain extent, empty themselves. However extensive the infiltration and serious the mischief may be, we need not despair of the patient if a free outlet can be obtained for the acrid and putrescent urine ; and in order to secure this, the infiltration must be followed by incisions as high as it extends. The parts must be covered with some warm and moist antiseptic dressing, the best being boric acid lint moistened with warm boric acid lotion, and at the same time they should be well dusted with iodoform. If this be not at hand the surface may be greased with carbolic oil (1 in 10), or terebene and oil and fomentations made of oakum wrung out of boiling water may be applied. These applications are cleaner than poultices, and should always be preferred. The patient will often experience great relief from frequent hot hip-baths, Condy's fluid or boric acid being added to the water. In this way the parts can be most thoroughly cleaned without pain to the patient.

If the patient survive the immediate impression upon the system produced by the gangrene and the urinary infiltration, he must be prepared to go through a severe trial to his constitutional powers, in the separation of the sloughs, the profuse discharge, and other sources of irritation that are set up. During this period he will require abundant support—the brandy-and-egg mixture, ammonia and bark, with any nourishment that he can take ; and much attention should be paid to the removal of the sloughs, to providing a ready outlet for discharges, and to keeping the patient as clean and as free from all local irritation as possible.

As soon as possible the stricture must be dealt with by one of the means already described, and thus the fistula in the perinæum allowed to heal.

**Perineal Abscess.**—By perineal abscess is meant a collection of pus in the perineum situated under the deep layer of the superficial fascia of this region. It is the confinement of the pus by the fascia which gives these abscesses their special character. Owing to the attachments of the deep fascia which have just been described, the pus formed in connexion with the urethra is shut off from the ischio-rectal fossa, just as extravasated urine is. If the abscess be left unrelieved, it may burrow widely around the bulb and along the urethra before it reaches the surface by perforating the fascia. It is very important, therefore, that such abscesses should be opened early.

The chief forms of perineal abscess met with are the following :—

1. **Abscesses arising from Suppuration in a Lacuna or Follicular Gland.**—These have already been described as an occasional complication of gonorrhœa. They are met with also in stricture. They may point slowly towards the surface, without actually communicating with the urethral canal. In other cases they open into the urethra, and then run the same course as abscesses commencing from the canal.

2. **Abscesses commencing from Ulceration in the Urethra behind a Stricture.**—These arise in the dilated pouch behind a tight stricture. As before stated, the mucous membrane at this part is thickened and opaque, and often pigmented, showing evidence of chronic inflammation. The openings of the ducts are dilated, sometimes giving the whole surface a reticulated appearance. The ulceration commences in one of the hollows thus formed. The inflammatory consolidation of the surrounding tissues prevents general extravasation ; but the pressure during micturition and the constant presence of retained urine causes gradual extension of the cavity till a distinct abscess is formed discharging imperfectly into the urethra. Such an abscess slowly extends till it reaches the surface. It then bursts, its cavity contracts to a narrow channel, and thus a urinary fistula is formed. At any period before it bursts superficially, its wall may be ruptured during a violent effort at micturition, and diffuse extravasation of urine may result.

3. **Abscesses from Injuries by Instruments.**—These occasionally arise from false passages made with a catheter or bougie ; they may also follow forcible dilatation or internal urethrotomy. More rarely they result from inflammation and ulceration of the mucous membrane around an instrument tied into a tight stricture. These abscesses usually form rapidly. If resulting from a false passage behind a tight stricture, they may lead to extravasation of urine ; but under other circumstances, as there is a free passage through the urethra, this is not likely to occur. If the injury is in the bulbous or spongy portion, the pus may burrow forwards along the urethra under the accelerator urinæ, and appear at the root of the penis in front of the scrotum.

4. **Suppuration of Cowper's Gland** is an occasional cause of a perineal abscess. It may occur from the irritation of a stricture, but far more commonly it is met with during the acute stage of gonorrhœa. The gland can at first be felt as a tender knot on one side of the middle line near the bulb. This gradually increases and becomes more tender, and at last fluctuation is felt. This form of abscess can be recognized, if seen early, by its situation, and by the fact that it is distinctly on one side of the middle line. At a later period it may burrow widely round the bulb and in the perineum, so that its exact origin cannot be determined. It usually causes some difficulty in micturition.

5. **Prostatic Abscesses** may, as before stated (p. 1138), occasionally point in the perinæum.

It will be seen that there are two distinct classes of perinæal abscesses: those that communicate with the urethra, and those that do not. The former usually end in urinary fistula.

The **Characters of a Perinæal Abscess** are those of a hard, rounded, elongated or oviform mass, situated in front of the anus, extending along the urethra, or perhaps occupying to some extent one side of the perinæum. Fluctuation is not to be felt so long as the pus is bound down by the superficial fascia; when it bursts beyond its limits, then that sign may be met with. But so long as it is under the fascia the abscess will be found to be surrounded by so dense a mass of indurated tissue, and so tightly bound down, that fluctuation, or even elasticity, is not appreciable by the most practised finger.

**Treatment.**—The use of local sedatives, fomentations, and poultices is of no avail in these cases. When once pus has formed in this situation it must be freely evacuated. No good can possibly come of delay, and every possible harm may result from the infiltration of pus among the important tissues of this region. The Surgeon must not wait for fluctuation, but when once the hard mass has fully formed must make a free incision into it. For this purpose he must keep in the mesial line, or as close to it as possible; for in all perinæal incisions "*medio tulissimus*" must be his motto.

**Urinary Fistulæ** commonly form in the perinæum and scrotum, as the result of abscess in these regions communicating with the urethra; occasionally, however, they are met with in other situations, as in the groin, the anterior abdominal wall, or the inside of the thigh. They usually communicate with the membranous portion of the urethra, but occasionally occur anterior to this. In number they vary considerably; when occurring in the scrotal and penile portions of the urethra, they are usually single; but when in the perinæum, they are often rather numerous, several apertures being occasionally met with about the perinæum, scrotum, and nates. In one case Civiale found as many as fifty-two. Their size also differs considerably; some admitting only the finest probe, while others are large clowæ. In a case under my care, the patient had a tunnel of this kind in the groin that would readily admit three fingers. They are usually tortuous, elongated, and narrow; sometimes constricted externally and more widely dilated behind. The surrounding parts are greatly condensed; the whole of the scrotum and penis is enormously enlarged, indurated, and almost cartilaginous in structure. The urine may escape almost entirely through the fistulæ, scarcely any being discharged through the urethral orifice; or there may be but a slight exudation from the fistulous openings.

The **Treatment of Urinary Fistula** varies according as it is complicated with stricture, and as it is situated in the anterior or the posterior part of the canal.

If there be a stricture, this, as the cause of the fistula, must be treated either by dilatation or by the perinæal section. If the stricture be not very tight and hard, dilatation commonly succeeds; the instrument being introduced every second or third day, until the urethra is dilated to its normal size, when the fistulous tracks will in most cases close. In some instances, however, the frequent introduction and withdrawal of the catheter is a source of irritation, and then it had better be left in. When this practice is

adopted, a moderate-sized elastic catheter should be used. If this be too small, the urine will flow between it and the sides of the urethra, and thus escape through the fistulæ; if too large, it stretches the urethral orifice of the fistula injuriously.

If the stricture be very tough and irritable, the better plan is to perform urethrotomy at once. In the majority of instances, internal urethrotomy appears to me to be the safest and simplest procedure, and I have very advantageously practised it in such cases. But if the fistulæ be very numerous, so as to riddle the perinæum and scrotum in all directions, the better plan is to perform perinæal section. In this way we not only divide the stricture, and thus at once remove all obstruction, but give a free exit to the urine, which, instead of escaping by narrow and sinuous passages, finds its way out readily through the new aperture that has been made, and this will eventually granulate and heal by the second intention.

The fistulæ, especially if small and recent, will sometimes heal kindly enough after the removal of the obstruction; but if extensive, old, and cartilaginous, they are of course little disposed to repair; and although the cause that in the first instance gave rise to them may be removed, yet they constitute an independent affection which requires special treatment.

The special treatment for urinary fistula must vary according to the size of the track, but more particularly with regard to the part of the urethra with which it communicates—whether it be a *Perinæal*, a *Scrotal*, or a *Penile* fistula. But in all cases, and wherever it be situated, there is one most important point to be attended to, viz. never to let the fistula be disturbed or irritated by the passage of urine over or through it, or it will never heal. Hence the urine must always be drawn off with the catheter, which the patient should be taught to pass for himself.

If the fistula be *Perinæal*, and of small size, a probe coated with melted nitrate of silver, or a wire made red-hot in the ordinary way, or by the galvanic current, and passed down it occasionally, may cause its contraction. If the fistula be single and large, its edges should be freely rubbed with nitrate of silver, or deeply pared and brought together by sutures, after which the urine should be drawn off, whenever required, by a catheter. If the fistulæ be large and numerous, it will be better to pass a grooved director down the principal ones, and slit them up so as to throw the several sinuses into one.

When the fistula is *Scrotal*, it often requires to be laid open, and to be made to granulate from the bottom, when it may be found to communicate with a large sloughy and ill-conditioned cavity in this situation.

When *Penile*, the fistula is usually much more troublesome to heal; its edges are thin, and the track is short and shallow. **Urethroplasty** may in such cases be practised with advantage. Operations of this kind require for their success very careful management and minute attention to detail; they very commonly fail in consequence of a small quantity of urine or of mucus escaping through the wound, and thus interfering with union of its lips.

In order to prevent this accident, which is fatal to the success of the operation, the urine must be drawn off with a catheter every third or fourth hour. Should this, however, not be practicable, a full-sized gum-catheter should be tied into the bladder, and the urine drained away through an india-rubber tube attached to it.

Urethroplastic operations may be varied according to the seat and extent of the fistulous opening. If the fistula be in the *perineum*, the parts around being thickened and indurated, its closure may often be induced by freely and deeply paring the edges, and then bringing them together with deep silver wire sutures.

When the fistula is *scrotal*, the edges should be freely pared, and the parts around widely dissected up so as to form large and thick flaps of cellulocutaneous tissue, which may be brought and held together by metallic sutures. In this way, if union be not obtained throughout the whole length of the fistula, it may be to a partial extent; and, after a time, a second or a third operation will complete the cure.

When the fistula is *penile*, the difficulties in effecting closure become immensely increased. This is owing to the thinness of the integumental structures and the absence of subcutaneous areolar tissue in this region, so

Fig. 927.—Urethroplasty.  
Nélaton's Operation: First Method.

Fig. 928.—Urethroplasty.  
Nélaton's Operation: Second Method.

that there is not sufficient thickness of the parts for ready plastic union. In these cases, the Surgeon has a choice of four operations:—

1. Nélaton has recommended the following procedure: The edges of the fistula having been pared, the skin around, to the extent of about an inch, should be dissected up subcutaneously through an opening made below the fistula, the edges of which must then be brought together by a few points of suture. The displacement of the skin covers in the aperture in the urethra and causes granulations to spring up, by which the fistula is closed (Fig. 927).

2. The edges of the fistula having been pared and the skin separated widely, lateral incisions may be made so as to take off all tension, and a strip of india-rubber may then be passed underneath the flaps of skin, in order to prevent contact with urine from disturbing the adhesions (Fig. 928).

3. Ricord, recognizing the fact that the occasional intrusion of a drop of

urine between the freshened edges of the integuments brought together to close the fistula is the most common cause of failure of union, recommended that, in those cases in which a perineal or a scrotal fistula happens to co-exist with a penile one, a catheter should be passed through the former into the bladder and left there during the whole of the operative procedures that are adopted for the closure of the penile fistula. Should no fistula exist in the perineum, he proposed to puncture the bladder, and to keep it emptied in this way until the penile fistula has been closed by one of the preceding operations, and then to allow the opening to close spontaneously; or, if it were situated in the perineum, to adopt surgical means for its occlusion.

4. Le Gros Clark successfully practised the following operation: Having pared the edges of the fistula, he made a transverse cut through the integuments of the penis, about an inch in length, above and below it. He then dissected up the flaps of skin so bounded, and brought them together by means of clamps or the quilled suture. By this operation a wide raw surface from each side is brought into contact, instead of a mere raw edge of cut

Fig. 929. — Urethroplasty.  
Clark's Operation: First Stage.

Fig. 930. — Urethroplasty.  
Clark's Operation: Second Stage.

integument, and there is consequently a greater chance of successful union resulting (Figs. 929, 930).

In all operations of this kind union will be promoted by keeping the part constantly bathed with a concentrated cold solution of boric acid. In this way decomposition of any mucus or urine that may accidentally find its way to the wound is prevented, and at the same time the lotion is so unirritating that it does not interfere with union. The lotion is best applied by means of a piece of boric acid lint, which must be frequently wetted and changed. If the urine can be efficiently kept from the wound, a dry dressing of iodoform or salicylic wool will be found the best.

**Stricture of the Female Urethra** is rare. When it occurs, it is usually near the external orifice, and is most commonly the result of gonorrhœa, injury during labour, or syphilis. The symptoms are the ordinary ones of irritability of the bladder, frequent desire to micturate, and some difficulty or delay in doing so.

The *Treatment* consists in the dilatation of the orifice by means of Hegar's dilators.

## URINARY VAGINAL FISTULÆ.

Fistulous communications between the urinary passages and the vagina commonly arise from sloughing produced by long-continued pressure upon the anterior vaginal wall during labour. They may also occur from malignant disease.

**Varieties.**—Urinary vaginal fistulæ are mainly of two kinds: *Vesico-Vaginal* and *Urethro-Vaginal*.

**Vesico-vaginal fistulæ** are the more common; they are usually situated high up in the vagina, communicating with the base of the bladder. They may be very minute or may form a large gaping orifice.

**Urethro-vaginal fistulæ**, occurring between the urethra and the vagina, are usually of small size, and linear.

**Results.**—The existence of a urinary fistula is always a source of the greatest discomfort to the patient. The dribbling of urine, usually continuous but occasionally intermittent, when the opening is near the fundus of the bladder, gives rise to irritation and excoriation about the external parts, and causes a penetrating ammoniacal odour to hang about the patient. The precise seat and extent of the opening can be determined in the case of large fistulæ by digital examination, combined with the passage of a sound into the bladder. In the case of small perforations or those high up, careful examination should be made with Sims's duck-bill speculum and retractors, the patient being placed in the semiprone or genu-pectoral position. It is often useful to draw down and fix the cervix during the examination. In doubtful cases the injection of milk into the bladder will determine the presence or absence of a fistula.

**Treatment.**—When the fistula is recent, very small, and especially if urethro-vaginal, it may be closed in a few cases by touching it with the

Figs. 931 and 932. — Knives for Paring the Edges in Vesico-Vaginal Fistula.

galvano-cantery. When it is large, however, its cure can be accomplished only by paring the edges and bringing them together with sutures. Before the operation the bowels should be freely opened by castor-oil and by an enema. It is of the greatest importance that the field of operation should be properly exposed and well illuminated, and for this purpose preliminary dilatation of the vagina is often required. A large but short Fergusson speculum is a useful addition to the duck-bill specula and retractors usually employed. The patient may be placed in the dorsal, lateral prone, or genu-pectoral position, whichever is the most convenient. The edges of the aperture are now to be freely pared. This is best done by seizing them with a hook-forceps or a double hook, and dissecting off the vaginal mucous membrane to the extent of about a quarter of an inch all round, by means of a fine small scalpel or angularly

set knife (Figs. 931 and 932). Care should be taken that the angles are well freed from cicatricial tissue, and that the vesical mucous membrane be not wounded. When the fistula is near the cervix it may be advantageous to incise the anterior lip or even to excise a wedge-shaped portion, so as to give free access to the fistulous opening. After the edges have been freely pared they are to be brought together with silver-wire sutures, passed by means of a hollow needle (Fig. 933), or by fine flat Hagedorn's needles. Silver wire or fine and strong silk is the best material for the sutures. The needle should be introduced about  $\frac{1}{4}$  to  $\frac{1}{2}$  an inch from the freshened edge, and brought out

Fig. 933.—Hollow Suture Needle.

through the corresponding point on the opposite side without transfixing the vesical mucous membrane. Between the deep sutures superficial ones should be placed so as accurately to approximate the surfaces: it is best to tighten the superficial sutures first and then the deep ones. Whenever possible the edges of the fistula should be brought together transversely to the long axis of the vagina. Trendelenburg and others have sutured vesico-vaginal fistulae through a suprapubic opening into the bladder, but it is probable that this method will only be required in very few and exceptional cases.

**After-treatment.**—The vagina after the operation is washed out with 1 in 2000 perchloride lotion, and iodoform dusted in the wound. Iodoform gauze is then lightly packed into the vagina, to be removed together with the stitches about the eighth day.

Sims's retention catheter (Fig. 934) may be introduced into the bladder for the first 48 hours; after this a catheter must be passed every four hours; catheterization should be continued until two to three days after the stitches have been removed. The bowels should be kept closed for the first three days; after this they may be opened with castor-oil and kept open every day with medicine if necessary.

Fig. 934.—Sims's Catheter.

#### TUMOURS OF THE URETHRA.

**Polypi** of the male urethra are rare, if we exclude the small polypoid masses of granulation tissue which are sometimes detected with the endoscope in cases of chronic gleet (p. 1159). A small granular florid mass is sometimes met with just within the orifice of the canal. It should be snipped off with a fine pair of curved scissors.

into the bladder. The nature of the disease was detected when perineal section was performed ; a ragged cavity being opened the dense tissue around which presented the typical naked eye and microscopic characters of squamous carcinoma. The patient left the hospital at his own wish three months later and was not heard of again. In Mikulicz's case the disease was removed together with the whole penis and its crura, but recurrence occurred in four months.

is of very rare occurrence. I have seen only one instance of it. Case of a man aged 22, in whom the penis and scrotum were perfect but not larger than the organs of an infant a few months old. Testes could be felt, but there was some thickened structure in which felt like an undeveloped testis. The prepuce was long. The little hair on the pubes. This person had sexual desires, and, in fact engaged to be married. He told me that he had erections, which became about an inch or an inch and a half long, and that there was a seminal emission of a glairy fluid. He was fair, fresh-coloured, fat, and had smooth rounded limbs, more like those of a stout young man. His voice was weak and feminine in tone. He led a sedentary indoor life, but said that he was strong and capable of physical exertion.

#### CONGENITAL MALFORMATIONS.

**Congenital Absence of the Penis** has been recorded in a few instances; it may be associated with other abnormalities. Double penis is a pathological curiosity. In three cases, one of which was recorded in this country by Ernest Hart, the malformation was associated with the presence of a third lower limb attached in front of the anus; urine came from each penis, and the scrotum also was double.

**Adhesion of Penis to Scrotum.**—I have once met with the condition in which the penis is tied down to the scrotum, so as to lie in between the testes. In this case the raphe of the scrotum appeared continued in a narrow rather firm band upwards to the under surface of the penis so that this organ was always bent downwards. The patient passed his urine downwards, apparently from the under surface of the penis.

aperture forms a narrow slit, wider behind than before, at the anterior extremity of which is a small eminence representing the rudimentary penis or clitoris. In the female the uro-genital aperture remains unclosed and the external folds of integument forming its lateral boundaries enlarge, forming the labia majora which cover the vascular bulbs corresponding to the corpus spongiosum of the male. These remain separate and distinct, but a small isolated portion becomes united in the middle line, forming the glans of the clitoris. In the male the two sides of the uro-genital aperture unite, forming the scrotum, and the bulbous and spongy portions of the urethra. At the same time the small eminence, which in the female becomes the clitoris, develops into the penis. The vascular bulbs, which in the female remain separate, unite in the male, forming the bulb of the corpus spongiosum. In the female no corpus spongiosum exists in the clitoris, the glans being an isolated nodule of erectile tissue. In the male the erectile tissue is continuous around the urethra from the bulb forwards.

Hypospadias consists in an arrest of the union along the middle line, and in proportion to the degree of the malformation the male organs come more closely to resemble the female in appearance. Hypospadias appears in three degrees. In the simplest form the glans is cleft along its under surface, the prepuce also showing a corresponding gap. In the second degree the corpora cavernosa and glans are well developed, but the urethra is cleft to the root of the penis, and thus resembles a large clitoris. The under surface shows a furrow in the line of the urethra, usually covered by a moist mucous membrane. Between the glans penis and the point at which the urethra terminates a firm dense band of fibrous tissue is often present, somewhat resembling in hardness and tension the cicatrix of a burn. In these cases when erection takes place the organ assumes a crescentic shape, with the convexity upwards, the tense hard cord that has just been mentioned stretching across its are like the string of a bow, thus rendering connexion impossible, and the sufferer practically impotent. The third and most extreme form of hypospadias is when the scrotum also is cleft and the urethra opens in the perinæum. This is usually accompanied by imperfect development of the penis, and by retained testicles. It is this malformation that has erroneously been considered to be an example of hermaphroditism. The cleft empty scrotum resembles the labia of the female, and the diminutive penis may readily be taken for a large clitoris.

Hypospadias affects only the parts in front of the membranous portion of the urethra, and consequently never leads to incontinence of urine.

**Treatment.**—The first degree of hypospadias requires no treatment, the cleft glans being not even an inconvenience. Intermediate degrees between the first and second require treatment only if the urethra is so short that the semen cannot enter the vagina during connexion, or if there is a tight band beneath.

In the second degree of hypospadias, the first step is to dissect away the firm fibrous band which prevents complete erection. Some months after this has been successfully accomplished, and when the scars have become supple, the attempt may be made to close the urethra. In order to do this successfully, it is necessary to provide an epithelium-covered lining for the new urethra. Many methods have been suggested for doing this, but by far the best is that of Anger, which is an adaptation to hypospadias of Thiersch's operation for epispadias. It is thus performed: An incision is made parallel

to the groove representing the urethra, and half an inch from its right margin; a transverse incision from each end of this is made up to the edge of the urethral groove. The flap thus marked, which we will call the right flap, is then dissected up, leaving it attached along the margin of the urethral groove. A similar flap is then raised on the left side, but on this side the incision is carried along the left margin of the urethral groove, and the flap turned outwards, its attached edge being in the position corresponding to the free edge of the right flap. The right flap is now turned over so that its skin surface forms the lining of the new urethra. A number of fine stitches are then inserted in the following way: The needle is first passed through the base of the left flap from the skin surface, next through the free edge of the right flap from the raw surface towards the skin; then it is made to catch the left edge of the urethral groove, and finally it is passed again through the base of the left flap. In this way the edge of the right flap is held in position, and the stitches can be removed from the surface. When these have all been passed, they may be tightened. A similar number of stitches are then passed through the free edge of the left flap, by which it is attached to the skin of the penis at the outer edge of the raw surface from which the right flap was raised. The raw surfaces of the two flaps are thus brought closely into contact, and an epithelial lining formed for the new urethra. During the healing, a catheter must be tied in, and the bladder drained. A small fistulous opening will usually be left at the lower end, which must be closed by a subsequent plastic operation. Several successful cases of this operation have been recorded, and it seems to be by far the most efficient of the many methods. The third degree of hypospadias admits of no treatment. The operation should not be performed on young children, as the parts are too small.

**Epiispadias.**—The upper surface of the penis is less frequently fissured. The malformation commonly occurs in conjunction with extroversion of the bladder, but a few cases are recorded in which the penis only was cleft. This condition may be remedied by Thiersch's operation above described.

**Phimosis.**—The prepuce is not unfrequently the seat of malformation or disease. The condition of it in which it is so much elongated that it extends beyond the glans, while at the same time it is so much contracted that it prevents the proper exposure of this portion of the organ, is termed *phimosis*. This may be either congenital or acquired.

In **Congenital Phimosis** the penis is often somewhat atrophied, and the development of the glans is prevented by the pressure of the narrow prepuce. The constricting band which prevents the retraction of the foreskin is always situated at the junction of the skin and the mucous membrane. Without marked contraction of the preputial orifice it may be impossible to retract the prepuce on account of its adhesion to the glans. In the majority of cases a long foreskin is simply a source of local inconvenience; but it may become a source of disease. Thus, in children, retention of the sebaceous secretion—"smegma preputii"—becomes a source of local irritation and inflammation from decomposition. The irritation thus kept up (Fig. 935) favours the early development of the habit of masturbation. In some cases the preputial orifice is so tight as to interfere with the discharge of the urine, which passes from the urethra into a kind of pouch between the glans and prepuce, distends this structure, and is then squeezed in a fine jet or in a scattered sprinkling

stream through the narrowed preputial orifice ; and irritability of the bladder, often presenting symptoms simulating calculus, may thus be set up. In very rare instances a fatal result has ultimately followed as the result of changes in the kidneys caused by the persistent obstruction. Calculous concretions may form between the glans and the prepuce in such cases as these. Whishaw, of Fyzabad, removed no fewer than 426 calculi, varying in size from a pin's head to a small bean, from this situation in a native of India, 60 years of age, who came under treatment for what appeared to be a large tumour of the end of the penis, the true nature of which was not detected until in removing it the knife grated against the contained calculi. Various affections of the genito-urinary organs in children, such as incontinence, intermittent flow of urine, hæmaturia, priapism, &c., have been shown by Bryant to be caused by congenital phimosis. The straining in micturition may give rise also to hernia and prolapse of the rectum. Hydrocele of young children will also be found to be very frequently associated with phimosis. Sayre has pointed out the important fact that reflex paralysis and various forms of spastic contractions, chiefly of the lower limbs, are due to the same cause, being readily curable by circumcision. In addition to these I have seen general spasmodic affections in children resembling chorea, resulting from congenital phimosis. At more advanced periods of life I have known it to be a cause of sterility, the semen being retained under the tight prepuce until erection had completely subsided. Congenital phimosis especially becomes a source of inconvenience in after-life if any gonorrhœal or venereal disease be contracted, as it renders exposure of the diseased part difficult or impossible, and interferes with the necessary treatment. In the opinion of some Surgeons, cancer of the penis, if not directly occasioned, is at all events predisposed to, by congenital phimosis.

Fig. 935.—Irritated Congenital Phimosis.

**Acquired Phimosis** usually results from repeated attacks of inflammation, or of specific disease in the part, giving rise to solid œdema, or to false hypertrophy of the prepuce.

In elderly men, phimosis will sometimes slowly come on as a consequence of the irritation set up by cracks, fissures, or superficial ulcerations round the preputial orifice, which becomes narrowed, so as to prevent the glans from being uncovered. It may occur in gouty or diabetic subjects as the result of repeated attacks of balanoposthitis (p. 1223). The preputial mucous membrane becomes thickened, and can be felt like a broad band under the loose and possibly slightly œdematous integument of the prepuce. This condition is a source of much irritation and annoyance, and requires relief by dilatation or by circumcision.

**Treatment.**—Every child who has a congenital phimosis ought to be circumcised ; and even those who, without having phimosis, have an abnormally long and lax prepuce, would be improved greatly in cleanliness, health, and morals by the same operation. It would be well indeed if the custom of Eastern nations, whether it be regarded as a religious rite or only as a time-honoured observance, were introduced amongst us. Phimosis, when not congenital, must be treated in accordance with its cause : thus, if it have resulted from inflammation, that must be subdued ; if from venereal disease, that must be remedied, when perhaps the contraction and elongation will gradually subside.

If, however, the phimosis, though acquired, be permanent, it should be subjected to operation.

A long foreskin, if a source of annoyance to an adult, may easily be remedied by keeping it constantly drawn back. At first the tendency for the prepuce to slip forwards must be overcome by wrapping a piece of dry lint round it, and securing it by an elastic band, which must be just tight enough to keep it in position. After a few weeks the foreskin will retain the retracted position, and after a year or so will be found to have undergone considerable diminution in size.

**Operations for Phimosis** may be conducted on three plans: the elongated and contracted prepuce may be dilated, or slit up, or circumcision may be performed.

1. **Dilatation of the Prepuce** by the expansion of a pair of forceps introduced through the orifice cannot be recommended as good treatment for congenital phimosis. It often causes so much swelling that circumcision becomes necessary, and as the administration of an anæsthetic is required it is much better to proceed at once to that operation. In the acquired phimosis of old men I have found that dilatation may speedily be effected by the introduction of a two-bladed dilator, and in certain cases in which any cutting operation is contra-indicated this may be the only available treatment.

2. **Slitting up of the Prepuce** upon its upper surface is an objectionable procedure, leaving the prepuce of abnormal length, and more or less fissured and knobbed. In all cases I prefer circumcision, as giving the most satisfactory result.

3. **Circumcision** is by far the most satisfactory treatment for phimosis, whether congenital or acquired. According to the Hebrew rite the operation is performed on the eighth day after birth, as follows:—The child being held on the lap of an assistant, the operator draws the foreskin slightly forwards, and then grasps it just in front of the glans by drawing it through a slit in a silver guard. This is not held perpendicularly, but is inclined from above slightly forwards and downwards, so as to avoid cutting the frænum, and to slice off the prepuce in an oblique manner. This is done by one stroke of a broad round-ended knife. The mucous membrane is then torn open between the finger and thumb along the dorsum of the penis, and is turned back so as to be brought into contact with the cut edge of the skin. A strip of dry lint is then twisted round the organ in the sulcus behind the glans, so as to keep back the mucous membrane, and also to restrain hæmorrhage by its pressure. Union is perfect in a few days. The operation is very rarely attended with any ill consequences. I have, however, seen it in one case followed by fatal erysipelas, and have heard of another instance in which death occurred from hæmorrhage.

The *Operation* is most conveniently performed as follows:—A general anæsthetic should as a rule be administered, although in exceptional circumstances cocaine may be used. Except in the case of young children hæmorrhage during the operation may be restrained by a tape or a piece of fine rubber tubing, tied tightly round the root of the penis. The Surgeon then draws the prepuce forwards until the portion of it which corresponds to the back of the glans is brought just in front of that structure. In young children especially care must be taken not to remove too much skin. The projecting prepuce is then seized just in front of the glans with a pair of narrow-bladed

polypus forceps or sinus forceps, which is held firmly by an assistant. The forceps are not held vertically, but are inclined slightly forwards below. With one sweep of a bistoury the Surgeon cuts off all that portion of the integument which projects beyond the forceps, which are then removed (Fig. 936). It will now be found that he has removed only a circle of skin, but that the mucous membrane lining it still tightly embraces the glans; this he slits up along its dorsal surface as far as the corona, by introducing the point of a pair of scissors at the preputial orifice. In doing this care must be taken not to introduce the lower blade of the scissors into the urethra. The mucous membrane is then turned back completely from the glans, any adhesions being separated and all smegma removed. The excess of mucous membrane is cut away with scissors, so that only a narrow strip remains around the base of the glans. If a tourniquet has been used this is now removed, and any vessels which spurt, usually one on each side of the penis and one or two in the frænum, are twisted or ligatured with the finest catgut. The edges of the

Fig. 936.—Circumcision in the Adult.

skin and mucous membrane are then adjusted with a sufficient number of fine sutures, the first of which should be passed opposite the frænum and the raphe of the penis. In young children many Surgeons dispense with sutures altogether, but a more satisfactory result is obtained by inserting at least four or six. If fine catgut is used it will be absorbed, and thus save the pain of taking them out, or if horsehair sutures are inserted very close to the edges of the skin and mucous membrane, and tightly tied, they usually work out in the course of a week. In young children the simpler the dressing the better. A convenient method consists in wrapping a narrow strip of butter-cloth spread with boric ointment around the line of the wound, and keeping it in place by a narrow strip of gauze fixed at its end with collodion to the abdominal wall at the root of the penis. In the adult an antiseptic gauze or wool dressing may be applied with a narrow bandage. This may be left unchanged for four or five days. Primary union usually occurs, except perhaps in the position of the frænum, where perfect apposition is not so readily obtained. The dressing is best removed by thoroughly soaking it in warm boric lotion.

There is usually a good deal of swelling of the mucous membrane about the frenum, and some solid oedema usually remains for some weeks after the operation. This gradually subsides, and a linear cicatrix remains, which causes the patient no inconvenience.

**Paraphimosis.**—In *paraphimosis* the prepuce has been forcibly drawn back behind the glans, which becomes strangled by the pressure exercised by the preputial orifice, so that the parts cannot be replaced in proper relation to one another. This accident principally occurs in boys, or in individuals who have naturally a tight prepuce, and who, on uncovering the glans, find it difficult to get this part of the organ back. This difficulty is speedily and greatly increased by the swelling from congestion that is set up in the constricted glans. It may also result from inflammatory swelling of the prepuce due to balanoposthitis, and other causes in cases in which no phimosis previously existed.

The **Treatment** is simple. The Surgeon should first try to reduce the swollen organ. He may often succeed in doing this by seizing the body of the penis between the index and middle fingers of each hand, and endeavouring

Fig. 937.—Reduction of Paraphimosis.

Fig. 938.—Incision in Operation for Paraphimosis.

to draw the prepuce forwards, at the same time that he compresses the glans between the two thumbs and pushes it back (Fig. 937). Should reduction not be effected in this way, the constricted and strangulating preputial orifice must be divided. In doing this, the Surgeon will observe that the glans is separated from the body of the penis by a deep and narrow sulcus, which is especially evident on the upper part of the organ. This sulcus, which is overlapped on one side by the skin of the penis, and on the other by the swollen mucous layer of the prepuce, corresponds to the inner margin of the preputial orifice; and it is by the division of this, in which the stricture is situated, that immediate relief will be given. This operation may readily be done by drawing the glans and swollen prepuce forwards, then passing the point of a narrow-bladed scalpel into the sulcus on the dorsum of the penis, and making a perpendicular incision about one third of an inch in length through the integuments at the bottom of the groove (Fig. 938). In consequence of the great stretching of the parts, the incision will immediately gape widely; so that, instead of being longitudinal, it will appear to be transverse; and then reduction of the glans may readily be effected.

**Balano-posthitis.**—*Balanitis*, or inflammation of the glans, and *Posthitis*, or inflammation of the prepuce, rarely occur independently of each other. Simple balano-posthitis is very frequently set up by accumulation of smegma and dirt beneath a long, tight prepuce, but the most acute form occurs as a complication of gonorrhœa or soft sores. The prepuce is much swollen, infiltrated, and reddened, and, while the inflammation lasts, continues in a state of phimosis; there is a muco-purulent discharge, and, especially when the glans is affected, a good deal of irritation and smarting. The glands in the groins are often tender and swollen, and occasionally suppurate.

A chronic form of balano-posthitis is apt to occur in gouty subjects, and has already been mentioned as a cause of acquired phimosis. Jacobson mentions two cases in which there was also Dupuytren's contraction of the palmar fascia, the gouty nature of which is generally accepted. The inflammation of the prepuce which occurs in diabetics is probably due to the irritation of the urine.

**Treatment.**—The disease requires to be treated on general principles. In the slighter forms the application of lead lotion, with the internal administration of salines, will usually suffice. In the severe forms, in which there is a purulent discharge from the orifice of the prepuce, and in which, in spite of constant fomenting, the prepuce cannot be retracted, it should be slit up along its dorsal surface in order that the exact state of affairs may be seen. In many cases it will be advisable to complete the circumcision; and this operation is also advisable if the patient is subject to repeated attacks of the simple form. In the gouty form circumcision may also be required, but in that due to diabetes operation must be avoided, unless the inflammation is intense and sloughing seems likely to occur.

**Herpes of the Glans and Prepuce** is characterized by the formation of small vesicles and minute ulcers upon the mucous membrane of this region, attended with much smarting and itching, and occurring chiefly in gouty persons with an irritable mucous membrane.

**Treatment.**—This slight affection is often very rebellious to treatment. In many instances local means alone will not suffice; for, though relief may be obtained by powdering the part with the oxide of zinc, or by using slightly astringent and cooling lotions, yet no permanent benefit will be derived unless constitutional treatment be adopted. Salines should be administered, and, if the patient is gouty, may be combined with colchicum and alkalies. For the cure of recurrent attacks Hutchinson speaks highly of arsenic.

**Persistent Priapism**, lasting for many days, is occasionally met with, as the result in most cases of venereal excess, and more especially of violent coitus during intoxication. The erection of the penis is not accompanied by any sexual desire, but is attended with great pain, a sense of weight about the perinæum, much anxiety, and constitutional disturbance. The organ is hard and unyielding. The pathology of this condition is obscure. By some it has been considered to be the result of extravasation of blood into the corpora cavernosa; by others, to depend on sympathetic or reflex nervous irritation. The effect of treatment would lead to the inference that the latter view is correct. Incisions into the corpora cavernosa to let out the blood supposed to be extravasated have been productive of no good, whilst the erection has rapidly subsided under full doses of bromide of potassium.

**Gangrene of the Penis.**—Sloughing of the integuments of the penis, to

a greater or lesser extent, not unfrequently occurs in persons of broken constitution as the result of inflammatory phimosi, simple or gonorrhœal (Fig. 939); or of syphilitic phagedæna, and indeed the glans and body of the organ may often be extensively destroyed by the latter cause. These various forms of the disease have already been described.

True *idiopathic gangrene* of the penis is, however, a very rare disease; and Demarquay, who specially directed attention to it, found but few instances of it in the records of surgery. It has chiefly been met with in people of advanced age or of broken constitution, who, whilst suffering from some local affection of the organ, have been attacked by acute febrile disease, such as typhoid or small-pox, or have become the subjects of pyæmia. In some cases it is probably embolic. The disease, when affecting the body of the penis, is often fatal—possibly by hæmorrhage on the separation of the slough. When the glans only is attacked, the prospect is better. But in either case mutilation of the organ to a serious extent will result.

Fig. 939.—Sloughing of the Prepuce, and Protrusion of the Glans.

Fig. 940.—Warts on the Glans and inner surface of Prepuce, which is slit up.

The *Treatment* of gangrene of the penis presents nothing special, with the exception of restraining hæmorrhage by means of the actual cautery, and preventing or repairing loss of substance in the urethral wall, if it be invaded by the disease and involved in the destruction resulting.

**Hypertrophy of the Prepuce** occasionally occurs as the result of chronic irritation or disease; it is usually of limited extent, and requires no special treatment; but in some instances it may become so extensive as to require operative interference. The hypertrophy is due to solid œdema of the prepuce and body of the penis, the organ being greatly enlarged and club-shaped. In these cases circumcision, with the excision of a V-shaped piece from the dorsum of the prepuce, will be found to give a satisfactory result. Vidal has figured a case in which the penis had attained such an enormous size that it reached to below the knees, and was as large as a thigh. This monstrous growth was successfully excised.

**Warts** on the penis have already been described. They may attain a very large size, as in Fig. 940, and are best treated by being snipped off with curved scissors.

**Horny Excrescences** have been observed to spring from the glans penis.

The most remarkable case of this kind on record is one by Jewett of Connecticut. It was that of a young man, in whom, after operation for congenital phimosis and the removal of warts, a horn grew from the left side of the glans penis, and attained a size of three and a half inches in length by three-fourths of an inch in diameter at the base. It could be handled and cut without pain, and the patient "was accustomed to amuse the inmates of the ward by lighting the end of the horn and allowing it to burn." It was excised, and did not return.

**Sebaceous Cysts** are occasionally met with, usually on the under surface of the penis or prepuce. **Dermoid Cysts** are very rare; they have been found in the raphé on the under surface of the penis along which the two halves unite to close the urethra.

**Fibrous Tumour of the Penis.**—The penis may be the seat of fibroid and other tumours. The accompanying drawing (Fig. 941) is an illustration of

Fig. 941.—Fibroid Tumour of the Penis, successfully removed.

Fig. 942.—Warty Carcinoma of the Penis.

one springing from the fibrous tissue of the corpora cavernosa which I removed some years ago from the under surface of the organ.

**Sarcoma of the Penis** is very rare. It appears to commence in the cavernous tissue. The only available treatment is amputation.

**Carcinoma of the Penis.**—The form of cancer met with in the penis is *Squamous Carcinoma*. It usually springs from the sulcus behind the glans, and thence invades the neighbouring portion of the organ. It always commences in the anterior extremity of the penis, affecting the body of the organ only by extension from the original starting-point. It appears in two forms, either as a flat tubercle or as a distinctly papillary growth. When it commences as a tubercle it appears as a hard pale reddish-white mass situated on the glans or between the prepuce and the glans. This increases in size, and extends deeply into the organ. At last a crack forms and allows a serous discharge to exude, which usually becomes very fetid. Ulceration then rapidly takes place. Sometimes the disease appears to be very distinctly localized; but after its removal it will usually be found to infiltrate the organ for a considerable distance.

The papillary form at first presents the appearance of ordinary warts (Fig. 942). It grows rapidly, and a deep-seated indurated base can be felt beneath

The flaps are united with sutures, and the urethra is slit up and adjusted with sutures to the edges of the opening in the upper flap.

If the amputation be performed too high up infiltration of urine may take place into the scrotum, and to prevent this, it may be safer to introduce an elastic catheter after the operation, and leave it in for a few days.

If the glands in the groin are distinctly, but not too greatly, enlarged, an attempt should be made to remove them at the same time as the amputation of the penis is performed.

In a case extending too far back to allow the performance of the ordinary operation, Pearce Gould successfully removed the disease by dividing the scrotum and dissecting away the whole organ as far back as the crura, leaving an opening in the perineum through which the patient subsequently passed water. This operation has since been repeated in many cases with success. It has been recommended to remove the testes at the same time, as they are somewhat in the way during micturition, but this seems hardly necessary.

If after amputation of the penis much inconvenience arises from the urine being passed downwards between the legs, it may best be avoided by following Ambrose Pare's advice of adapting a funnel, which may be made of metal, or ivory, to the pubes over the stump, and thus carrying the urine clear of the person.

#### DISEASES OF THE SCROTUM.

**Hæmatoma of the Scrotum.**—In rare instances, as the result of an injury or severe straining effort, an extravasation of blood occurs in the loose cellular tissue of the scrotum. The importance of the condition lies in the fact that it is likely to be mistaken for hæmatocele of the tunica vaginalis, in which the blood is often effused around as well as within the serous cavity (p. 1246).

McCarthy has recently recorded an unusual case of this so-called "extra-vaginal hæmatocele." The patient was seventy-four years of age, and was admitted to the London Hospital on account of a large globular swelling in the left half of the scrotum. Above, the swelling presented a tubular prolongation which extended into the inguinal canal, and over its lower part the skin was discoloured. The tumour fluctuated but was not translucent. The swelling had repeatedly been tapped, and, according to the patient, clear fluid had been drawn off.

There was no history of any other injury, nor of cough or violent exertion. The swelling was tapped and 10 ounces of dark blood-stained fluid drawn off. In ten days the sac had refilled, and a smaller quantity of similar fluid was withdrawn. A month later, the swelling having again filled, an incision was made, and a large cavity containing dark fluid and lined with fibrine was opened. In this cavity lay the testicle, with its tunica vaginalis distended with 2 ounces of clear fluid. The operation was followed by rapid recovery. The condition present was evidently due to gradual alterations in an extravasation of blood, which possibly in the first instance was the result of tapping the hydrocele. McCarthy points out that, with the exception of the slight discoloration of the skin, the signs were those of a hydrocele, opaque either from the thickness of its walls or the character of its contents.

**Inflammatory Edema** of the scrotum is an erysipelatous inflammation of this region, and derives its chief peculiarity from the circumstance of its giving

rise to great effusion into and swelling of the areolar tissue of this part and of the penis, with a tendency to rapid sloughing, by which the integument may become affected to such an extent as to lay bare the testes. This disease usually originates from some local source of irritation, as fissures, cracks, or urinary extravasation (Vol. I., p. 957). There is a peculiar form of "inflammatory oedema" of the scrotum and penis, which is apt to occur as a sequela of small-pox and scarlet fever; rapid and extensive infiltration of the parts occurs, with a tendency to speedy gangrenous disorganization of the areolar tissue and skin.

The **Treatment** consists in elevating the scrotum, fomenting it well, and making early and free incisions into it, particularly at the posterior and dependent parts of the scrotum and penis, with the view of relieving the tension and thus preventing the liability to slough. Should this occur, the case must be treated on ordinary principles, when cicatrization will speedily ensue, however extensive the denudation of parts may be. The constitutional management must be conducted with special attention to the maintenance of the patient's strength.

**Elephantiasis of the Scrotum** has already been described at p. 42.

**Squamous Carcinoma** occasionally affects the scrotum; and as it occurs principally in chimney-sweeps, it has appropriately enough been termed *Chimney-sweeps' Cancer*. The disease appears to arise from the irritation of the soot lodging in the folds of the scrotum (Vol. I., p. 1054). It may also occur in workers in tar and paraffin. Butlin, who recently lectured on this subject before the Royal College of Surgeons, does not think that there is sufficient evidence to show that the generally accepted opinion that chimney-sweeps' cancer is much rarer now than formerly is founded on fact. He concludes that the rarity of the disease on the Continent is due to the adoption of a special costume by foreign sweeps which protects them from the soot.

The disease commonly commences as a tubercle or wart, which after a time cracks and ulcerates, and assumes the ordinary characters of a carcinomatous ulcer. It gradually spreads, and may at last involve the greater part of the scrotum, and even invade the testis. After a time the inguinal and pelvic glands may be affected; and the patient, if deprived of his covering of soot, will be found to be cachectic-looking.

Butlin has made the interesting suggestion that certain rare instances, in which a carcinomatous growth in the inguinal glands has occurred without any evidence of the existence of a primary tumour, may be explained by supposing that the primary growth has failed to develop although it has caused infection of the lymphatics.

The *Treatment* consists in excising widely the diseased portion of the scrotum, provided the inguinal glands be not involved to such an extent as to render any attempt to remove them inadvisable. The disease has a great tendency to recur, and the recurrent growth may arise, not in the position of the original tumour, but in some other part of the scrotum, the skin of which is usually thickened and warty. Recurrence in the glands is not uncommon.

## CHAPTER LXXIII.

## DISEASES OF THE TESTIS AND CORD.

## MALPOSITION OF THE TESTIS.

THE testes are, in the fœtus, situated in the lumbar region below the kidneys, and by a gradual transition they descend into the scrotum a short time before birth. In its descent the testicle is preceded by a pouch of peritoneum, the *processus vaginalis testis*, which normally becomes afterwards closed above, and forms the *tunica vaginalis*. Although much doubt exists as to the exact way in which the descent of the testicles is brought about, it seems probable that the most important agent in the process is the *gubernaculum testis*. The existence of this fibro-muscular structure has long been recognised, but our knowledge of its development and relations has been largely increased by the recent researches of Lockwood and others. Above, the gubernaculum ends in fibres which are attached to the vas, the epididymis, the body of the testis, and the peritoneum of the back of the abdomen. Below, the fibres have been traced to the abdominal wall in the position of the internal abdominal ring, where others pass along the inguinal canal, some ending on the pubes, and others in the scrotum and perinæum. Lockwood has also described a band, which can usually be found in the earlier months, passing outwards into Scarpa's triangle.

It is probable that the *processus vaginalis* as well as the testis itself owes its descent to the action of the gubernaculum, the upper fibres of which pass to the peritoneum. Under normal circumstances it is supposed that the testis is drawn to the position of the internal abdominal ring by the abdominal fibres of the gubernaculum. It is then drawn along the inguinal canal by fibres passing to the pubes, and finally drawn into the scrotum by the scrotal assisted by perinæal fibres.

The descent of the testis may merely be delayed so that, instead of the gland being in the scrotum at birth, one or both do not leave the abdomen until some time afterwards; in other cases the testis is permanently arrested at some spot along the line of its normal descent, whilst very rarely the organ leaves its proper path and strays to the perinæum or thigh.

A **retained testis** may continue to lie within the cavity of the abdomen; it may be arrested at the internal abdominal ring; it may remain in the inguinal canal, or may project just beyond the external abdominal ring, without properly entering the scrotum. The testicle is often very movable, and may be slipped upwards completely inside the abdomen and downwards to the lower end of the canal.

When the testis is completely retained, no other symptom exists except the absence of the organ from its normal position; but when it occupies the inguinal canal it is often the seat of pain, due no doubt to the compression to which it is exposed. It may also, as has been stated at p. 867, become complicated with, or be mistaken for, a hernia, and may present many diagnostic difficulties.

In rare instances the testis misses the scrotum and passes into the perinæum, where it usually lies close to the anus. The explanation of this malposition is probably to be found in the fact that a prolongation of the fibres of the gubernaculum can usually be found passing to the perinæum. Still more rarely the testis has been known to escape by the crural canal on to the thigh.

There is a very important question connected with malposition of the testis, viz., Is the organ when undescended prolific? Curling and others were of opinion that it is not, but more recent observations tend to show that the organ is at first functionally active, but that it "ages prematurely." In some cases of double cryptorchism spermatozoa have been found in the seminal fluid, whilst in other cases they have been absent; and it would appear that this depends largely upon the age of the patient, and whether or not the testicle has been the seat of attacks of inflammation. The compression to which a testicle is exposed in the inguinal canal is harmful to its functional activity; the organ is often smaller than normal, and is liable gradually to undergo degenerative changes. In the present state of our knowledge of this subject, it may be concluded that a man with both testicles retained is by no means necessarily sterile, but that he is likely to become so at a comparatively early age.

Not only is a testicle retained in the inguinal canal especially liable to inflammation from slight injuries, but should gonorrhœal epididymitis occur, the symptoms are intensified by the compression of the surrounding tense structures. There is also a liability to severe acute symptoms due to torsion of the cord, and it is probable that a retained testicle is more prone to malignant disease than an organ in its natural position.

**Inflammation of the Testis in the Inguinal Canal** may sometimes take place, even in adults, when the organ has not descended through the external ring, giving rise to a train of somewhat puzzling symptoms, which closely resemble those of strangulated hernia; with which, however, it must be borne in mind that it may be associated (p. 867). On examination, a large irregular tumour, in some parts hard, in others soft, very tender, and occasioning a sickening sensation when pressed upon, will be found in the situation of the inguinal canal. There is usually a tendency to vomiting, with some constipation, and colicky pains in the abdomen. On examining the scrotum it will be found that the testis on the affected side is absent; and on passing the finger into the external ring, the organ can be felt to be lodged in the canal. In consequence of the proximity of the peritoneum to the inflamed testis, this membrane occasionally becomes involved in the morbid process; and, as the result of the constriction of the tendinous and aponeurotic tissues in the situation, sloughing has occasionally occurred. Either of these conditions may lead to a fatal termination.

**Torsion of the Spermatic Cord** was first described by Nicoladoni in 1885, and since the publication of cases in this country by Whipple and Bryant the condition has received considerable attention, and must be regarded as one of great practical importance. The accident is especially liable to occur when the testicle is imperfectly descended and freely movable. There is frequently a definite history of some exciting cause, such as a jump or muscular effort, which is rapidly followed by severe pain, often accompanied by vomiting. Almost immediately a tumour makes its appearance in the groin, and thus the close resemblance of the symptoms to those of a strangu-

lated hernia is obvious. When, however, as rarely happens, the affected testicle is in its normal position, the case is more likely to be mistaken for one of acute inflammation of the organ. Of 18 recorded cases in which the diagnosis made is stated, 11 were thought to be strangulated hernia, 2 inflammation of the testicle, and in 5 only the true nature of the condition was suspected or definitely recognized. Bryant and others have pointed out that the vomiting is rarely so severe or persistent as in hernia, whilst the general symptoms of strangulation of intestine are absent. The chief difficulty would therefore consist in distinguishing the case from one of strangulated hernia in which the sac contains omentum or in which the whole lumen of the bowel is not obstructed.

The rapid development of a swelling in these cases is due to the sudden engorgement of the testis with blood, the gland being described as having the appearance of a ripe plum. There may also be an effusion of blood-stained fluid into the tunica vaginalis.

*Treatment.*—In one case recorded by Gifford Nash the condition was diagnosed an hour and a half after the appearance of the first symptom and the half twist of the cord was undone by manipulation, the swelling of the testis and epididymis disappearing almost at once. As a general rule, however, the case is not seen until such treatment is impossible, even if the diagnosis be clear. An incision is therefore necessary, and removal of the affected testicle is probably always the best course to adopt. If the testicle be in the inguinal canal the necessity of removal is obvious, but even if the testicle be in its normal position and the torsion can be relieved, atrophy will probably follow, as in Bryant's case, in which this treatment was adopted, or actual sloughing may take place. It is interesting to note that in Nash's case, mentioned above, the testicle subsequently became considerably smaller than the other.

**Treatment of Misplaced Testis.**—No treatment is required for a testicle retained in the inguinal canal if the patient is an infant and the condition is not complicated with hernia. When, however, the patient is older—preferably between eight and ten years—an operation may be undertaken with the object of transplanting the gland into the scrotum, and thus relieving the inconvenience of a testicle in the groin, and possibly preventing its subsequent atrophy. The difficulties of the operation are twofold. In the first place it may be found difficult or even impossible to free the testicle sufficiently to allow it to be drawn downwards into the scrotum; the vas deferens is long and lax, but the vessels may be short, and firm adhesions present. Secondly, when the testicle has been brought down into the scrotum the difficulty is to keep it there.

The operation consists in making an incision over the inguinal canal and extending it downwards to the scrotum. The testicle is exposed and carefully separated from the surrounding structures, great care being taken not to damage the vas. As a rule the tunica vaginalis is found open into the peritoneum, and must be divided above the testicle. The testicle can, as a rule, now be gently drawn into the scrotum, the tissues of which are separated to receive it. Various methods have been devised with the object of keeping the testicle in its new position.

The simplest consists in passing a single silk suture through the tissues at the bottom of the scrotum and the tunica albuginea. This, however, often

fails to prevent the testicle being gradually drawn upwards again. Another plan consists in attaching a silk suture to the testicle, passing the two ends out through the bottom of the scrotum, and knotting them over a pad of gauze included in the dressing, or, as Watson Cheyne has suggested, to a light wire frame which fits round the scrotum. After about ten days the projecting part of the silk is cut off. Horsley has obtained good results by loosely fixing the upper end of the testicle by means of a silk suture to the periosteum covering the ramus of the pubes. The silk is passed with a curved needle on a handle, care being taken not to wound the crus penis. In any case the external abdominal ring must be sufficiently closed with sutures.

If the testicle lies in the perinæum it can usually be transplanted into the scrotum without great difficulty. It must be dissected out, and left attached by the cord only. An incision is then made into the scrotum, the testicle placed in its proper position, and secured by a fine stitch. The treatment of retained testis complicated with inguinal hernia has already been considered at p. 874.

**Retroversion of the Testicle** is not very uncommon. The organ is completely turned round, so that the epididymis is placed in front. In a case of this kind which I had an opportunity of examining after death the epididymis and vas deferens were considerably larger than natural. If a hydrocele form in such a case, it will be seated behind the testis.

#### NEURALGIA OF THE TESTIS.

A painful or irritable condition of the testicle may occur without any actual disease of the organ; the pain being seated either in the epididymis, which is the part naturally the most tender, in the body of the testis, or extending along the cord to the loins and groins. It is usually paroxysmal, and is accompanied by great tenderness, and commonly by some fulness of the organ, which feels soft and flaccid; but it is difficult to make a proper examination, on account of the agony that is induced by touching the part. This disease occurs chiefly in young men of a nervous temperament, and is frequently associated with great mental despondency, sometimes amounting to a suicidal tendency.

The **Causes** are obscure: in many cases the disease appears to be connected with a neuralgic temperament, but in others it is associated with some dyspeptic disorder, or may be dependent upon local irritation; thus, external piles, or the pressure of a varicocele, will often give rise to it. In middle-aged or elderly men it is often gouty, most commonly affecting the left testicle.

The disease is usually of a very chronic character. In some instances, however, it ceases spontaneously, after having lasted for weeks or months.

**Treatment.**—When the neuralgia is dependent upon constitutional causes the treatment is extremely unsatisfactory. The administration of tonics, such as iron, zinc, or quinine, the local application of sedatives, as of atropine ointment or the tincture of aconite, may be of service. In other cases, cold bathing or douching will be beneficial; and, in all, keeping the part supported with a suspensory bandage will be advantageous. When it is due to gout the patient must be treated for that condition. In the event of there being any local irritation, that should be removed: thus, I have known the disease to

cease after the excision of external piles; and when it is connected with varicocele, proper measures must be adopted for the relief of that affection.

The application of glycerine and belladonna or of a mixture of equal parts of chloral and camphor may give relief.

In extreme cases, Astley Cooper recommended castration; but such a proceeding is altogether unjustifiable in a disease that is either constitutional, or dependent on local causes which are readily removable.

#### ACUTE INFLAMMATION OF THE TESTIS.

**Acute Inflammation of the Testicle** may be seated in the body of the organ, constituting *Orchitis*, or the epididymis alone may be affected, constituting *Epididymitis*. But although the inflammation may remain limited to one or other of these structures, in the large majority of cases both are eventually involved.

**Causes.**—By far the most common cause of acute inflammation of the testicle is direct extension from the urethra. This variety, in which the epididymis is always primarily affected, is met with in gonorrhœa (p. 1169), and as the result of irritation set up in the canal by the passage of instruments or the lodgment of calculi. To the same class probably belong the cases in which an attack of epididymitis occurs as a complication of chronic inflammation or hypertrophy of the prostate, especially in gouty subjects. Inflammation, affecting chiefly the body, may occur as the result of an injury, such as a squeeze, blow, or severe strain. Orchitis may also occur as a sequela of certain acute infective diseases; of these mumps is by far the most important, but amongst others in which the same complication has been observed may be mentioned typhoid fever and smallpox. Apart from the epididymitis which is met with in gouty subjects, probably as the result of urethral or prostatic inflammation, the existence of a true gouty orchitis in which the body of the testicle is affected seems undoubted. Orchitis has also been met with in association with other manifestations of acute rheumatism, but, as Jacobson remarks, before a diagnosis of "rheumatic orchitis" is made, not only must any urethral or other cause be excluded, but care must be taken to distinguish neuralgic pains in the epididymis or testis, to which gouty and rheumatic subjects are especially liable, from a supposed inflammation of the testicle.

The **Symptoms** necessarily vary, not only according as the disease is of an acute or subacute character, but as it primarily affects the body of the testis or the epididymis. When it commences in the latter structure it is the globus minor that is commonly first affected; it becomes swollen, hard, and tender. The inflammation may be confined throughout to this part; but most frequently it invades the whole of the organ, which becomes uniformly enlarged and somewhat ovoid; it is frequently accompanied by a good deal of effusion into the tunica vaginalis, constituting the *Acute Hydrocele* of Velpeau. As the inflammation subsides, the different characters presented by the enlargement of the two constituents of the organ again become apparent. The swelling is therefore due partly to general enlargement of the organ, but in some cases to inflammatory effusion into the tunica vaginalis.

The pain is always very severe, with much tenderness and a sensation of weight, and commonly extends up the cord into the groin and loin. It is generally greatest when the body of the testis is affected, owing probably to the enveloping fibrous tunic preventing the expansion of the organ. Hence it is often spasmodic and paroxysmal, extending up the course of the cord. There are usually considerable swelling and redness of the scrotum, with turgescence of the scrotal veins, and a congested state of the cord, with sharp pyrexia, nausea, and perhaps occasional vomiting.

As the disease subsides, the body of the testis first resumes its normal character and shape, the epididymis often continuing hardened and enlarged for a considerable period. In fact, the induration that forms in the epididymis may be permanent, implicating the whole or a portion of its convolutions.

Gosselin has shown that this induration of the epididymis following inflammation frequently causes complete obstruction of the canal, and if occurring on both sides, produces sterility. In 19 such cases he found spermatozoa absent from the semen, and the patients consequently incapable of procreation, although the appearance of the testes and of their secretion was scarcely altered, and the virile powers of the patients remained unimpaired. Curling also mentions several such cases, and points out the necessity of continuing the treatment of epididymitis until the last trace of induration has disappeared. At a later period treatment is almost useless.

**Subacute Orchitis** usually comes on with the same symptoms, though in a less marked form than in the acute variety. The swelling, however, is considerable, though of a softer kind. Should it become chronic, the testis often remains permanently enlarged and hardened, assuming an oval shape, being smooth, heavy, and uniformly expanded, with a sensation of weight, dragging, and severe pain, and a good deal of tenderness on pressure. This form of orchitis occasionally occurs in old people.

Orchitis may occur idiopathically, without any assignable cause in the way of external injury or local irritation in the urethra or prostate. This form of the disease is most common in middle-aged men, and more especially in those who are gouty. In fact, the disease is in all probability one of the many local forms of gouty inflammation. It is not very acute but lingering, liable to recurrence, and to be followed either by hydrocele or chronic induration of the epididymis.

**Atrophy of the Testis as a consequence of Inflammation** is more liable to follow the orchitis of mumps in young men above the age of puberty than any other inflammatory affection of the organ. It is remarkable how rapid and how complete the wasting of the testis will be in these cases. A few weeks after the subsidence of the inflammation the testis may be found to form a small soft mass not larger than a filbert.

Atrophy of the testis may sometimes gradually ensue also as a result of chronic epididymitis, and the consequent induration of this structure. Strangulation of the vascular supply to the testis occurs, and the whole organ at last wastes so as to leave nothing but a small hardened mass in the scrotum.

**Treatment of Acute Orchitis.**—The patient should be kept in bed with the testis raised on a small pillow between the thighs, and hot fomentations diligently applied. At the same time the swollen gland may be painted with a mixture of equal parts of glycerine and extract of belladonna. This treat-

ment will usually be found to give the patient relief; but if the case be seen very early, before much swelling has taken place, the application of cold by means of Leiter's tubes (Vol. I., p. 214) or Otis's coil may sometimes cut the inflammation short and give immediate relief. Local blood-letting is often of great service when there is much pain. It is best carried out by puncturing the veins of the scrotum—a far better method than applying leeches, the bites of which are apt to become irritated. This little operation may be very effectually done by directing the patient to stand up, and to foment the scrotum for a few minutes with a hot sponge, so as to distend the veins; these may then be punctured at various points with a fine lancet, and the parts well fomented, so as to encourage the flow of blood. In this way six or eight ounces may be taken in the course of a few minutes; when enough has escaped, the further flow may be arrested by laying the patient down and elevating the part.

If there be much effusion into the tunica vaginalis, constituting acute hydrocele, relief may be afforded by tapping. Puncture of the testis itself, which has been recommended, is a needless and dangerous proceeding. I have known of a case in which it was followed by abscess in the gland, ending in its complete destruction.

The *Constitutional Treatment* during the acute stage consists in the administration of salines and antimony, with hyoscyamus in full doses, so as to give an aperient, a diaphoretic, and a sedative together; when this begins to act, great relief is usually afforded.

As the inflammation subsides, the treatment must be changed. When there is merely swelling and hardness left, with but little pain or tenderness, the testis may advantageously be strapped, so as to give good support and to promote absorption of plastic matter. Fricke of Hamburg has strongly recommended strapping in the acute stage; but I cannot say that I have ever seen any advantage derived from it at this period of the disease, though I have many times seen it tried; it has usually appeared to me to increase, sometimes very considerably, the pain in the part, and the general uneasiness.

In **Subacute Orchitis** much benefit is usually derived from a short course of Dover's powder and calomel, with early strapping of the testis. When the organ has become enlarged and indurated, as the result of chronic inflammation, it may advantageously be strapped either with simple plaster, or with one composed of equal parts of the emplastrum ammoniaci cum hydrargyro and soap-plaster; mercury in small doses, more especially the perchloride, being continued for some length of time, until the inflammatory products are absorbed and the hardness disappears.

In **Strapping a Testicle**, the scrotum should be shaved, and then drawn tightly upwards on the affected side. The Surgeon should next pass a long strip of plaster, an inch broad, above the enlarged testicle and round the corresponding side of the scrotum, so as to isolate it. Another strip is now passed from behind, in a longitudinal direction, over the lower end of the testis, and upwards upon the anterior part of the scrotum; and then, by a succession of horizontal and vertical strips, neatly overlapping and drawn tightly, the organ is completely enveloped and compressed. To be of any service, the strapping must be tightly and evenly applied; but at the same time care must be taken not to strangle the scrotum by drawing down the upper strips of plaster too forcibly. In a case of syphilitic disease of the

testis, in which I was obliged to have recourse to castration, the whole of the side of the scrotum had sloughed away, leaving the testis exposed and fungating, in consequence of the tight strapping which had been employed before the case came into my hands.

After the swelling has subsided, the patient must wear a suspensory bandage for some months.

The *Induration about the Epididymis*, which usually remains after epididymitis, must be treated by prolonged counter-irritation with tincture of iodine, or by the application of the iodide of lead or iodine ointment. So long as any induration is left it is doubtful whether the secretion is able to find its way through the thickened epididymis.

**Abscess of the Testicle** as the result of orchitis is rare, but is less exceptional after some forms of the disease than others. Gonorrhoeal epididymitis is followed by suppuration only in extremely rare instances. Marmaduke Sheild, who has recently investigated this subject, has collected a considerable number of cases in which suppuration has followed the passage of instruments. Thus, abscess of the testicle has been known to follow catheterization, and also lithotomy and lithotripsy. Traumatic orchitis rarely suppurates. With regard to the inflammation of the testicle which follows specific fevers, Terrillon and Monod state that orchitis after typhoid more frequently ends in suppuration than any other variety, whereas Sheild was unable to find a single recorded case in which abscess of the testicle had occurred after mumps. Wilks and Moxon mention four cases in which they found abscess of the epididymis in pyæmia. Simple abscess of the testicle must be carefully distinguished from those due to tuberculous or syphilitic disease, and also from suppuration in the cavity of the tunica vaginalis.

In true abscess of the testicle the pus forms under the tunica albuginea, adhesion takes place between the testis and the scrotum, the fibrous coat gives way, and the pus gets vent externally through the integuments. Into the aperture that necessarily results a portion of the secreting tissue of the gland sometimes projects, and, becoming inflamed, forms a red, granular, and fungous mass, protruding through and overlapping the edges of the aperture. The *treatment* consists in making an incision as soon as the presence of pus is suspected; if a fungus testis forms, it must be treated as described at p. 1252.

**Inflammation and Abscess of the Cord.**—In some cases the inflammation of the testis may extend, or the disease may, from the first, be limited to the areolar tissue of the cord, giving rise to tumefaction, with a good deal of pain and tenderness, and eventually abscess, accompanied by the usual signs of suppuration. The *Treatment* of such a case must be conducted on ordinary principles, early discharge for the pus being secured.

**Chronic Orchitis** of a persistent character constitutes a distinct disease of the testis, so closely allied to some forms of tumour of this organ in its character and pathology, that it will be more convenient to consider it with the Solid Enlargements of the Gland (p. 1251).

#### HYDROCELE.

By **Hydrocele** is meant an accumulation of serous fluid, formed in connexion with the testis or cord. In the most common form the fluid occupies

ment will usually be found to give the patient relief; but if the case be seen very early, before much swelling has taken place, the application of cold by means of Leiter's tubes (Vol. I., p. 214) or Otis's coil may sometimes cut the inflammation short and give immediate relief. Local blood-letting is often of great service when there is much pain. It is best carried out by puncturing the veins of the scrotum—a far better method than applying leeches, the bites of which are apt to become irritated. This little operation may be very effectually done by directing the patient to stand up, and to foment the scrotum for a few minutes with a hot sponge, so as to distend the veins; these may then be punctured at various points with a fine lancet, and the parts well fomented, so as to encourage the flow of blood. In this way six or eight ounces may be taken in the course of a few minutes; when enough has escaped, the further flow may be arrested by laying the patient down and elevating the part.

If there be much effusion into the tunica vaginalis, constituting acute hydrocele, relief may be afforded by tapping. Puncture of the testis itself, which has been recommended, is a needless and dangerous proceeding. **Chronic Orchitis** of a persistent character constitutes a distinct disease of the testis, so closely allied to some forms of tumour of this organ in its character and pathology, that it will be more convenient to consider it with the Solid Enlargements of the Gland (p. 1251).

#### HYDROCELE.

By **Hydrocele** is meant an accumulation of serous fluid, formed in connexion with the testis or cord. In the most common form the fluid occupies

the sac of the tunica vaginalis ; but in other instances it forms distinct cysts, either in connexion with the testis or upon the cord. It will be convenient to describe hydrocele of the testis and hydrocele of the cord separately.

**HYDROCELE OF THE TESTIS.**—1. **Hydrocele of the Tunica Vaginalis, or Vaginal Hydrocele,** is the ordinary form of the disease. It may occur as the result of acute orchitis, the inflammation of the testis causing the effusion of a quantity of fluid into its serous investment (p. 1234). This, however, is not the kind of hydrocele that is commonly met with ; the fluid so poured out as the result of active inflammation usually becoming absorbed as the parts recover their normal condition. The true or primary hydrocele occurs as a chronic disease, without any signs of inflammation of the testicle, or, at most, with but slight tenderness of that organ. It is most frequently met with in individuals about the middle period of life, commonly without any evident exciting cause, either constitutional or local. It is very common in men who

have lived long in warm climates, and Fayer considers it in some cases to have a malarial origin. Hydrocele is also very frequently seen in infants when but a few days old, and may very possibly be present at the time of birth.

The **Symptoms** of hydrocele are tolerably evident. The disease begins with a degree of swelling and weight about the testis ; the swelling may at first be soft, but after a while becomes hard and tense ; or it may be so from the commencement. There is no impulse in it when the patient coughs. Whatever its original condition, the tumour soon becomes oval or pyriform in shape, being narrowed above, rounded and broad below : it is smooth and uniformly tense and hard : it usually fluctuates, but may have merely a semi-elastic feel. It reaches upwards along the cord towards the external abdominal ring, which, however, is rarely invaded by it.

Fig. 943.—Double Hydrocele, extending through the external abdominal ring and simulating hernia.

and the cord is usually distinctly to be felt above the upper limit of the tumour. Most commonly the size varies from that of a goose's egg to a small coconut ; but sometimes it may attain a considerably greater magnitude than this, and will then cause much inconvenience, as it reaches up close to the external ring, and drags over the penis, causing that organ to be buried in it, so as to interfere with micturition. Gibbon, the historian, had an enormous hydrocele, which was tapped by Cline, who drew off six quarts of fluid.

The most characteristic sign of hydrocele is its translucency. This may always be detected by the Surgeon grasping the posterior part of the tumour with one hand, so as to put the integuments of the fore part on the stretch, then placing the edge of the other hand along the most prominent part of the swelling, and having a lighted candle held close behind. Another very simple and efficient method of determining the translucency is by putting the end of a stethoscope against the tumour, and looking down the tube against the light. If the walls of the sac be thick, or the fluid dark, the transmissibility

of light through it may not be perceived unless the examination be conducted in a darkened room, or it may even become completely opaque. It must not be forgotten that in infants a hernia may be translucent on account of the thinness of the structures at that age.

We have already seen that the ordinary hydrocele of the tunica vaginalis may vary as to size: it may also differ as to shape; in some cases being globular, in others constricted in the middle, or of an hour-glass shape (Fig. 943).

The quantity of liquid varies considerably; there are usually from six to twelve or twenty ounces, but I have known a hydrocele to contain more than one hundred and twenty ounces. The fluid is generally clear and limpid, and of a straw colour. The specific gravity is from 1020 to 1024. It contains albumen in large quantities, but not quite equal in amount to that in pure blood serum. Fibrinogen is abundantly present, but the fibrin-ferment is wanting, consequently the fluid is not spontaneously coagulable. Clotting can, however, be at once determined by the addition of a little blood serum containing white corpuscles. In very large and old hydroceles the fluid may become of a dark-brownish or chocolate hue, owing to the admixture of disintegrated blood; and it will then be found to contain flakes of cholesterine. The sac is usually thin; but in some old cases it becomes thick and dense, lined by a kind of false membrane, and divided by septa or bands, occasionally to such an extent as almost to separate it into distinct compartments. When the sac is thick, and the fluid opaque and turbid, there may be considerable difficulty in detecting the translucency.

The testis is often somewhat enlarged, especially about the epididymis, and frequently slightly tender, more particularly in the early stages of the complaint. It is almost invariably situated in the posterior part of the sac (Fig. 944), but may sometimes be found towards its anterior part. When this is the case, the epididymis will be found turned towards the front, owing to the organ being retroverted. If the hydrocele is of any size and tense, the testicle is lost in it. Its situation can then be recognized by the characteristic pain elicited by pressing on it, and by the opacity of the tumour at that point.

Two uncommon varieties of hydrocele of the tunica vaginalis need short mention.

In the so-called **Congenital Hydrocele**, the funicular portion of the processus vaginalis having remained unobliterated, the sac of the hydrocele is in communication with the peritoneal cavity, and the fluid occupies the same position as the intestine does in a so-called congenital hernia. It differs from an ordinary vaginal hydrocele only in the fact that by raising the tumour and gently squeezing it the fluid can be gradually made to flow back into the general peritoneal cavity.

The name **Infantile Hydrocele** has been applied to a hydrocele of the tunica vaginalis in which the funicular process has been obliterated only at the internal abdominal ring and remains patent below. The hydrocele has therefore a narrow prolongation above which occupies the inguinal canal. The extension of swelling into the inguinal canal and the consequent existence of a slight impulse on coughing render this variety of hydrocele more easily mistaken for hernia than the ordinary form; it is, however, distinguished by its translucency, irreducibility, dulness on percussion, and distinct fluctuation.

The *Coverings* of a hydrocele are the same as those of the testis. Besides the integument, prolongations from the intercolumnar, cremasteric, and transversalis fasciæ may be traced over the surface of the swelling (Fig. 945).

The **Treatment** of hydrocele is *Palliative* and *Curative*. By the *Palliative* treatment the Surgeon seeks simply to relieve the patient of the annoyance caused by the bulk or weight of the tumour; but the *Curative* has for its object the permanent removal of the disease.

The **Palliative Treatment** consists in the use of a suspensory bandage and cooling lotion, or in tapping with a fine trochar. These simple means, however, will sometimes succeed in effecting a radical cure. Thus, in infants, it will happen that the application of evaporating lotions or mild counter-irritants may remove the effused fluid; and indeed it is seldom that any other plan of treatment than this is required in young children. A useful lotion for

Fig. 944.—Hydrocele of the Tunica Vaginalis laid open.

Fig. 945.—Dissection of a Hydrocele, showing its coverings.

the purpose consists of one composed of 3j of chloride of ammonium, 3j of spirits of wine, and  $\text{ʒviij}$  of water; or tincture of iodine may be used. If there be a communication with the peritoneum, a truss should be applied over the inguinal canal. In adults it occasionally happens that simple tapping of the tumour has effected a cure. Many years ago a gentleman from Cuba consulted me for a small hydrocele which had been forming for several months; I tapped it with a fine trochar, and drew off about five ounces of fluid. This was followed by a radical cure. This case bears out a remark made by Brodie, that the few instances in which he had known simple tapping to produce a radical cure occurred in West Indians. I have, however, several times seen hydroceles disappear after having been tapped a few times, without any other treatment, in persons who had never been in hot climates. This simple operation is not, however, altogether free from danger: I have known an old man die from inflammatory œdema of the scrotum after having been

tapped, and tetanus also has followed this operation. After tapping, it usually happens that the hydrocele slowly forms again, attaining its former bulk at the end of about three months. Occasionally it will be found that the hydrocele returns more and more slowly after each tapping; so that, by repeating this simple process at intervals of three, then six, then twelve months, the disease will finally disappear. I have several times seen this occur, chiefly in old men. When a congenital hydrocele has been tapped, the sac soon fills again by drainage into it from the peritoneum; and, indeed, in such a case the fluid of an ascites has been drawn off by tapping the tunica vaginalis.

In tapping a hydrocele a few precautions are necessary, the principal being to avoid puncturing one of the scrotal veins, or injuring the testis. In the majority of cases the testis is situated at the back of the tumour, and is consequently altogether out of the way of the trochar. Its situation should, however, always be determined before the operation. This may be done by pressing with the finger firmly on different points of the sac in succession. The patient will usually be able at once to tell when the testicle is pressed upon by the peculiar "testicular sensation." The seat of the gland may be

Fig. 946.--Tapping a Hydrocele: *a*, Introduction of Trochar; *b*, Position of Cannula.

further determined by the want of translucency at the spot at which it is situated.

The operation is then performed as follows:—1. The trochar should be well washed in carbolic acid lotion (1 in 20). 2. The patient should be made to lie down or sit on a chair, lest he become faint. 3. The Surgeon, then grasping the hydrocele, draws the scrotum back so as to make the coverings on the front of the tumour as thin and smooth as possible. 4. He then selects a spot a little below the middle of the tumour where no vein is visible, and there taps the hydrocele. 5. The trochar must be held with its handle in the palm of the hand, and the index finger must be firmly pressed against the side about three quarters of an inch from its point to prevent its accidentally slipping in more deeply than is intended. It should not be thrust in with a sudden plunge—which is always painful and startling to the patient—but should be steadily pushed forwards, the tumour at the same time being pressed against its point. In this way the operation is almost painless, especially if care is taken to avoid blood-vessels and their accompanying nerves. The trochar is to be pushed in directly backwards (Fig. 946, *a*), but as soon as the trochar is withdrawn the cannula should be inclined obliquely upwards, so as to avoid the chance of pressure against the testis (Fig. 946, *b*). 6. When all the fluid has escaped, the cannula is slowly withdrawn, the edges of the small puncture are pressed together and covered with a little cotton-wool and collodion.

suspensory bandage should then be put on, and rest enforced for a few hours. The fluid sometimes escapes with a pulsatory movement, apparently communicated by the arteries of the cord. If the testicle have been found in front, the hydrocele should be tapped at the side or behind.

Before using the trochar, it is well to see that the cannula fits closely round the neck of the trochar; and, above all, that the instrument has not become rusty by having been carelessly put aside after use on a previous occasion.

The means adopted in the **Curative Treatment** of hydrocele are very various, but may be grouped in three classes:—1. The injection of irritating fluids into the cavity; 2. Drainage; and 3. Partial excision of the sac.

In order that the radical cure, in whichever way undertaken, should be safe and efficient, it is necessary, in the first instance, that the disease should have been allowed to attain a chronic condition, more particularly if the hydrocele have been of rapid growth. In order to prevent its attaining too large a size, it will be well to adopt palliative tapping once or twice before attempting the radical cure. Care must also be taken to remove all inflammation and tenderness about the testis before having recourse to this mode of treatment. If attention be not paid to this, recurrence of the hydrocele will probably ensue.

The treatment by **Injection** is that which is commonly employed. It consists in tapping the tumour in the usual way, and then throwing a sufficient quantity of stimulating fluid into the tunica vaginalis through the cannula to excite a moderate degree of inflammation in it. Port-wine, or a solution of the sulphate of zinc of the strength of ʒi to ʒiij, was formerly employed, but their use has been entirely abandoned since the introduction of iodine and carbolic acid for the purpose.

**Injection of Iodine.**—The injection of tincture of iodine, originally introduced by Sir J. R. Martin, whilst practising at Calcutta, is commonly regarded as a more certain and safe mode of treatment than any other. Many Surgeons prefer the liquor iodi to the tincture, believing it to be more certain in its effect. The operation is performed as follows: The hydrocele is tapped in the usual way and all the fluid withdrawn. If the patient dreads the pain, one drachm of a 5 per cent. solution of cocaine may be injected through the cannula and allowed a few minutes to render the part anæsthetic. The amount of the tincture of iodine injected should vary from two drachms to half an ounce, according to the size of the hydrocele. It is injected with a glass syringe, which must fit the cannula. After injection the Surgeon should rub the scrotum gently over the testis, so as to diffuse the injection equally throughout the sac. One half the quantity thrown in should then be allowed to escape, the cannula should be removed, and the puncture closed with a piece of strapping or wool and collodion. The cannula used for this purpose should be made of platinum and not of silver, which is apt to become corroded and made brittle by the iodine. A good deal of inflammation, with fresh effusion into the sac, will generally be set up, usually accompanied by subacute inflammation of the testicle. The patient should therefore keep in the recumbent position for a few days with the testicle raised. In favourable cases the effusion slowly and completely disappears, but for several weeks at least a suspender should be worn.

Useful as the iodine injection is, it sometimes fails in producing a radical cure of the hydrocele. This is sometimes due to the injection failing to brace

about sufficient inflammation. In other cases, the fluid effused as the result of the operation, instead of slowly disappearing, remains imperfectly or altogether unabsorbed. If the walls of the hydrocele are much thickened, injection may fail, as the cavity cannot collapse. In successful cases the result may sometimes be due to complete obliteration of the cavity of the tunica vaginalis by adhesions; but this is not necessarily so, and examination of the parts after death, in cases previously cured by injection, has sometimes shown a complete absence of adhesions.

The proportion of cases in which the iodine injection fails to bring about a radical cure of the hydrocele is variously estimated by different Surgeons. Thus, Martin stated that in India the failures scarcely amount to 1 per cent.; Velpeau calculated them at 3 per cent. I am not aware that any statistics of this mode of treatment in this country have been collected; but the general opinion of Surgeons would appear to be decidedly in its favour, as being the safest plan of treatment that has yet been introduced. In this opinion I fully concur: yet it is by no means improbable that the success of the iodine injection in this country would prove to be not quite so great as is generally believed. I have seen a considerable number of cases of simple hydrocele of the tunica vaginalis, both in hospital and in private practice, in which a radical cure had not been effected, although recourse had been had to the iodine injection by some of the most careful and skilful Surgeons of the day, as well as by myself. It is especially apt to fail in men advanced in years. In them there is either not sufficient inflammation excited, or if it be, the fluid that is as a consequence effused into the tunica vaginalis is not re-absorbed.

**Injection of Carbolic Acid.**—The use of carbolic acid, instead of iodine, as an injection for hydrocele, has been recommended by Levis of Philadelphia. The advantages claimed for carbolic acid over iodine are that it is more certain and less painful, and also that it produces a more rapid cure with less risk of complications.

Levis recommends that a drachm of pure carbolic acid be liquefied with 5 or 10 per cent. of glycerine. This is injected through the cannula, by which the fluid has been withdrawn, by means of a large hypodermic syringe. Or the Surgeon may follow Jacobson's suggestion to introduce the needle of an exploring syringe into the hydrocele, then to tap the hydrocele in the ordinary way, and after withdrawing the cannula, to screw the syringe on to the needle which is already in position and inject the liquefied carbolic acid. It cannot yet be considered proved that recurrence is less common after carbolic acid than iodine injections. The danger of carbolic acid poisoning seems to be extremely small.

**Incision and Drainage.**—The simple method of introducing a good-sized drainage-tube into the hydrocele and applying an antiseptic dressing has been found frequently to fail to effect a radical cure, the sac refilling after the tube was removed.

*Free incision* was, therefore, recommended by Volkmann. In his operation the sac is incised along its anterior aspect and the fluid evacuated and the cavity washed out with carbolic acid lotion (1 in 20); the tunica vaginalis is then attached to the skin by a few points of suture and the parts dressed antiseptically. The operation is not followed by orchitis, and the wound heals in about two weeks. The results have been very satisfactory, but ~~relapses~~ have occurred even after this.

**Partial Excision of the Tunica Vaginalis**, as recommended by Von Bergmann, must be regarded as the most certain method of treatment, and is available in cases in which from the thickness of the sac-wall injection is unlikely to be successful, or in which it has failed. The operation consists in freely exposing and opening the distended tunica vaginalis, separating the parietal layer from its coverings, and cutting it away at a short distance from the testicle. The edges of the divided tunica vaginalis are sutured to those of the skin.

Kocher and Juillard, however, advise that the sac should not be so extensively removed. They expose the tunica vaginalis and separate it from the superficial coverings of the testicle, great care being taken not to injure the vas deferens or vessels which may be spread out on the sac. All bleeding being arrested, the sac is opened and as much cut away as will leave a sufficient covering for the testicle. The edges of the sac are then united by catgut sutures, and finally the wound in the skin is united in the same way. Kocher recommends no drainage. Juillard drains the external wound. If all goes well no inflammation of the testicle or the sac follows, and the patient is well in eight days.

In hydrocele of children and infants **Acupuncture** will often be found to effect a cure. The scrotum having been put upon the stretch, the hydrocele is punctured at two or three points with a large darning-needle, introduced slowly by being rotated between the finger and thumb. From the punctures thus made the serum slowly escapes into the cellular tissue of the scrotum, whence in two or three days it is absorbed.

This mode of treatment will be found the safest and most effectual in the hydroceles of young children in whom it would be extremely dangerous to attempt a cure by injection of iodine. It may always be safely employed if the application of the lotion before mentioned fails to cure the disease.

It is not always prudent to have recourse to the radical cure in the treatment of hydrocele. In persons advanced in years, or of feeble and unhealthy constitution, the inflammation excited in the tunica vaginalis by any of the means just described may run on to such an extent as to give rise to inflammatory oedema, and even sloughing of the scrotum, with great danger to life. In these subjects it is much safer and usually sufficient to temporize with the hydrocele, and only to tap as occasion arises from the increasing size of the swelling.

**Encysted Hydrocele of the Epididymis.**—In this variety of the disease the fluid does not lie in the tunica vaginalis, but is contained in a cyst which projects from the surface of the epididymis.

Curling pointed out the fact, that small pedunculated cysts about the size of currants, and composed of a fine serous membrane, lined with testated epithelium, are very frequently found beneath the visceral tunica vaginalis covering the epididymis. They are delicate in structure, contain a clear limpid fluid, and are very liable to rupture. They are met with at all ages after puberty. According to Gosselin, after the age of forty they occurred in at least two-thirds of the testes examined to ascertain their presence. Such cysts as these may remain stationary, of small size, undiscernible during life; they may rupture into the tunica vaginalis; or they may enlarge and become developed into tumours of considerable size.

Three vestigial structures are present in the neighbourhood of the epidid-

mis, which may possibly be connected with the origin of these cysts : 1. The *Vas aberrans*, a remnant of the Wolffian duct, which forms a branched convoluted tube leading from the commencement of the vas deferens and extending a short distance up the cord ; 2. The *Organ of Giralès*, a relic of the Wolffian body, which comprises a few small convoluted tubes lined with columnar epithelium, situated immediately above the head of the epididymis ; and 3. The *Hydatids of Morgagni*, a relic of the Müllerian duct, which persists as the small pedunculated cysts above mentioned.

The fluid of these cysts possesses the remarkable characteristic, discovered by Liston, of containing spermatozoa (Fig. 947). Though spermatozoa do not always exist in this fluid, yet they are usually met with, sometimes in small quantities, at others so abundantly as to give it a turbid or opalescent appearance. This admixture of spermatozoa with the clear fluid of the cyst is probably due, as pointed out by Curling, to the accidental rupture of a seminal duct into an already existing cyst. Spermatozoa have, also, but very rarely, been found in the fluid of an ordinary hydrocele of the tunica vaginalis ; and then probably their presence was due to the rupture of one of these cysts into the tunica vaginalis. Hence their presence in the fluid of hydrocele may in most cases be considered as characteristic of the encysted variety of the disease.

The *Signs* of encysted hydrocele of the epididymis differ in some respects from those presented by hydrocele of the tunica vaginalis. The tumour is smaller, more irregular in shape, and does not envelop the testis completely, but is situated behind and above it, in connexion with the epididymis.

The *Diagnosis* from ordinary hydrocele of the tunica vaginalis may be made by observing : 1. That the testis is below and in front, and not covered in by the encysted form of the disease ; 2. That the tumour is more globular or irregular, and less pyriform ; 3. When tapped, the fluid will usually be found to be opalescent.

*Treatment*.—In many cases, when the cyst is small, no treatment is necessary, and in others the swelling reappears so slowly after simple tapping that this alone is sufficient. Injection with strong tincture of iodine or with carbolic acid may bring about a cure, but the treatment does not seem so frequently successful in this as in the last form of hydrocele. If injection fail an incision should be made, and the cyst-wall either partially excised, or, if possible, completely enucleated.

**Encysted Hydrocele of the Body of the Testis.**—This name has been applied to cysts, usually small in size, which are very rarely met with in connexion with the body of the testis, where they lie between the tunica vaginalis and the tunica albuginea. In Astley Cooper's work a multilocular cyst of considerable size in this position is figured, but such a condition is exceedingly rare, and as a rule these cysts are of no practical importance.

**HYDROCELE OF THE SPERMATIC CORD.**—This occurs in two forms, the Encysted and the Diffused.

Fig. 947.—Spermatozoa from Encysted Hydrocele.

**Encysted Hydrocele of the Cord.**—This disease is characterized by the presence of a round or oval tumour, situated on the cord, below or within the inguinal canal. It is smooth, elastic, and, if of sufficient size, may show semi-transparency on examination by transmitted light. It can be pushed up into the abdomen, unless the testicle be drawn firmly down so as to put the cord on the stretch, when the cyst becomes fixed. It receives no impulse on coughing, and does not alter in size on being steadily compressed. Occasionally more than one cyst may be met with. It appears to be due, in most cases, to imperfect closure at one or more points of the funicular portion of the processus vaginalis, and to distension by fluid of the unclosed portions. In some instances in which the cyst lies at the lower end of the cord, it is possible that it arises as a cystic growth from the vas aberrans or the organ of Giralda. These tumours may occur at all ages, but are met with chiefly in the young, and are not unfrequent amongst children. The fluid of a hydrocele of the cord is lighter in colour than that of one of the tunica vaginalis.

The *Treatment* of these cysts is best conducted by dissecting them out. If simply punctured they speedily fill again; injection of iodine is uncertain, and may give rise to troublesome inflammation. In dissecting them out care must be taken not to injure the constituents of the cord. If they rupture, and the whole wall cannot be got away, recurrence is very likely to occur.

The name *funicular hydrocele* is sometimes used for a rare condition in which the funicular process remains open, but is shut off below from the tunica vaginalis. A reducible swelling forms in front of the cord from accumulation of fluid in the open process.

**Diffused Hydrocele of the Cord** consists in the infiltration of the spermatic cord with serous fluid, contained in fairly distinct spaces, and giving rise to an oval or oblong irregular circumscribed tumour, extending below and into the inguinal canal. The *Treatment* consists in the application of blisters, or of counter-irritant plasters. Should the disease prove very troublesome, an incision might be made into the swelling, so as to let out the fluid and allow the cysts to become consolidated.

#### HÆMATOCELE.

By **Hæmatocele** is meant an accumulation of blood in connexion with the testicle or spermatic cord. In the large majority of cases the blood is effused into the cavity of the tunica vaginalis.

**Hæmatocele of the Tunica Vaginalis** is of two kinds, traumatic and spontaneous. The *Traumatic* is by far the more common form, usually arising from a blow on or a squeeze of the testis, by which one of the veins ramifying on the surface of the gland is ruptured, and blood is poured into the tunica vaginalis. It may arise also in tapping a hydrocele, from the point of the trochar being pushed too directly backwards and puncturing the testis, or wounding a vessel in the cord, or occasionally from a blow upon a hydrocele. *Spontaneous Hæmatocele* is a disease of rare occurrence, arising apparently from the rupture of an enlarged spermatic vein into the tunica vaginalis. It attains a larger size, and is altogether a more formidable affection, than the traumatic hæmatocele.

**Characters.**—In whatever way occurring, a hæmatocele slowly but gradually increases until it attains about the size of a duck's egg, or even that

of a cocoa-nut. It is seldom that it becomes larger than this ; but cases are recorded in which the tumour has attained an enormous magnitude. I once operated on a case in which a spontaneous hæmatocele had existed for six years ; it was as large as a melon, and contained, besides about a quart of dark thin blood, a handful of partially decolorized and tough fibrin, the greater portion of which was firmly adherent to the inside of the greatly thickened tunica vaginalis in filamentary and laminated masses, with here and there nodules interspersed. The whole of the interior of the tunica vaginalis closely resembled an aneurismal sac.

The fluid contained in the hæmatocele, when the disease is recent, consists of pure blood. The blood so effused will continue fluid for years ; but at last it may decompose and set up fatal inflammatory mischief ; in some rare instances the tumour becomes partly solidified by the deposit of masses of fibrin lining the interior of the tunica vaginalis, which are sometimes decolorized and arranged as in the case just referred to and in one recorded by Bowman. When the hæmatocele is of old standing, changes take place both in the effused blood and in the sac. The blood becomes at first dark and treacly. As chemical changes advance further it becomes converted into a dirty-brownish fluid, full of shreds of partly decolorized fibrin and crystals of cholesterine. The tunica vaginalis becomes thickened and indurated, and may undergo calcification. This change I found in a patient whose disorganized testis I removed for a hæmatocele of nearly forty years' standing.

The **Symptoms** are generally sufficiently obvious. The occurrence of the tumour subsequently to a blow, strain, or injury, its gradual increase in size, its heavy but semi-elastic or obscurely fluctuating feel, and the absence of translucency, form the most important signs. Its shape is somewhat uncertain. When recent it may have the pyriform shape of a hydrocele, but an old hæmatocele is always more or less oval or rounded in form and smooth on the surface, and thus comes closely to resemble a solid tumour. Except in very old cases, in which atrophy of the testicle from pressure has occurred, the peculiar "testicular sensation" will be perceived by the patient if the gland is pressed upon.

**Diagnosis.**—Hæmatocele may be mistaken for hydrocele, hernia, and other scrotal swellings. The mode of distinguishing it will be described at the end of this chapter, with the diagnosis of scrotal tumours in general. It is most frequently confounded with solid tumours of the testicle ; and upon this fact is founded the excellent rule of practice never to remove a doubtful tumour of the testis without first ascertaining, by an incision into its substance, that it is not a hæmatocele.

**Treatment.**—When the effusion of blood is only moderate in amount, and of quite recent occurrence, further hæmorrhage may be prevented by keeping the patient lying flat on his back with the scrotum raised on a small pillow, and an ice bag or evaporating lotion applied. If the blood shows no signs of undergoing absorption, the Surgeon may evacuate it with a trochar and cannula while it is still fluid. Every care must be taken to avoid setting up suppuration by the use of an imperfectly cleaned instrument. In a case under my care, although the hæmatocele had existed for three years, a complete cure followed the operation of tapping. Such simple treatment as this, however, cannot be depended upon, and it usually becomes necessary to lay open the

sac. This should be done very freely, the altered blood clot and fibrinous deposit being thoroughly removed from the sac. The operation can generally be completed by partially excising the sac wall and suturing its divided edges to those of the skin. The incision should be loosely plugged with a strip of gauze, and an antiseptic dressing applied. The remaining cavity is allowed to granulate from the bottom and thus become obliterated. If the tumour were of very large size, and the tunica vaginalis much thickened, hardened, and parchment-like, with adherent and laminated fibrin, castration might possibly be required. In the instance to which I have already referred, and which is represented in Fig. 948, this was rendered necessary in consequence of these conditions, and was successfully done.

**Hæmatocele of the Spermatic Cord** has been observed by Pott, Curling, Bowman, and others; it is a rare disease, and usually occurs in the form of a tumour of considerable size, suddenly arising after a strain or some violent exertion, giving rise to rupture of a varicose spermatic vein. It commences in the inguinal canal, and thence extends downwards along the course of the cord, through the abdominal ring into the scrotum; but it does not surround or implicate the testis, which can be felt free and movable at its lowest part. On incising such a tumour as this, a quantity of blood, partly fluid and partly coagulated, has been found, sometimes contained in a cavity occasioned by the laceration and separation of the tissues of the cord and scrotum. The most remarkable case of this kind on record is one related by Bowman, in which the tumour, after existing for ten years, had attained so enormous a size, that it reached to the patella, and was so heavy as to require both hands and a considerable effort to raise it from its bed. In this case, death appears to have resulted from decomposition of the contents of the tumour.

Fig. 948.—Hæmatocele with thickened Tunica Vaginalis and adherent Fibrin.

**Diagnosis.**—In its early stages, hæmatocele of the cord would run considerable risk of being confounded with an *inguinal hernia*. The more diffused character of the swelling, however, its irregular feel, its semi-fluctuating sensation, and the impossibility of reduction, might enable the diagnosis to be made (p. 866.) Hæmatocele of the cord may always be distinguished from an accumulation of blood in the tunica vaginalis, by the testicle not being implicated in the former case, but surrounded by the fluid in the latter.

The **Treatment** of this disease must in the earlier stages be of a palliative kind, consisting in rest, support of the tumour, and the application of evaporating lotions. Care should be taken not to incise it at this period, lest the loss of blood from the ruptured vein, after the evacuation of the contents of the tumour, become uncontrollable. In one instance I have known fatal consequences from this cause ensue in half an hour after making an incision into the tumour and turning out the coagula. When, however, the disease has reached a chronic stage, and is no longer increasing, it may be incised, and its contents being turned out, the cavity may be allowed to granulate.

## VARICOCELE.

**Varix**, or **Enlargement of the Spermatic Veins**, is a disease that is commonly met with from the age of puberty to about the thirtieth year, seldom commencing later than this. It usually occurs in feeble individuals having the scrotum lax and pendulous; and in some cases appears to have been brought on by venereal excesses.

The spermatic veins passing from the testicle and epididymis form a considerable plexus of small vessels in the cord, known as the *pampiniform plexus*. In the inguinal canal the branches join into two or three veins, and these again into a single vessel which accompanies the spermatic artery beneath the peritoneum on the psoas muscle and opens on the right side into the vena cava, and on the left into the renal vein. The effect of this arrangement is that the lower part of the veins is subject to considerable tension from the weight of the long column of blood.

In varicocele the veins undergo changes similar to those already described in varices of the lower limb; they become dilated and thickened, except where thin-walled pouches form in the walls, and are very tortuous. When cut across the open mouths of the vessels stand open like that of an artery.

The veins of the left side are much more frequently affected than those of the right side; and never, I believe, are the right veins affected without those of the left side participating in the disease. In these cases of double varicocele, the left side is almost invariably the more seriously affected; but I have seen exceptions to this in one or two instances.

Various theories have been advanced in explanation of this peculiar liability of the left side to be affected. The theory that there is an obstacle at the mouth of the left vein, due to its pouring its contents into the renal vein at right angles to the flow of blood through that vessel into the vena cava, is probably altogether erroneous. Possibly the pressure of a loaded sigmoid flexure on the left spermatic vein may in some instances serve as a partial explanation. It does not appear that any constant difference exists in the arrangement of the valves on the two sides; a valve is usually present at the termination of each vein; this is not unfrequently absent on the left side, but, according to Rivington, a valve will then generally be found in the renal vein close to the entrance of the spermatic. W. G. Spencer, who believes that varicocele is due to a persistence and subsequent enlargement of foetal veins, which usually disappear, finds that at an early period the veins of the left spermatic cord are much more numerous than those of the right.

**Symptoms.**—The symptoms of varicocele consist of a tumour of pyramidal shape, having a soft knotted or knobbed feel, owing to the irregularly swollen and convoluted condition of the veins, with its base upon the testis and the apex stretching up to the external ring. The swelling increases when the patient stands up, if he take a deep inspiration, cough, or make any violent exertion. Its size varies from slight fulness of the veins to a large mass, several inches in circumference at the base. When the patient lies down, it goes up to a certain extent, but immediately returns to its former magnitude when he stands up. It is attended by a sensation of weight and sometimes of pain of a neuralgic character, which is occasionally very acute in the scrotum, the groins, and the loins, more particularly when the tumour is unsupported. This pain is greatly increased on the patient walking or riding; so that in

some cases he is almost debarred from taking exercise, and is prevented from following any active occupation. Debility of the generative organs, with a tendency to seminal emissions and much mental depression, frequently accompanies varicocele. Although the testicle of the affected side often feels rather smaller and softer than its fellow, atrophy as a result of varicocele is extremely rare. Rupture of one of the dilated veins may occur from external injury, giving rise to an enormous extravasation of blood into the areolar tissue of the scrotum. Of this Pott relates a case. I have known the accident to be attended with fatal consequences. A man who "had been romping with his wife" received a blow on a varicocele, when an enormous extravasation of blood rapidly formed in the scrotum and the cord, for which he was admitted into the Hospital. The tumour was incised, and large masses of coagula were turned out. The patient shortly after, in the absence of assistance, suddenly became faint and died of venous hæmorrhage. The bleeding was found to have proceeded from a ruptured spermatic vein.

**Diagnosis.**—The diagnosis of varicocele is always sufficiently easy: its peculiar convoluted feel, its broad base and narrow apex, the manner in which it goes up when the patient lies down, and returns again when he stands up, are sufficient to distinguish it from all other scrotal tumours. From *Inguinal hernia* the disease may be distinguished by attention to the test described at p. 868.

**The Treatment** of varicocele must be conducted with reference to the severity of the symptoms occasioned by it, and to the extent of the disease. When, as is usually the case, it gives rise to but slight inconvenience, palliative treatment is sufficient; but if, as occasionally happens, the disease be a source of actual suffering, or tend to the induction of generative debility, with much mental disquietude or hypochondriasis, then the Surgeon may feel disposed to endeavour to cure the varicocele radically.

**The Palliative Treatment** of varicocele consists in improving the condition of the general health by the use of tonics, improving the tone of the part by cold douches and sea-bathing, and supporting the scrotum in a well-made suspensory bandage.

**The Radical Cure of Varicocele** consists in the obliteration of the enlarged veins, on the same principle that guides us in the management of varix in other situations.

The circumstances for which operation may be practised are as follows:—

1. When the existence of a varicocele disqualifies the sufferer from admission into the public services. One of the cases in which I have effected a radical cure was that of a man in the prime of life, who, wishing to enlist in the Marines, was refused solely on the ground of his having a small varicocele. This I cured by operation, and the man afterwards entered the service.

2. In some cases, the presence of a varicocele of inordinate size causes a distressing sense of weight and pain in the loins and groins, and often inability to stand or walk for any length of time. Here, when the patient is in continual discomfort, or more or less prevented from pursuing his ordinary avocations, it is perfectly justifiable to resort to operation.

3. Cases not uncommonly occur where the pressure of the enlarged veins on the spermatic nerve produces repeated attacks of spermatorrhœa. These cases are, however, more frequently met with out of hospitals, than in individuals of the class who apply to such institutions for relief. In fact,

young men of the more highly educated classes are very subject to varicocele, especially those who habitually lead a sedentary and studious life, as, for instance, young clergymen and lawyers. In these persons a peculiarly hypochondriacal state is brought on by the tendency of the mind to dwell on the condition of the genital organs, and the patient is constantly fidgeting about the local and tangible disease he observes in them.

Since the introduction of the antiseptic treatment of wounds the various methods which were at one time adopted for the subcutaneous ligature or strangulation of the enlarged veins have been superseded by the more certain plan of ligature and excision. The operation is thus performed: An incision, from one and a half to two inches in length, is made over the spermatic cord, commencing above just below the external abdominal ring. The skin and superficial fascia are then dissected carefully through until the cord is exposed. An assistant then feels for the vas deferens, and holding this back with the thumb and index finger of the two hands he makes the mass of veins project prominently into the wound. These are readily isolated *en masse* from the vas behind, and secured above and below with silk. The part of the veins which lies between the ligatures is then excised, and by tying the two ligatures together, as suggested by W. H. Bennett, the cord is correspondingly shortened.

Another method consists in isolating the individual veins and ligaturing and excising them separately. This necessarily increases the length of the operation, and in separating the veins it may be difficult to avoid wounding them. It has, however, been claimed as an advantage of this method that the spermatic artery is not occluded, whereas, when the veins are tied *en masse*, it seems certain that the spermatic artery is also included. It does not, however, appear that there is any risk of atrophy of the testicle as the result of this. The small wound may safely be completely sutured without drainage, and the first dressing may be left unchanged for a week, at the end of which time the wound will usually be found to have united by the first intention.

#### SOLID ENLARGEMENTS OF THE TESTIS.

All solid enlargements of the testicle were formerly classed together under the term **Sarcocoele**; and when they were conjoined with fluid accumulations in the tunica vaginalis, they were termed **Hydro-sarcocoele**. There seems, however, no advantage in the continued use of these terms. Solid enlargements of the testicle may be divided into *Chronic Orchitis*, *Syphilitic* and *Tuberculous Disease*, and the true *Tumours*.

**Chronic Orchitis.**—In this a chronic enlargement of the testis results from inflammatory mischief in the organ not arising from syphilis or tubercle. Such cases are undoubtedly rare. Our increased knowledge of both tubercle and syphilis has taught us that the great majority of cases formerly classed as simple orchitis are really due to one of these two causes. Still, excluding all such cases, a residue is left to which the name of simple orchitis may be applied.

**Causes.**—Chronic orchitis may be a consequence of acute inflammation from any cause. It also arises from blows or squeezes in old people. Most commonly it is associated with some disease of the urinary organs, such as stricture or chronic enlargement of the prostate. In other cases it may be associated with rheumatism or gout.

**Symptoms.**—The testicle feels hard, smooth, and solid, though perhaps slightly elastic at points; it is ovoid in shape, and usually about as large as a duck's egg. It is heavy and but slightly painful, and, except in very old cases, the testicular sensation is present. The cord is usually somewhat thickened, and, as well as the groin, is the seat of pain of a dragging character. The tunica vaginalis occasionally contains serous fluid lying in front of and obscuring the testis. The scrotum is always healthy, and almost invariably one testicle only is affected.

Occasionally simple chronic inflammation may terminate in **Suppuration**. In these circumstances, a part of the indurated testicle softens and becomes prominent, the skin becomes red, shining and thinned, and adhesions form between it and the gland beneath. At last the abscess bursts, and through the aperture a fungus (**hernia testis**, or **benign fungus of the testicle**)

Fig. 949.—Hernia Testis.

speedily protrudes, which grows sometimes slowly, sometimes rapidly, perhaps attaining a very considerable size (Fig. 949). As the fungus increases, the organ appears to atrophy, but in reality is pressed out of the scrotum and merges into the fungus. This fungus is not a new growth, but is composed of the tubules of the testis and inflammatory products. It is in the form of a pale reddish-yellow granular mass. If small and firm, it may become very chronic; but if large, rapidly growing, and loose-textured, it speedily destroys the secreting structure of the testis, leaving nothing but a thickened epididymis and a contracted and shrunken tunica albuginea. In other cases no fungus appears, but a fistulous track may be left, leading to an imperfectly

drained cavity surrounded by indurated tissue, and this may remain unhealed for months or even years. Occasionally, instead of bursting, the abscess may become surrounded by dense fibroid tissue and remain stationary, and this dense wall has been known to calcify. Although the occasional occurrence of abscess of the testicle as the result of simple chronic orchitis seems probable, it may be regarded as practically certain that many cases have been in reality tuberculous.

**Structure.**—On making a section of a testicle affected with simple chronic inflammation, the tunica vaginalis will be found to be more or less adherent, and perhaps separated from the tunica albuginea in parts by small collections of fluid. The tunica albuginea is thickened, often presenting on its external surface a series of firm, glistening layers. The septa of the testis are seen to be thickened, rendering the whole organ hard and firm, and giving it a bluish-grey appearance. The microscope shows that the chronic inflammation chiefly affects the intertubular tissue, but in many cases this is accompanied by catarrhal overgrowth of the epithelium.

**Prognosis.**—Simple chronic orchitis usually terminates in recovery, but the organ may be left somewhat enlarged and indurated, or in other cases it may undergo atrophy as the inflammatory products become absorbed.

**Treatment.**—Strapping and the administration of an alterative course of perchloride of mercury may be tried. If the organ do not diminish in size

if it be a source of much inconvenience to the patient, it must be removed. If accompanied by hydrocele the tunica vaginalis must be tapped, but on no account should injection of iodine be resorted to. If abscesses form, they must be opened. When a fungus has protruded, means must be taken to repress or remove this, lest it go on to complete destruction of the testis. If it be of small size, the best plan will be to sprinkle it with iodoform, and to strap it tightly down with a piece of lint and strapping. If it be larger, it may be shaved off, and the cut surface then dressed with some antiseptic application; care being taken during cicatrization to repress the granulations below the level of the surrounding integument by strapping and pressure. Syme recommended that the pressure should be effected by the integument of the part; an elliptical incision being made round the fungus and the edges of the opening in the skin through which it protrudes pared away, the scrotal integuments are freely separated by dissection from their subjacent connexions, and brought together over the protruding mass and secured by sutures. This operation I have practised with success. Should the fungus be of very large size, so as to include within itself the whole or greater part of the structure of the testis, it may not be possible to save any of that organ; and in these circumstances it is better to remove the whole gland; if left it could never be of any service, and would continue slowly to suppurate.

**Tuberculous Disease of the Testicle**, although occasionally met with in individuals apparently strong and healthy, usually occurs in those of a feeble or cachectic constitution, most frequently in early manhood, but occasionally in advanced life or childhood, and, although often associated with phthisis, it may occur without any evidence of tubercle in other organs. It is very common to find both glands affected, but the disease is usually more advanced in one than in the other. In some cases it arises apparently as a sequence of gonorrhœal epididymitis, or there may be a history of some injury to the testicle. The disease almost invariably commences in the epididymis, which becomes swollen, indurated, and slightly tender. The globus minor is generally affected before the globus major. As the disease progresses, it spreads upwards along the vas deferens until it may reach the prostate and vesiculæ seminales, and forwards through the mediastinum testis into the body of the gland. In some rare cases, it is said to commence in the body of the gland. The progress of the disease is usually slow, but it may go on rapidly to almost complete destruction of the testis. In a well-marked case the following conditions will be found. The testicle is moderately enlarged, but on examination this enlargement will be found to be chiefly in the epididymis, which can be felt as an irregular, craggy, nodulated mass, half surrounding the body of the gland in the form of a crescent situated at its posterior aspect. In the hard mass, which often considerably exceeds the body

Fig. 956.—Tuberculous Disease of Testicle. The epididymis is completely converted into a caseous mass. The disease has invaded the upper end of the body, in which a few separate tubercles are also seen.

of the gland in bulk, spots of softening may be felt. The gland itself may seem soft and natural, or a nodule or two may be felt in its substance. The affection is not as a rule complicated by hydrocele, and in the earlier stages the scrotum is unaffected. The spermatic cord will usually present no general thickening, but the vas deferens is enlarged. Instead of feeling like a piece of whipcord between the fingers it may be as large as a quill. If the disease have extended to the vesiculæ seminales, these can be felt *per rectum* to be enlarged and hardened. There is little or no pain, and on squeezing the gland the ordinary sensation will be perceived by the patient except in a very advanced stage of the disease. As the disease advances, one of the craggy nodules softens, and the skin becomes adherent over it. This process is accompanied by more acute inflammation, usually causing marked increase of pain and tenderness. The adherent skin becomes red and shining, and finally gives way, and the tuberculous abscess discharges, leaving an unhealthy cavity yielding thin pus mixed with soft, shreddy, whitish-yellow sloughs. In some favourable cases the cavity may granulate and close completely, or leave merely a fistulous opening discharging small quantities of serous fluid. In most cases, however, the process of softening extends, other nodules break down, and a great part of the testicle may be destroyed. If an abscess should form in the body of the gland, a hernia or fungus testis may follow, as in simple chronic orchitis. Occasionally exuberant granulations may sprout out from the region of the epididymis, closely resembling the true fungus testis. The general health suffers greatly, and in a large proportion of cases tuberculous disease of the lungs makes its appearance. Most commonly the opposite testicle also becomes affected. Death usually results from the disease of the lungs, but may occur from acute general tuberculosis with tuberculous meningitis. Occasionally the disease may extend to the urinary tract, and terminate fatally from tuberculous disease of the kidneys. In other cases the disease of the testis may occur after that of the kidney and prostate, forming merely a part of general genito-urinary tuberculosis.

In some cases of phthisis, in which the testicles enlarge, and yet give but little trouble, the whole organ, both body and epididymis, may be found converted into a uniform soft cheesy mass. A specimen of two such testicles, from a patient who died from disease of the lungs, is in the museum of University College. In cases of acute general tuberculosis, grey granulations have been found in the testicles.

**Structure.**—On making a section from before backwards through a typical specimen of tuberculous disease of the testicle, the following conditions will be found. The tunica vaginalis may be perfectly healthy, or may be here and there adherent to the tunica albuginea. The tunica albuginea will be normal in appearance, except in the immediate neighbourhood of the tuberculous growth, where it will be thickened. That part of the body of the gland nearest the surface may be perfectly healthy in appearance; there is no thickening of the septa, and the tubules can be teased out under water as in a healthy testicle. As we approach the mediastinum, the gland becomes studded with small hard nodules, not growing in the septa, but in the glandular substance of the testis. In their earliest stage these are merely hard semi-transparent granulations: but they soon show signs of undergoing fatty degeneration in the centre, so that the majority have the appearance of small bodies about the size of a millet-seed, having a yellow opaque centre, and a delicate greyish semi-trans-

parent growing margin. Still nearer the mediastinum these yellow spots coalesce, and form a solid cheesy substance, continuous with a still larger mass of the same kind, which represents the epididymis, and half surrounds the body of the gland in the shape of a crescent. In this larger mass patches of softening are found, forming the tuberculous abscesses above described, and these may extend into the body of the gland. On making transverse sections of the vas deferens, its walls will be seen to be thickened, and its centre filled up with a yellow cheesy material. If the disease be further advanced, the whole gland may be converted into a single cheesy mass, in which softening may be taking place at various parts.

The exact nature of the change that takes place in the production of the condition above described, has given rise to much difference of opinion ; some authors maintaining that the primary change consists in an overgrowth of the epithelium of the tubuli seminiferi and epididymis, which afterwards

Fig. 951.—Tuberculous Testis. *a.* Tubuli seminiferi: *b.* Giant-cells (40 diam.).

undergoes fatty degeneration ; and others asserting that the primary growth takes place between the tubules, and that the changes in the epithelium are secondary.

The accompanying drawing (Fig. 951) represents a section of one of the small outlying nodules in the body of the gland. It will be seen that the change consists in an accumulation of small round cells in a more or less perfect reticulate stroma between the tubules, separating them from each other. At the same time the walls of the tubules have undergone a change, being infiltrated with cells in the same way. The tubules also are choked with epithelium, which in some parts of the same testicle was found to be undergoing fatty degeneration. Towards the centre of the nodule the intertubular growth also becomes caseous. Scattered through the new growth are many large masses of protoplasm containing many nuclei, the tuberculous giant-cells. It is most probable, therefore, that the change commences in the vascular tissue between the tubuli seminiferi, and gives rise to secondary

proliferation of the epithelium; both the intertubular growth and the proliferated epithelium afterwards undergoing fatty degeneration, and forming cheesy masses.

**Prognosis.**—The prognosis of tuberculous disease of the testis is extremely bad. Treatment is of little if any avail, and the patient in the great majority of cases dies sooner or later of disease of the lungs, from general acute tuberculosis or from extension of the disease to the bladder, prostate, and even to the kidneys. In some cases, however, after the abscesses have burst, the cavities may heal, and the testicle remain withered, but free from active disease.

**Treatment.**—The more I see of this disease the more convinced I am that the sooner the diseased organ is removed the better will be the patient's chance of prolongation of life. The danger of infection of the system by acute tuberculosis from a tuberculous testis is so great, that when once the diagnosis has been made castration should not be delayed. In most cases however the operation is at best calculated to give the patient only temporary relief, as the disease usually extends along the vas deferens beyond the reach of the knife, and will continue to progress in the vesiculæ seminales and prostate, unless the patient succumb early to tuberculous disease of the lungs or brain. Before undertaking it, the urine must be examined for pus, and the state of the prostate and vesiculæ seminales ascertained from the rectum, as the operation would, of course, be useless if the affection of the testicle were merely a part of tuberculosis of the whole genito-urinary tract. Should the patient decline to submit to the operation, or his health be so bad that its performance is not advisable, the treatment must be conducted on general principles: alteratives, tonics, especially the iodide of iron, with cod-liver oil, and general hygienic means calculated to improve the health, must be steadily persevered with. Local applications are of little avail. The abscesses must be opened when they form. The cavity should be thoroughly scraped out with a sharp spoon and dressed with iodoform. Under this treatment it sometimes heals rapidly, but the cure is rarely permanent. If fungus form, it is of little use to try to treat it by the methods before described; if the body of the testis be deeply infiltrated with tubercle, no good could result.

**Syphilitic Disease of the Testicle.**—The testicle may be affected in the secondary and tertiary stages of the acquired disease, and also as the result of inherited syphilis in infants. In the secondary stage of acquired syphilis one or both epididymises are occasionally affected. In the later stages of the acquired disease, and also in the inherited form, the body of the testicle is primarily affected, and, as in other viscera, the simple inflammatory and the gummatous varieties are met with.

The **Simple Inflammatory Form**, which has been accurately described by Virchow, consists essentially of a chronic inflammatory overgrowth of the connective tissue between the tubuli seminiferi. The disease may uniformly affect the whole gland or be limited to localized patches. If the whole gland be affected, the organ slowly enlarges to perhaps more than double its natural size. The enlargement will be found to affect the body of the gland, the epididymis undergoing but little if any change; in fact, it may be so far concealed by the thickening round it as to be scarcely recognizable. The aëd and vas deferens are unaffected. The body of the gland feels hard, almost cartilaginous, and the surface is smooth or perhaps slightly irregular. There is no pain, except a dragging sensation in the groin due to the increased

weight of the testicle. There is little or no tenderness, and in the more advanced stages testicular sensation is absent. There is no tendency to softening or to the formation of abscess. The disease is almost always accompanied by hydrocele, but at the same time adhesions may exist at various parts between the parietal and visceral layers of the tunica vaginalis, dividing the fluid into two or more portions, or limiting it to a small part of the surface of the testicle. Most commonly only one testicle is affected, but both may be attacked. In the localized form the induration is limited to one or more portions of the gland, the remainder being soft and healthy.

**Structure.**—On making a section from before backwards, the following appearances are found : If hydrocele exist, the tunica vaginalis will be opaque and thickened, and probably adherent at various points to the surface of the testicle. If no hydrocele be present, the tunica vaginalis may be uniformly adherent. The tunica albuginea will always be found greatly and irregularly thickened, and from it proceed opaque white dense fibroid processes into the substance of the gland. These may in extreme cases be so abundant that no healthy gland substance can be seen between them ; in less severe cases,

Fig. 952.—Syphilitic Gummata of the Testis. *a*, *b*, Gummata cut across ; *c*, Section of Globus minor ; and *d*, Cord.

patches of healthy tubular substance are found at various parts of the organ. A process of cicatricial contraction taking place in these fibroid processes may lead to a dimpling of the surface of the organ. The microscope shows that the change is due to an inflammatory small round-celled growth, which afterwards undergoes a development into a dense fibroid tissue, situated in the connective tissue between the tubuli seminiferi (Fig. 952). The new growth separates and presses on the tubules, and may cause their destruction in large areas.

The **Gummatous Form** is an aggravation of that just described, and presents the same symptoms, with the addition of those caused by the presence of the gummata. These form hard craggy nodules on the surface of the gland, the irregularities so produced being much greater than those arising from simple fibroid induration. The gummata have little tendency to soften, and discharge externally ; yet in rare cases they may do so.

**Structure.**—On making a section of a gland in this condition, more or less of the fibroid induration, above described, will always be found combined with thickening of the tunics of the testicle. The gummata vary in size, from a pea to a hazel-nut. They are of an opaque yellow colour, irregular

shape, and dense leathery hardness. They may be tolerably sharply circumscribed to the naked eye, but are usually surrounded by a zone of fibrous induration of an opaque white colour. The microscope shows around them the same small-celled growth above described, situated between the tubules. The new growth is vascular in the most recent parts. In the older parts the changes described in the chapter on Syphilis (Vol. I., p. 1133) may be seen in their walls, causing their gradual obliteration. Nearer the centre the tubules are found to be pressed upon and destroyed, and the cells of the new growth commence to undergo degeneration; until, in the yellow part of the gumma, nothing but granular *débris* is to be recognized. The gummata may be distinguished from tubercle by their greater toughness and more opaque yellow colour. Tubercle is rarely limited to the body of the testis; gummata, on the other hand, are rarely limited to the epididymis.

**Prognosis.**—If the disease be recognized and treated early, complete recovery

Fig. 953.—Syphilitic Testis. a. Tubuli Seminiferi; b. A part of the round-celled growth beginning to undergo fatty degeneration (180 diam.).

may confidently be hoped for; although relapses are of frequent occurrence. In the more advanced stages, the prognosis is not so hopeful, for, although under proper treatment the new growth may be absorbed, the gland will remain shrunken, puckered, and indurated. This is only what would be expected; for the tubuli seminiferi, as above stated, become more or less extensively destroyed by the pressure of the new growth in the later stages of the disease.

The **Treatment** is that recommended in Chapter XXXVI. for constitutional syphilis. Locally, the hydrocele may be tapped (but on no account injected), and pressure may be applied, by strapping over some mercurial ointment.

**Diagnosis of the Simple, Tuberculous, and Syphilitic Enlargement.**

—The diagnosis of these affections is in some cases easy, in others very difficult. Whatever the form of disease may be, if it be complicated by hydrocele, this may first be tapped in order that the gland may be accurately examined. The hydrocele in these cases may not be translucent, as the tunica vaginalis is often thickened. It must be remembered that hydrocele is a very rare complication of carcinoma, or of adenoma; it is rare with tuberculous disease; less rare with simple chronic orchitis, and very common with syphilitic disease.

From hæmatocele and tumours, the diagnosis may be made by attention to the rules laid down on p. 1266. It having been determined that the swelling is due to one of the three above-mentioned causes, it remains to ascertain which it is. This may be done by attention to the following points: The cord is often thickened and tender in simple chronic orchitis; in tuberculous disease, the vas deferens alone is affected, being frequently considerably enlarged; in syphilis the cord is perfectly healthy. In simple chronic orchitis, the epididymis may be swollen, but the chief enlargement is in the body; in tuberculous disease, the epididymis is almost always the starting-point of the disease, and is enlarged more than the body; in syphilis, the body is first and almost exclusively affected. In chronic orchitis, the enlargement is usually uniform and smooth, and fluctuation is rarely present; in tubercle, the enlarged epididymis is craggy and nodular, and spots of softening may be felt; in syphilis, the body of the gland is greatly indurated, often nodulated, and softening is very rare. The testicle is usually painful and tender in chronic orchitis; in tubercle it is sometimes tender, seldom painful; in syphilis, it is almost invariably perfectly painless, and free from tenderness. The constitutional condition of the patient should also be carefully inquired into. Chronic orchitis usually arises as a sequence of injury, or perhaps gonorrhœa, in patients possibly strumous, gouty, or rheumatic; tuberculous disease occurs almost always in cachectic subjects, with a tuberculous history and a tendency to phthisis. The lungs should therefore be carefully examined. In syphilis, the ordinary symptoms of constitutional syphilis may be present, or a syphilitic history may be obtained. In tuberculous disease, the vesiculæ seminales may often be felt through the rectum to be enlarged, and nodules of tubercle may be felt in the prostate.

#### TUMOURS OF THE TESTIS.

**SIMPLE TUMOURS.**—**Adenoma**, or, as it has been called, *Cystic Sarcoma*, is the most common non-malignant tumour of the testicle.

**Structure.**—The essential feature of this tumour is the presence of cysts, varying in size from a cavity just visible to one as large as a walnut. Between these cysts is a varying amount of solid tissue. The whole tumour lies within the distended tunica albuginea, but will be found to possess a delicate capsule of its own, between which and the tunica albuginea is a delicate layer of a pale yellowish-brown colour, composed of the tubular substance of the testicle spread out over the mass of the growth. The attachment of the tumour is towards the mediastinum testis, and this suggests that the growth springs from the region of the rete testis, the cysts being believed to be derived from the obstructed and dilated tubes of that part of the gland.

Microscopic examination shows that the cysts are lined with an epithelium, sometimes small and cubical, sometimes flattened. The interstitial tissue is composed of young connective tissue in various degrees of development.

This is the typical structure of adenoma testis, but various modifications are met with. In the first place, the proportion of cysts to stroma varies greatly. The contents of the cysts may be clear and thin, or mucous and tinted, or stained with blood. More rarely they are filled with an atheromatous pulp. Occasionally some of the smaller cysts are filled with laminated epithelium, forming pearl-like bodies.

The stroma may be purely composed of spindle cells, or spindle and round cells mixed, or spindle cells with a good deal of fibrous tissue between them. Almost invariably cartilage is present. It is usually in tortuous columns,

Fig. 954.—Adenoma of the Testicle. The external covering is the tunica vaginalis; the next layer is the tunica albuginea; the thin imperfect layer under this is the tubular substance of the testicle spread out over the true capsule of the tumour.

which are clearly visible to the naked eye, and can be picked out of a thick section with a needle. It has been suggested that these columns of cartilage are lying in dilated lymphatics, but careful microscopic examination suggests rather that they are formed by chondrification of the embryonic matrix. The matrix in other cases may assume a myxomatous form, the intercellular substance being mucous in appearance and the cells stellate in form. In many cases the intercellular substance sprouts up into the cysts, forming intra-cystic growths still covered with epithelium. These tumours are usually simple and distinctly encapsuled, but in some cases they became malignant. This may occur from an exuberant growth of the embryonic tissue of the stroma, or, according to Rindfleisch, actual cancerous transformation may take place, the stroma assuming the form of a cancer stroma and the epithelium of the spaces taking on the active growth

of a true carcinoma. Many of these variations may occur in different parts of the same growth.

**Symptoms.**—These tumours are most common in young adults or middle-

Fig. 955.—Section of an Adenoma of the Testicle showing the cysts, the embryonic interstitial tissue and the columns of cartilage.

aged men, and are often attributed to a blow. They cause a steady increase in the size of the testicle, unaccompanied by pain or tenderness. The growth is of varying rapidity, but they often take a year or more to attain

any considerable size. They are firm and elastic, and fluctuating points can not uncommonly be detected in them. The cord is unaffected till a late period unless they become malignant. The epididymis is early flattened out by the growth and cannot be recognized. If not removed they may attain a very great size, and at last the skin covering them may give way and the growth may fungate and bleed.

**Diagnosis.**—The tumour is distinguished from hydrocele by its want of

Fig. 956.—Adenoma of the Testicle more highly magnified, showing the stroma composed of spindle cells and fibres, and the cyst lined with cubical epithelium and part of a column of cartilage.

translucency, its more globular form and its weight. All doubt may be cleared up by an exploratory puncture.

**Treatment.**—The only treatment is early removal, always preceded by an incision into the mass to make sure that it is not a hæmatocele or a hydrocele.

**Enchondroma of the Testicle.**—Cartilage, as before stated, is almost always present in the adenoma of the testis. It may, however, appear alone, in larger or smaller nodules, or infiltrating the gland. It usually commences in the body, and may invade the epididymis. According to Cornil and Ranvier, whenever it reaches any considerable size it is no longer purely cartilaginous, but is mixed with sarcoma tissue and complicated with cysts, so that both clinically and pathologically it merges into the disease just described as cystic sarcoma.

**Fibroma** has been recorded, but is of extremely rare occurrence.

**Dermoid Cysts** are occasionally met with in the testicle, usually in the body of the gland, causing atrophy of the tubular substance by their pressure. They are of course congenital, but are of very slow growth, and may not be noticed till adult life. They usually contain turbid fluid or an atheromatous pulp, often mixed with hairs. In other cases they may lie outside the gland in contact with the epididymis. A case of this kind occurred in University College Hospital lately in which the cyst, which was about the size of the normal gland, lay in contact with the globus minor. It was dissected away without injuring the gland, and was probably a scrotal dermoid which had become adherent to the epididymis.

In other cases foetal remains may be found in the cyst. One of the most remarkable of these tumours that I have seen was under the care of the late

John Marshall. The diseased organ, which was about the size of an ostrich's egg, and felt partly solid and partly fluid, was found after removal to be composed of a large cyst filled with an oily fluid, like melted butter, which solidified on cooling. After removal Marshall found that the sac contained some foetal *débris*, and it was doubtless of an embryonic character. The patient, who was about thirty years of age, had been affected with the tumour from early infancy.

**MALIGNANT TUMOURS.**—**Sarcoma** of the testicle without the presence of the cysts just described is not very common. It is indistinguishable from cancer before removal, presenting the same rapid growth, and softness of structure, giving rise to a smooth elastic globular or oval enlargement of the testicle. It is usually met with in younger subjects than cancer, sometimes even in young children.

Its microscopic structure varies. Small round-celled sarcoma is by far the most common variety, and often runs a very malignant course. Myxo-sarcoma, with large spindle cells intermixed with it, has been described. In very rare cases tumours containing striated muscular fibres mixed with spindle cells have been found in the testicle. They exactly resemble the congenital tumours of the same structure met with in connexion with the kidney.

The *Treatment* consists in early removal of the gland by castration.

**Carcinoma of the Testicle** not unfrequently occurs, and is invariably of the soft glandular variety.

**Characters.**—Cancer of the testicle most commonly occurs in the first instance in the body of that organ, rarely, if ever, affecting the epididymis primarily. The ordinary characters of encephaloid are always well marked in this affection; and the tumour eventually fungates, becoming softened and pulpy. The mass on section is soft, pink in colour, with large yellow patches of fatty degeneration scattered through it. Its substance is often broken down in parts by hæmorrhage. It is impossible to distinguish it from a soft sarcoma without microscopic examination. The microscopic structure is that of a soft glandular carcinoma. The stroma is small in amount but extremely vascular, and encloses spaces of great size filled with large cells of irregular form.

A carcinoma of the testicle may rapidly attain a very considerable magnitude, becoming as large as a cocoa-nut in a few weeks or months. When of this size it is, of course, abundantly supplied with blood-vessels; consequently the spermatic artery and accompanying veins will be found a good deal dilated. The lymphatic glands in the neighbourhood speedily become enlarged, as may be ascertained by deep pressure in the flank. The inguinal glands do not in general become affected until the skin has become implicated by the progress of the disease. It is then also that the cancerous cachexia rapidly develops itself.

The **Symptoms** of carcinoma of the testicle are usually somewhat obscure in the early stages, although they become clearly and distinctly developed as the disease progresses. It is most commonly met with after middle life. The patient first complains of some degree of dragging pain and weight in one of the testes, which on examination will be found to be indurated and enlarged, though preserving its normal shape. The enlargement continues until the testicle attains about the size and shape of a duck's egg, being somewhat tense and elastic, but smooth and heavy. As it increases in size, which it usually does with rapidity, it becomes rounded and somewhat doughy or pulpy.

in parts, where, indeed, it may almost be semi-fluctuating, though in others it continues hard and knobbed. This alteration in feel is partly due to softening of the substance of the tumour, and partly to its making its way through the tunica albuginea. The scrotum is much distended, reddened, and purplish, and becomes covered by a network of tortuous veins; the cord may become somewhat enlarged, hard, and knotty. As the disease advances, the scrotum becomes adherent at some of the softened parts, ulceration takes place, and a fungus projects, which presents all the characteristic signs of fungus hæmatodes; it does not commonly happen, however, that the disease is allowed to go so far as this before removal. The pain is not very severe at first, but after a time assumes a lancinating character, extending up the cord and into the loins.

**Treatment.**—The only treatment of any avail in cancer of the testicle is the removal of the diseased organ. This operation is not performed so much with the view of curing the patient of his disease, which will probably return in the lymphatic glands or in some internal organ, as of affording temporary relief from the suffering and encumbrance of the enlarged testicle. It is therefore an operation of expediency, and should be done only in those cases in which the disease is limited to the testicle, the cord being free and the glands not evidently involved; so that, if recurrence take place, it may not be a very speedy one.

An **Undescended Testis** may become the seat of a tumour, just as it may be affected by inflammation. The combination of malposition of the organ and a tumour is necessarily rare. But its possible occurrence must be borne in mind by the Surgeon, as it may lead to the necessity of an operation for the removal of the diseased mass from the inguinal canal. Cases of this kind are recorded by Storks and J. M. Arnott. The tumour in the first case was as large as a cocoa-nut; in the second as a man's fist. Both were medullary. The operation consists in exposing the tumour by a free incision—if necessary, carried through the tendon of the external oblique—opening the tunica vaginalis, enucleating the mass, and tying with care the shortened spermatic cord, which would probably be the most difficult part of the operation. The possible co-existence of a congenital hernia must be remembered. But it is remarkable that peritonitis does not appear to be the chief danger of this operation. In neither of the cases above referred to did it occur, the patient dying of erysipelas in Arnott's case; of recurrent cancer, a year after the operation, in that of Storks.

#### SOLID TUMOURS OF THE SPERMATIC CORD.

**Fatty Tumours** are not very uncommon. They most commonly occur as small isolated masses near the inguinal ring. They grow slowly and are of no importance except from their resemblance to hernia. The tumour can be pushed through the external ring, but it has no impulse on coughing, nor is there the characteristic slip and gurgle of a hernia as it goes back. Large lipomata invading the scrotum as well as the cord have also been recorded.

**Fibromata and Myxomata of the Cord** have been recorded, but are merely pathological curiosities.

**Sarcomata** have also been met with in this region.

## OPERATION OF CASTRATION.

This operation may be required for the various non-malignant affections of the testicle that have resisted ordinary constitutional and local treatment, and have become sources of great annoyance and discomfort to the patient; in the early forms of malignant disease, also, it may advantageously be practised. Before the operation the parts should be thoroughly shaved, the skin cleansed, and a carbolic towel applied for two or three hours. The patient should be lying on his back on a suitable table, and the parts around the seat of the incision should be covered with towels wrung out in 1 in 20 carbolic lotion. The Surgeon should stand on the same side as the testicle to be removed, and should grasp it at its posterior part with his left hand, in order to make the scrotum in front of it tense. The incision should extend from the external abdominal ring to the lower end of the scrotum. If the operation is being performed for malignant disease the incision will have to be extended upwards, in order that the inguinal canal may be opened and the cord reached at as high a level as possible. If the disease, as often occurs in tuberculous cases, has involved the skin, the affected part must be included between two curved incisions, meeting above and below at the points already indicated. By a few touches with a broad-bladed scalpel, whilst the skin is kept upon the stretch, the tumour is separated from its scrotal attachments, and left connected merely by the cord, which must then be divided. In some cases it will be found advantageous to expose and divide the cord in the first instance before dissecting out the tumour from the scrotum, as in this way a better command over it is obtained. The *division of the cord* constitutes the most important part of the operation, for, unless care be taken, it may retract into the inguinal canal and bleed freely. This accident is best prevented by separating the cord cleanly from the sheath—more especially the cremasteric fascia—and seizing it with clamp forceps above the point at which the ligature is to be applied. The simplest method of ligature consists in transfixing the cord with an aneurysm needle and tying the two halves separately with stout silk, the ends of which are for the present left long. The cord is next divided about half an inch below the ligatures, and it is then allowed to retract slightly, in order to make sure that the ligatures are efficiently applied and that bleeding is not being prevented merely by traction. If no oozing takes place from the stump it is drawn gently down into view and the ends of the ligatures cut off.

Another method consists in picking up the vessels separately in force-pressure forceps, and applying a fine ligature to each. The veins must be tied as well as the arteries. The arteries requiring ligature are usually the spermatic, the cremasteric, and the artery of the vas. The spermatic artery will be found in front, and the artery of the vas deferens behind. This method, which is far more tedious than simple transfixion, has been supposed to be followed by less pain than when the nerves of the cord are included in the ligature. I have not, however, found that much pain is complained of after the ligature *en masse*, and in castration for malignant disease this method certainly has the advantage that it allows the Surgeon to divide the cord at a higher level than he would otherwise do, especially if the incision be prolonged upwards and outwards, and the inguinal canal opened.

In castration for tuberculous disease it is better to separate the vas deferens

from the other constituents of the cord and to divide it separately. If it be found diseased it may be drawn down and a further piece removed in the hope of getting above the disease.

A large number of vessels usually require ligature in the scrotum. All bleeding from this source must be very thoroughly arrested, otherwise the loose tissues of the scrotum may become distended with extravasated blood and very troublesome suppuration may result. After the operation the wound must be accurately closed with sutures and a drainage-tube inserted at its lower end.

There is one danger that may occur in castration in children. It is that in young subjects the *processus vaginalis testis* may not be obliterated, and that thus the peritoneum may be opened up into the wound on dividing the cord. In one case I have known this condition lead to fatal peritonitis.

In some cases considerable induration and tenderness persist in the position of the stump of the divided cord, and occasionally the ligatures set up irritation, and may lead to a small abscess, which refuses to heal until the ligatures have come away. After castration for tuberculous disease a chronic abscess may form around the cord, probably as the result of the *vas deferens* having been diseased above the point of division.

#### GENERAL DIAGNOSIS OF SCROTAL TUMOURS.

The diagnosis of scrotal tumours is not only of considerable importance, but is often attended with very great difficulty; the more so, as they are frequently associated with one another, so that much tact and care are required to discriminate their true nature. Thus, it is not uncommon to find a hydrocele and a hernia; a hydrocele and a varicocele; or these affections co-existing with a solid tumour of the testicle. In other cases, again, as in Fig. 957, a carcinomatous tumour may co-exist with a hydrocele of the tunica vaginalis, and with an encysted hydrocele of the cord; and the different forms of hydrocele may occur together.

Tumours of the scrotum may, from a diagnostic point of view, be divided into two distinct classes:—1, the Reducible; and 2, the Irreducible.

1. **Reducible Tumours.**—These are Hernia, Congenital Hydrocele, Diffuse Hydrocele of the Cord, and Varicocele; in all of which the swelling can be made to disappear more or less completely by pressure and by the patient lying down; re-appearing on the removal of the pressure, or on his assuming the erect posture. The mode in which the tumour disappears tends greatly to establish its diagnosis; though the general character of the swelling, and the history of the case, afford important collateral evidence on this point.

a. In **Hernia** there are the ordinary signs of this affection, such as impulse on coughing, &c. On reducing the tumour, it will be found that its return into the abdomen is accompanied by a gurgling noise, and by the sudden slip upwards of an evidently solid body. In the other reducible tumours, the

Fig. 957. —Carcinoma of the Testicle, with Hydroceles of the Tunica Vaginalis and of the Cord.

diminution and eventual disappearance under pressure are more gradual, and there is no reduction of the mass as a whole.

*b.* The gradual squeezing out of the contents of a **Congenital Hydrocele**, together with its translucency, and the early age at which it occurs, will establish its true character. It must be remembered, however, that hernia in very young infants may be translucent if the gut contains little or no fecal matter.

*c.* In the **Diffuse Hydrocele of the Cord** there is a uniform semi-fluctuating swelling in and near the ring; in which, however, there is no gurgling, &c., no complete reduction, nor sudden disappearance, as in hernia. It is also less defined, and has a less distinct impulse on coughing.

*d.* **Varicocele** may always be distinguished by its pyramidal shape, and is knotted, soft, and irregular feel. After being reduced when the patient lies down, it will, when he stands up, fill again, even though the Surgeon compress the external ring with his fingers. This sign, which distinguishes it from a hernia, occurs also in congenital hydrocele; from which, however, the varicocele may be distinguished by the absence of translucency, the want of fluctuation, and the general feel of the tumour.

2. **Irreducible Scrotal Tumours** are of various kinds: such as Omental Hernia, Hydrocele, Hæmatocele, the various forms of Solid Enlargement of the Testicle. These tumours, though presenting certain characters in common, yet differ somewhat in the predominance of particular signs. Thus, the shape of the tumour is usually pyriform in hydrocele, globular in hæmatocele, and oval in enlargement of the testicle; though this is subject to much variation. The weight is least in hydrocele and greatest in solid enlargement, proportionately to the size of the tumour. The characters of the surface present considerable differences, being smooth and tense in hydrocele and hæmatocele: often irregular, hard, or knotted in the other varieties. The rapidity of the formation of the tumour is greatest in hæmatocele.

*a.* **Irreducible Scrotal Hernia** may be recognised by its irregular feel, by its impulse on coughing, by its occupying the canal and concealing the cord, and by the testicle being distinctly perceptible below it.

*b.* **Hydrocele of the Tunica Vaginalis** is recognizable by its translucency; and the amount of opacity conjoined with this will enable the Surgeon to distinguish the degree of enlargement of the testis, which is conjoined with it.

*c.* In **Hæmatocele** the tumour is of sudden or rapid formation, somewhat globular, opaque, but not very heavy or hard, and smooth upon the surface.

*d.* In **Solid Enlargements of the Testicle** the tumour is heavy for its size, frequently globular or irregular in shape, sometimes knotted, and usually attended with a good deal of dragging pain in the groin, and frequently with some enlargement of the cord.

In these three forms of scrotal tumour, viz., hydrocele, hæmatocele, and solid enlargement of the testicle, the diagnosis can always be made at once from hernia, by the Surgeon feeling the cord free above the tumour.

The point of most importance in the diagnosis of solid enlargements of the testicle is to distinguish the malignant tumours, sarcoma and cancer, from other forms of disease. In malignant tumours, the rapidity of growth, the softness and elasticity of the mass, the implication of one testis only, and the early enlargement of the cord, with its indurated and knobbed condition, are

important signs; especially if the disease occur in young men. In a more advanced condition, the softening of the swelling at parts with a tuberculous condition of the rest, and the occurrence of fungus with speedy constitutional cachexia, will point to the malignant nature of the tumour. In cases of great doubt and difficulty an exploratory puncture may be made, when the contents of the groove in the needle or of the fine cannula will probably determine the character of the growth. In more than one instance, in which there was much obscurity, I have seen the true nature of the disease cleared up in this way.

#### SPERMATORRHOEA AND IMPOTENCE.

Various forms of debility, of loss of power, or of irregularity of action in the generative organs of the male, are confounded together under the terms **Spermatorrhœa** and **Impotence**. These conditions require a more careful consideration on the part of the educated Surgeon than they have hitherto received, as their existence is a source of much distress to the sufferer. They are certainly one cause of conjugal unhappiness, leading perhaps to infidelity on the part of the wife, and occasionally even to suicide of the husband. These affections, which are of extreme frequency amongst all classes of the community, have scarcely received that attention on the part of the profession generally which their importance deserves; the unfortunate sufferers thus are too often driven into the hands of those pestilent quacks who flourish in the metropolis, and infest almost every town in the country, by whom they are not unfrequently ruined in health as well as in purse.

The **Sexual Melancholia** that accompanies these conditions is one of their more striking characteristics. The patient is languid in manner, depressed in spirits, his countenance is pale and haggard, eye dull, expression listless, and he is devoid of all energy. He takes no interest in the ordinary affairs of life, his whole thoughts are concentrated on his own condition, and he feels himself degraded as being unfit for that duty which is alike the first and the lowest of man. This state of mind is commonly the result of some local irritation or disease, re-acting on a morbidly sensitive nervous system; and on examination, the Surgeon will commonly find some local condition that has been the starting-point of the mental malady. Balanitis, phimosis, or varicocele in the male are common occasioning causes. But the most frequent direct exciting cause is undoubtedly masturbation.

We may recognize at least three distinct varieties of generative debility in the male, which may in some cases amount to actual impotence: 1, True Spermatorrhœa, or Seminal Flux; 2, Spasmodic Spermatorrhœa, or Spermatorrheas; and, 3, Aspermia, or Want of Seminal Secretion.

1. **True Spermatorrhœa, or Seminal Flux**, is rare, and is met with chiefly between the ages of eighteen and thirty. It is commonly the consequence of masturbation, or of debility of the generative organs induced by gonorrhœa, or of the continued struggle to repress the natural sexual desires by a life of enforced continence. In this condition there is a mixture of irritability and of debility. The generative organs are excited by slight emotional causes, or by trivial and ordinary physical stimuli—a thought, a look, a word, the movement of a carriage, the effort of straining at stool, will excite the secretion of the testes, which the debilitated state of the parts allows to escape with a feeble ejaculatory effort, or in a kind of leakage of a few

drops from the urethra. In the slighter cases, and in the earlier stages of the malady, these emissions take place but occasionally—three or four times a week, chiefly in the morning, in the mid-state between waking and sleeping, and are preceded by an erection. In the more advanced stages, the emissions occur once or oftener in the twenty-four hours without an erection; the semen at last, when discharged, flowing back into the neck of the bladder, escaping with each discharge of the urine, or being squeezed out after defæcation. The patient's physical and mental state becomes seriously implicated in these more advanced cases of true spermatorrhœa. His countenance is pallid, anæmic, and sallow; his features are drawn, their expression is listless; his eyes lifeless; his spirits depressed, often to the lowest depths of despondency and despair. Connexion is impracticable, as the discharge of semen takes place either before erection occurs, or without its occurrence.

**Diagnosis.**—The first point in making a diagnosis is to ascertain that there is some real disease, and that the patient is not merely the subject of hypochondriasis or sexual melancholia. Various conditions are mistaken for spermatorrhœa by a nervous patient. The white discharge of phosphates occurring at the end of micturition (p. 1029), when the urine is alkaline in some forms of dyspepsia, is often believed by the patient to be seminal fluid; and as this condition is frequently accompanied by the languor of dyspepsia, and is common in those who sit up too late at night and overwork themselves, this harmless condition may give rise to the deepest mental depression.

Prostatorrhœa (p. 1140) is very apt to be confounded with spermatorrhœa; but the diagnosis may always be effected by a microscopical examination of the discharge.

An occasional involuntary emission is not spermatorrhœa. It is common to young men of excitable temperament, and is often the occasion of much groundless alarm. It occurs at that period of life when the generative power is at its highest development. It is simply the result of a hypersecretion of the testes and overflow of the semen. For it, early and congenial marriage is the only remedy. Unless this be adopted, Nature will assert herself. "*Naturam expellas furcâ, tamen usque recurret.*"

The escape of a small quantity of seminal fluid from the vesiculæ seminales while straining at stool is of common occurrence in young men leading a continent life; it need cause no anxiety, and requires no treatment beyond a purge and a cold hip-bath.

Frequent nocturnal emissions in many cases are merely a symptom of dyspepsia, the languid feelings of which the patient complains being very often due to this much more than to the loss of semen. The loss of semen by an involuntary emission causes no more depression than a corresponding loss during coition, and if occurring not more than twice a week has no evil effect. It is the constipation and dyspepsia accompanying it that are the real source of the symptoms.

**Treatment.**—The curative treatment of true spermatorrhœa should consist in giving tone to, and in lessening the irritability of, the genito-urinary organs. With this view, the preparations of iron, phosphorus, nux vomica, and cantharides will be found the most effective. The syrup of the phosphate of iron and strychnine, or the tincture of the perchloride of iron, in combination with those of nux vomica and cantharides, will be found of the greatest service. But under any form of treatment the cure will be slow, and long-

continued perseverance in the use of remedies is imperatively necessary. In addition to these means the cold hip-bath should be assiduously employed. This the patient should use every night and morning ; remaining in it, at first, for about three minutes, but gradually increasing the time of immersion to ten or fifteen. In some cases the cold shower-bath appears to give more tone, and then should be preferred. The patient must sleep on a hard mattress, be lightly covered, and eat no supper. Some satisfactory mental occupation should also be provided, or travelling if possible. These means, useful as adjuncts, will not, however, cure the patient. For this purpose, the local irritability must be removed by the application of nitrate of silver to the prostatic and bulbous portions of the urethra. It will usually be found that there is a good deal of tenderness in these situations, felt on pressing upon the perinæum, or on passing an instrument into the urethra, when, as the point enters the bulb, the patient will suffer much pain. The continuance of this irritation certainly keeps up the seminal emissions, and thus maintains the debility of the genital organs, and the nervous irritability, that are so characteristic of these cases. It may most effectually be remedied by the application of nitrate of silver, as originally recommended by Lallemand. I have employed,

Fig. 958.—Syringe-catheter for applying Caustic to the Urethra.

with much advantage in such cases, the instrument here figured (Fig. 958). It consists of a silver catheter, having about a dozen minute apertures near the end. In the interior is contained a slender piece of sponge, about two inches long, fixed to the expanded end of a firm stylet that moves with the catheter. The instrument is charged by filling the sponge with some solution of nitrate of silver by withdrawing the stylet. It may then be well oiled ; and, being passed down to the spot to be cauterized, the solution is forced out of the aperture by pushing down the rod, which compresses the sponge. I have found this syringe-catheter far safer and more manageable than Lallemand's or any other *porte-caustiques* that act by protruding a spoon or sponge, which is apt to be grasped by the spasmodic action of the muscles of the part, often being returned with difficulty into the shaft, and not without risk of lacerating the mucous membrane. I generally use a solution of the strength of 3j of the nitrate to an ounce of water ; though sometimes only a half or a third of this strength can be borne. The application usually occasions a good deal of irritation for a time, sometimes even a muco-purulent discharge, and can be repeated only at intervals of from ten days to a fortnight. Any undue amount of irritation, particularly after the application, must be subdued by ordinary treatment. After the nitrate of silver has been used two or

three times, the treatment may be advantageously continued by passing twice a week a similar instrument charged with glycerine of tannin. This acts as an admirable astringent, and often acts better than the nitrate.

2. **Spasmodic Spermatorrhœa**, or **Spermatospasmos**, more frequently occurs between the ages of twenty-five and forty. It is frequently predisposed to by residence in a warm climate, or by the existence of some disease about the generative organs, such as stricture, varicocele, neuralgia testis, &c. In these cases there is not, properly speaking, a seminal flux; but complete connexion cannot be effected, as erection and ejaculation are either simultaneous acts or the erection partially subsides before the emission takes place. This form of generative debility is often as much dependent on mental as on purely physical causes.

**Treatment.**—This is a condition of irritability rather than of debility. It often occurs in strong and otherwise healthy men, accustomed to field-sports and out-of-door exercises. There is no evidence of anæmia or of debility of any kind. Hence tonics are not necessary. The remedy most to be relied upon is bromide of potassium in doses of 20 to 30 grains, with cold bathing, and, perhaps, when there is urethral irritation, blisters to the peritæum and along the penis, and belladonna to the interior of the urethra. In addition to these means, it is of the first importance to enjoin moderation in food and drink, and above all, avoidance of alcoholic stimulants.

3. **Impotence** arising from absence of all sexual desire or power, or from premature decay of that power, is not unfrequently met with, and often in individuals who are otherwise strong and healthy; sometimes, indeed, in those endowed with great muscular power, and much given to athletic exercises. This want of sexual desire may be looked upon in many instances as a natural deficiency in the organization of the individual, for which treatment can do little. In other cases it arises from exhaustion of the nervous system by habitual physical or mental over-exertion, by excessive sexual indulgence, over-training, or study carried to an injurious degree. Complete absence of seminal secretion—*Aspermia*—except in cases of atrophy or absence of the testes, must be especially rare. In a patient of mine who died at 54 years of age, and who, according to his own and his wife's account, had been completely impotent for twenty-four years, spermatozoa in considerable quantities were after death found in the testes, which were carefully examined with the view of ascertaining whether they ever secreted semen. Retention of both testicles, or atrophy of both glands from mumps, may cause impotence. Temporary impotence from nervousness is not uncommonly met with in young men immediately after marriage. In these cases the treatment recommended by Astley Cooper, of ordering some harmless medicine, and forbidding the patient to attempt connexion, will usually be effectual.

**Sterility** in the male is a condition that has attracted some amount of attention of late years. It is, of course, not unfrequently connected with, and is probably dependent on, the same conditions that give rise to the various forms of sexual debility that have just been described. But it may occur independently of any of these states—in individuals, indeed, who are possessed of a very considerable amount of sexual desire and vigour. It would appear to be due to some morbid condition of the seminal fluid, in consequence of which the spermatozoa are either absent, or are possessed of insufficient vitality to effect impregnation. The causes of this condition are very obscure; but over-

indulgence in sexual intercourse appears to be amongst the most frequent. It would seem as if each individual were endowed with a certain amount of procreative power, which, if early exhausted, or habitually wasted in indiscriminate intercourse, cannot be restored. Hence, polygamists in the East, or their Western congeners, do not propagate, as a rule, more than the average number of children. Amongst organic causes of this state, chronic epididymitis appears to be the most frequent (p. 1235). The only *Treatment* that can be adopted with any prospect of success, is, in the one case, prolonged avoidance of sexual excitement, and in the other, the removal of local disease existing in the urethra or testis, such as stricture, or thickening or condensation of structure, by the long-continued use of absorbent remedies on general principles. Tonics are valueless in such cases.

Sterility arises also from malformation of the penis, such as complete hypospadias, and more rarely from the size of the male organ rendering complete coition impossible.

In conclusion, I need scarcely say that, in the treatment of that general melancholia or hypochondriasis which accompanies these various affections, much good may be effected by means that directly influence the spirits and the mental condition of the patient. He should be encouraged to travel, to occupy himself with healthy out-door pursuits and amusements, to take regular exercise, to avoid all enervating habits; and, above all, his mind should be cheered by the hope of eventual cure. Should there be any local disease, such as balanitis, phimosis, or varicoccele, that should be subjected to treatment or operation.

## CHAPTER LXXIV.

## DISEASES OF THE FEMALE GENERATIVE ORGANS.

By W. A. MEREDITH, C.M., M.B.

SOME important surgical affections of these organs, such as vesico-vaginal and recto-vaginal fistulæ, lacerated perinæum, &c., have already been discussed. The remaining affections, implicating the Vulva, the Vagina, the Uterus, and the Ovaries, are of the greatest practical interest; but, as their full consideration would lead me far beyond the limits that can be assigned to them in this work, and indeed, belongs to another department of Medicine, I must content myself with a brief indication of the principal surgical points deserving attention.

## INTRODUCTION OF INSTRUMENTS.

**Speculum Vaginæ.**—Vaginal specula of various shapes and materials are commonly used by Surgeons. For examination of the os and cervix uteri, the most convenient and generally adaptable instrument is the ordinary cylindrical glass speculum (Fig. 959), of which the inner mirror-like surface reflects a strong body of light into the bottom of the tube. It has the additional advantage of being readily cleansed, and is not stained by iodine solutions. A similarly shaped instrument—made of box-wood—is useful for the protection of the vaginal wall during application of the actual cautery to the cervix. For exploring the vaginal canal in cases of fistula, &c., recourse should be had to the metal duck-billed speculum, or to one or other of the bivalve varieties of this instrument.

Fig. 959. — Cylindrical Speculum.

**Introduction of the Speculum** can readily be effected without unnecessary exposure. There are two positions in which the patient may conveniently be placed for this purpose. In the first, she lies upon her back with the nates well raised and brought to the edge of the bed or couch, her knees apart, and her feet resting on two chairs; the Surgeon, standing or sitting in front of her, separates the labia with the thumb and forefinger of his left hand, and then passes the speculum gently and steadily between and under them, exerting any pressure that may be required *backward* on the perinæum. This position is in some ways the most convenient for inspection, and for the local application of remedies; but it is often objectionable to the patient, as it appears to entail much exposure, although in reality it need not do so. The other mode of introducing the speculum, which should always be adopted when practicable, consists in placing the patient on her left side in the semi-prone position, with her left arm drawn backwards beneath her and

the knees well flexed, so as to bring the nates close to the edge of the couch; the instrument is then introduced in the same manner as before, the Surgeon sitting *behind* the patient. In whichever way the speculum be used, no force should be employed; the patient should be placed opposite a good light, and care should be taken that the instrument be introduced fairly to the cervix, the position of which may previously have been ascertained by tactile examination.

**Female Catheter.**—The use of the catheter is often required in various diseases, and after operative procedures involving the genito-urinary organs of women. It should be introduced without exposure, by the aid of touch alone—the patient lying on her back with the knees well flexed and somewhat separated. The Surgeon, standing at the right side of the bed, passes his right index finger within the orifice of the vagina and feels the urethra like a cord beneath the arch of the pubes; on tracing this forward, the meatus urinarius, situated immediately above the vaginal outlet, may readily be detected, and the catheter, held in his left hand, is then slipped into the urethral canal along the palmar surface of his right forefinger. The female silver catheter, as generally supplied, has the disadvantage of not readily admitting of

Fig. 960.—Self-retaining Female Catheter (Vulcanite).

thorough cleansing; and, for all practical purposes, the ordinary male gum-elastic catheter—No. 8 or 9—answers equally well. Whichever form of instrument be employed, it should be thoroughly flushed through with plain water immediately after use in order to ensure the removal of any vaginal mucus which may have lodged in it, and be subsequently washed in some antiseptic before being put away. When in constant use, as after certain operations, the catheter, after being washed, should always be kept immersed in an antiseptic solution—of 1 in 20 carbolic acid in the case of a metal instrument, or of 1 in 1000 corrosive sublimate lotion for a gum elastic one. For cases requiring retention of a catheter within the bladder, recourse may be had to the instrument here depicted (Fig. 960), which is fitted, when in use, with a length of rubber tubing through which the urine flows into a vessel beneath the bed containing some antiseptic fluid.

#### DISEASES OF THE EXTERNAL ORGANS AND VAGINA.

The **Vulva** is liable to numerous morbid affections, most commonly of inflammatory origin.

The **Labia Majora**, when involved in the *acute inflammation* accompanying an attack of gonorrhœa, especially in young, full-blooded women, may

occasionally become the seat of an abscess originating in the vulvo-vaginal gland, and requiring evacuation by a free incision on the inner aspect of the affected labium. *Chronic inflammation* of specific origin, or resulting from prolonged irritation caused by the presence of a concealed fissure or ulcer, may induce a kind of solid œdema, sometimes leading to considerable hypertrophy of one or both labia. This condition is usually curable in its early stage by removal of the source of irritation which has led to it; but when of long standing, it may occasionally necessitate surgical interference. The disease known as **Noma** or **Gangrenous Vulvitis**, occurring in young, badly-fed children, has been referred to elsewhere (Vol. I., p. 935).

**Large Condylomata** or **Verrucae** are often met with here as a result of syphilitic or gonorrhœal disease, and if neglected, may ultimately form irregular pendulous masses requiring extirpation by the knife or scissors, or preferably by means of the cautery.

**Fibro-cellular Tumours**, originating as outgrowths from the natural structure of the labia, are occasionally met with, and may require removal by excision with Paquelin's cautery knife.

**Squamous Carcinoma** may develop on the labia, although its more common seat of origin is in the neighbourhood of the clitoris. It usually appears as a nodular growth, which soon ulcerates, forming a sore with raised indurated and sharply defined margins, bleeding readily. While the disease is yet limited, and the neighbouring glands are but slightly, if at all, involved, excision of the affected tissues by the knife, followed by a free application of the cautery, is the proper treatment to adopt.

**Cystic Tumours** of the labia are not unfrequently met with, and may sometimes resemble rather closely the ordinary form of labial hernia, with which, however, their incompressibility and irreducibility, as well as the absence of any impulse on coughing, will prevent their being confounded. These cysts, which require removal by a little simple dissection, usually contain a clear glairy fluid, the retained secretion of the vulvo-vaginal gland; sometimes, however, the fluid is turbid and of a dark brownish hue from admixture of blood. Tolerably free hæmorrhage from the vascular tissues of the labium may follow their removal, requiring for its arrest the use of the cautery, or the firm pressure of a pad secured by a T-bandage. Occasionally these cysts project on the *inner* surface of the vaginal orifice, in which situation a simple incision, followed by removal of an elliptical portion of the cyst wall, is usually sufficient to effect a cure.

**Varix** and **Hæmatoma**.—A varicose condition of the veins of the labia and adjacent structures, apart from pregnancy, is occasionally, though rarely, met with, and may require surgical interference, not only on account of the discomfort arising from it, but also in order to avoid the risk of the formation of hæmatoma by subcutaneous rupture of the distended vessels. Destruction of varicose veins in the region of the *mentus urinaria* can be effected with Paquelin's cautery, care being taken to protect the healthy mucous membrane from injury by the employment of a bone speculum. In case requiring operation for the removal of greatly enlarged *labial* veins, the safest plan to adopt is that of transfixing the affected labium with a stout pin, and then strangulating the entire mass of diseased vessels by means of an elastic ligature. A *suppurating* hæmatoma of the labium should be carefully opened and thoroughly evacuated, and treated antiseptically.

**Occlusion of the Vaginal Outlet** in young children, due to congenital adhesion between the nymphæ, is a condition which usually occasions a good deal of anxiety to the parents. It may, however, easily be remedied by tearing through the adhesion with a blunt probe while the opposed nymphæ are forcibly separated by the thumb and finger of the operator's left hand; a small strip of oiled lint should be placed in the vaginal orifice to prevent reunion of the torn surfaces.

**Imperforate Hymen** in young adults is a congenital malformation causing serious inconvenience and even possible risk to life owing to the resulting retention of the menstrual secretion, which may accumulate to an immense extent, becoming gradually converted into a thick chocolate-coloured fluid of the consistence of treacle. The condition may not attract attention until the age of seventeen or eighteen, when the non-appearance of the menstrual flux, in spite of periodical constitutional disturbances, usually leads to an examination which reveals the cause of the obstruction. The hymen, as a tense elastic membrane, projects downwards between the labia owing to the pressure of the fluid distending the vagina, which may be felt *per rectum* as an elastic swelling filling the pelvis and occasionally extending upwards into the abdomen as far as the umbilicus, bearing the uterus as a small firm tumour on its upper surface.

*Treatment* for the relief of this condition is best undertaken about midway between the menstrual periods, as indicated by recurrence of the molimina. The operation required, unless carefully performed, is by no means free from risk. The patient having been placed in the lithotomy position, the parts are first thoroughly cleansed with an antiseptic solution. A small vertical incision, one inch in length, is next made in the region of the hymen by cautiously dividing the obstructing tissues until the retained fluid is reached. The use of Paquelin's cauterizing knife for this purpose is preferable to that of an ordinary scalpel, as tending to obviate risk of septicæmia. In opening the membrane, care should be taken to avoid injury to the urethra, an accident to be guarded against by ordinary caution. Once the opening is made, the fluid should be allowed to escape slowly without the assistance of any pressure whatever from above, in order to avoid the risk of rupturing the Fallopian tubes or any vascular adhesions around them, by promoting too rapid collapse of the distended sac. When the fluid ceases to flow, the vertical opening is to be enlarged by two lateral incisions converting it into the form of a cross, and the cavity may then be very gently irrigated by a stream of warm carbolized lotion (1—40). Finally, a small plug of iodoform gauze is placed in the newly-made orifice, and covered over with a pad of antiseptic wool, which should be changed as often as may be rendered advisable by the amount of discharge. The use of the catheter is usually required for a day or two after the operation. The patient should remain in bed for a fortnight.

**Partially Perforate Hymen** in young newly-married women is a condition which may occasionally call for interference; incision of the rigid membrane with a probe-pointed bistoury, followed by forcible dilatation under an anæsthetic, is the proper treatment in such cases. When severe spasmodic pain of the character usually described as *laginismus* is habitually induced by attempted coition, its origin, failing other causes such as urethral caruncle, small fissures or ulcerations, etc., may occasionally be traced to a hyperæsthetic condition of the remains of the hymen. In these cases, excision with curved scissors of a complete ring of the sensitive tissue at the vaginal orifice

will usually cure the condition ; and this the more surely, if followed by forcible dilatation and the introduction of a firm plug of iodoform gauze, which may be left *in situ* for several days.

**Hypertrophy of the Clitoris** and its prepuce may be met with as a rare congenital condition ; the organ being found enlarged and elongated, and in some cases even constituting a tumour of considerable size. Under such circumstances, excision of the abnormal clitoris with the help of Paquelin's cautery may be necessary on account of the irritation caused by it. Removal of a *normal* clitoris as a means of cure in cases of epilepsy and of erotomania, is a procedure as unscientific as would be that of removing the glans penis for the cure of similar affections in the male. The operation, at one time recommended and practised, has been proved by the experience of the profession to be as useless in its results as it is unscientific in its principle. *Carcinoma of the Clitoris* requires excision of the diseased organ, to be followed by a free application of the cautery.

The most common affection of the *meatus urinarius* is that known as urethral caruncle or vascular growth, the treatment for which has been described elsewhere (Vol. II., p. 1185).

**Perineal Abscess**, occurring as a result of chill or of local injury, requires early incision with a view to avoiding burrowing of pus and possible formation of fistula.

**Rupture of the Perinæum**, caused by the passage of the child's head during parturition, is an accident of not unfrequent occurrence in the case of primiparæ. The after-importance of the injury, from a surgical point of view, depends upon the extent and depth of the laceration. If merely the soft tissues between the posterior commissure of the vulva and the margin of the anus have been torn through, the rupture is styled *incomplete* ; and the necessity for subsequent surgical interference will depend somewhat upon the co-existence of any prolapse of the posterior vaginal wall. Should this complication be present, a plastic operation for the repair of the torn perinæum and the restoration of the parts to their normal condition is the proper treatment to adopt. In cases where the laceration has extended onwards through the anal sphincter muscle, the condition is described as one of *complete rupture*—a much more serious state of things than that above alluded to, and one which imperatively demands surgical interference in consequence of the loss of control over the lower bowel involved by the injury. For a detailed description of the operation for repair of ruptured perinæum, the reader is referred to Vol. I., p. 898.

**Prolapse of the anterior or of the posterior wall of the vagina** is not unfrequently met with in hospital practice. In either instance the condition usually originates in continued neglect on the part of the patient with regard to regularity in emptying the bladder or the lower bowel respectively. Unless proper means be adopted to rectify the tendency to prolapse by due regulation of the patient's habits, combined with the use of astringent injections or pessaries and the wearing of some suitable form of "support," the condition may become extremely troublesome owing to gradual implication of the floor of the bladder in the prolapse of the anterior vaginal wall (*cystocele*), or of the rectum in the case of a protrusion of the posterior wall of the passage (*rectocele*). The two conditions not uncommonly coexist in varying degree in cases of uterine prolapse.

Operative procedures undertaken with a view to remedy a prolapse of the *floor of the bladder* by excising a portion of the mucous membrane of the anterior vaginal wall are by no means very satisfactory ; and the condition in question may generally be best treated by the wearing of an artificial support. In cases of *rectocele*, on the other hand, much benefit may be derived from the usual operation for the repair of ruptured perinæum, combined with the removal of a wedge-shaped portion of the redundant mucous membrane covering the prolapsed bowel, by which means the original outlet is narrowed and the protrusion supported.

A somewhat rare condition, termed *sacculated dilatation of the urethra*, in which the lower wall of this passage projects into the vaginal canal in the form of a small oval protrusion, causes much discomfort owing to the escape of the small amount of urine contained in the pouch subsequently to the completion of micturition. The proper treatment consists in excising an elliptical portion of the vaginal mucous membrane underlying the urethra, and adapting the edges with silkworm-gut sutures.

**Congenital Absence of the Vaginal Canal** is a rare malformation, usually associated with imperfect development of the uterus and its appendages, but occasionally met with in women otherwise perfectly well formed as regards the external organs of generation and the mammary development. The actual condition may be detected by digital exploration of the rectum while a sound is in the bladder : the two cavities will be found in close apposition without any intervening organs, the point of the bladder sound being felt thinly covered through the gut. **Complete Absence of the Uterus and Ovaries** can be further confirmed, if desirable, by combined rectal and abdominal palpation while the patient is deeply anaesthetized. No surgical interference can be entertained in such cases ; and none is required, as the imperfect development of the uterus precludes the possibility of any menstrual accumulation. The condition known as **Atresia Vaginæ**, or **Imperforate Vagina**, is one of congenital partial occlusion of the canal. The symptoms arising from it are identical with those caused by retention of the menstrual secretion in cases of imperforate hymen ; the chief distinguishing feature from this latter condition being the absence in these cases of any notable bulging of the hymen at the vaginal outlet—a fact accounted for by the thickness of the obstructing tissues.

Before attempting to restore the patency of the original canal, it is important to form a tolerably accurate idea of the depth of the obstruction and of the position of the distended sac by means of combined rectal and vesical exploration with a bladder sound. This latter should be retained *in situ* by an assistant in such a manner that the urethra and bladder may be kept well drawn upwards out of harm's way during the operation, while the Surgeon's left index finger in the rectum protects the bowel from injury, and serves as a guide in tearing through the septum.

A transverse incision is now made over the seat of the hymen—about midway between the urethra and the anus, and the obstructing tissues are gradually torn through by the right forefinger of the operator, aided by occasional touches with the scalpel or scissors, until the distended sac is reached. This is punctured and evacuated with precautions similar to those already recommended in cases of imperforate hymen. The newly-restored canal is then carefully packed with strips of iodoform gauze, which should be replaced at the end of twenty-

four hours by a tightly-fitting vulcanite plug. This may be allowed to remain in the passage for three or four days, when it is to be replaced by a similarly-shaped plug of stout glass, having a central perforation to allow of the escape of fluid through it. By means of these dilators, which are maintained in position by tapes fastened over the everted rim, and thence passing upwards in front and behind to be secured to a waistband, the canal is kept patent until it is fully cicatrized. The inevitable tendency to contraction of the newly-made orifice must subsequently be kept within limits by means of a suitable pessary or by the occasional use of dilators.

An *acquired* form of atresia is sometimes met with in which partial obliteration of the upper part of the vagina with occlusion of the cervical canal has resulted from cicatrization following injuries inflicted during parturition. The obstruction in such cases may occasionally be overcome by the forcible passage of a uterine sound. Should this prove impossible, a long exploring needle may be introduced through the obstruction into the uterine cavity while the cervix is steadied by the help of a tenaculum; a fine-bladed tenotomy knife is then cautiously passed upwards into the cervical canal along the needle track, and the obstructing tissues are divided in a radiating manner sufficiently to allow the introduction of a glass cannula, through which the retained blood is allowed to escape.

**Various discharges** connected with the female organs of generation fall under the observation of the Surgeon; they may proceed from the mucous membrane covering the external parts, or from that lining the vagina; or, again, from the interior of the cervical canal or of the uterine cavity. When derived from the *external organs* or the *vaginal canal*, these discharges are frequently, although not necessarily, of gonorrhœal origin, and then require to be treated in the way that has been mentioned at p. 1173, Vol. II. When of a simple nature, proceeding from mere excessive secretion from the mucous glands of these parts, the use of astringent injections, combined with attention to the general health, will usually succeed in effecting a cure.

Vaginal discharges of a *purulent* character may occur in *young children*, as a result of constitutional debility. Occasionally such discharges lead to a suspicion that the child has been improperly tampered with; and, although they may of course be occasioned by some violence inflicted on the genitalia or may even be actually due to gonorrhœal infection, it must be borne in mind that in the great majority of instances such symptoms arise solely from constitutional conditions, and are in no way referable to external causes. The *Treatment* consists in attention to strict cleanliness, the use of warm lead lotions, and improvement of the general health, with removal of any local cause of irritation, such as thread worms from the lower bowel.

*Discharges* dependent upon unhealthy conditions of the *cervix* and lining membrane of the *uterus* usually require special treatment, for the details of which the reader may best refer to works devoted to the Diseases of Women, where a consideration of the nature and management of *uterine displacements* will also be found.

#### TUMOURS OF THE UTERUS.

The so-called **Fibroid**, or more correctly **Fibro-myomatous Growth**, constitute by far the most common form of uterine tumour. Structurally, they

consist of fibrous and of unstriped muscular tissue combined in varying proportions, and hence constituting growths of varying density, according to the relative preponderance of one or the other of these component elements.

The *ordinary fibro-myoma (hard fibroid)*, occurring either singly or as multiple formations in the body of the uterus, is characterized by a marked excess of the fibrous elements, which are commonly arranged in concentric bundles around one or numerous centres. The growth, of a more or less distinctly circumscribed nature, is usually directly continuous at one point with the uterine tissues, but is elsewhere surrounded by a layer of areolar structure, constituting what is known as its *capsule*. This latter contains numerous ramifying vessels, often of considerable size; but the vascular supply to the substance of the tumour, derived from vessels entering it at its uterine base, is as a rule comparatively scanty—a fact which accounts for the slow rate at which these tumours generally grow.

The comparatively rare type of tumour known as a *soft fibroid*, or true uterine *myoma*, and characterized structurally by a very great preponderance of muscular tissue, partakes more of the nature of a hypertrophic growth, inasmuch as its substance merges gradually into that of the surrounding uterine wall. A condition of this sort generally gives rise to a symmetrical tumour, which grows very rapidly, in consequence of its great vascularity, and is accompanied by profuse uterine hæmorrhage.

In the great majority of cases, ordinary fibro-myomatous disease of the uterus gives rise to no symptoms warranting surgical interference of any kind. The normal tendency of these tumours is to grow slowly until the age of the menopause is reached, and then gradually to undergo a process of natural involution, consequent upon their diminished vascularity, until they finally disappear completely. In a comparatively small proportion of instances, however, active treatment may become necessary as the best means of saving life under one or more of the following conditions, viz., persistent and uncontrollable uterine hæmorrhage; severe pain or other serious pressure symptoms caused by pelvic outgrowths; rapid increase in the size of an abdominal tumour (sometimes due to cystic or other degenerative changes).

In considering the question of *surgical treatment*, the ordinary classification of intramural or interstitial, subperitoneal, and submucous growths may conveniently be followed, always with the understanding that the two last-named are secondary developments of the intramural variety, the terms “subperitoneal” and “submucous” indicating the direction followed by the original growth in the process of its gradual extrusion from the substance of the uterine wall. As a general rule, it may be stated that the amount of uterine hæmorrhage induced by fibro-myomata is proportionate to the degree of enlargement of the uterine cavity caused by their presence, and is further dependent upon the propinquity of any growth to the mucous membrane lining the cavity. Thus, a pedunculated subperitoneal tumour may exist without the occurrence of any unusual menstrual loss, while a comparatively insignificant submucous or polypoid growth often gives rise to most persistent and alarming hæmorrhage.

The **Diagnosis** of a uterine tumour, apart from the symptoms of pain and hæmorrhage already alluded to, is to be arrived at by physical examination—notably by combined abdominal and vaginal (or rectal) palpation—by which means the consistence and contour of the growth are to be made out, and its continuity with the uterus definitely ascertained.

The **Operative Treatment** of uterine tumours varies somewhat, according to the site and connexions of the growth or growths.

The **Subperitoneal** variety, when unaccompanied by much co-existent enlargement of the uterine body, may occasionally require operative interference on account of the size of the tumour and the consequent peritoneal irritation caused by its presence. The operation usually performed under such circumstances is known as *Myotomy*, or more correctly as *Myectomy*. In the case of a *pedunculated* tumour, the growth, having been extracted from the abdominal cavity through a median incision, is supported by an assistant while the Surgeon secures the pedicle by means of a tightly applied ligature of stout silk; the two ends of this, threaded together on a straight needle, are then passed through the substance of the pedicle immediately above the level of the constricting ligature; the needle is withdrawn, and the threads brought round again on either side are firmly tied together above the knot of the first loop. The pedicle is now divided, and the cut edges of its peritoneal investment are sutured together across the face of the uterine stump with a view to avoiding the subsequent formation of adhesions thereto. In dealing with a *sessile* outgrowth, the body of the uterus should first be encircled temporarily by an elastic ligature for the purpose of controlling hæmorrhage. The tumour is then cut away, and a wedge-shaped portion is excised from its uterine base so as to leave two flaps of tissue with an outer covering of peritoneum; after being suitably trimmed down, these are to be accurately united face to face by three or four successive rows of fine silk sutures, the first row of which must obliterate the angle at the base of the flaps, while the last one unites the edges of the divided peritoneum.

The surgical treatment of tumours involving the body of the uterus entails the performance of one or other of two operations, known as *Oöphorectomy*, and abdominal *Hysterectomy*.

**Oöphorectomy, or Removal of the Uterine Appendages** (ovaries and tubes), is an operation aiming at the premature induction of an artificial menopause, with the view of thus promoting the decrease and final absorption of the uterine growths. The procedure in question, compared with the alternative operation of hysterectomy, has the advantage of entailing much less immediate risk to life—its average mortality in skilled hands amounting to only about 5 per cent.; but, on the other hand, it must be noted that its ultimate results as regards the immediate arrest of hæmorrhage and subsequent wasting of the growth are not always completely satisfactory; and further, that it is not applicable in all instances—notably in the case of uterine myoma (soft fibroid), and in cases of large multiple tumours when the size and position of the individual growths may render it impossible to effect with safety the complete removal of the appendages.

The **Operation** is performed as follows: The abdominal cavity having been opened by the usual median incision, the Surgeon, standing on the right side of the patient, introduces the fore and middle fingers of the left hand and explores the surface of the tumour until he detects the position of the left ovary and tube, which should be firmly grasped between his two fingers, and thus brought up into view—a manœuvre to be somewhat facilitated, if the ovary be deeply situated, by drawing the summit of the tumour over towards the right side. When fully raised, the ovary and tube are securely held in the operator's left hand, while he clamps the broad ligament well beneath the

ovary with a pair of large pressure forceps. A single-thread ligature of No. 4 silk is now passed through the broad ligament immediately below the forceps by means of a handled needle, which is withdrawn leaving a loop of silk on one aspect of the pedicle, and the two free ends of the ligature on the other. One of these latter is now carried round the outer edge of the broad ligament and passed through the projecting loop; the forceps are removed while an assistant holds up the ovary and tube; and the free ends of the ligature which thus encircles the compressed tissues by a twisted or figure-of-8 loop, are drawn upon firmly before being tied together at the inner border of the pedicle, and thence brought round on either side to be again united at the outer border, where they are finally cut short. The ovary and tube are then cleanly removed, and the stump is dropped in, the same procedure being subsequently repeated on the opposite side.

The operation of **Abdominal (Supravaginal) Hysterectomy**, involving removal of the entire mass of a fibro-myomatous tumour, including the body of the uterus with its appendages, should never be undertaken without the most careful forethought as to the necessity for its adoption. The possibility of discovering in any given instance of uterine tumour, when interference is

Fig. 961.—Serre-nœud with wire.

undertaken with the object of dealing with the uterine appendages, that their removal cannot be effected, and that resort must consequently be had to the major operation, should always be kept in view when considering the advisability of operative treatment in these cases.

The performance of hysterectomy in the case of a more or less symmetrical tumour not involving the lower segment of the uterus, although necessarily entailing risk to life, offers no very serious difficulty to any one accustomed to deal with abdominal growths. On the other hand, the removal of a multiple tumour with a broad pelvic base opening up the layers of one or both broad ligaments, is an undertaking which may tax to the utmost the knowledge and skill of the most experienced Surgeon.

The following are the steps of the operation in a case presenting no special difficulties of any kind. The tumour, having been turned out of the abdominal cavity, is held up by an assistant while the operator encircles the uterus, usually at or about the level of the junction of the body and cervix, with a flexible wire connected with the instrument known as Kœberlé's *serre-nœud* (Fig. 961). Both uterine appendages should be included in the loop, while care is taken that no portion of intestine be nipped by it, and that the bladder be kept well out of harm's way in front. The wire, having been properly secured, is tightened by means of the spiral screw sufficiently to control

haemorrhage, and a stout pin (Fig. 962) is then passed through each broad ligament and through the uterine tissues immediately *above* the constricting loop, before cutting away the mass of the tumour together with the appendages. After this has been done, the distal portion of the uterine stump is carefully trimmed down, and the edges of its peritoneal investment including those of the divided broad ligaments on either side, are laced together across its upper surface by means of a continuous silk suture in order to prevent subsequent retraction. While these steps are being taken, the constricting wire should be further tightened by an occasional turn of the screw. The abdominal parietes are now adjusted carefully around the uterine stump supported externally by the transfixing pin, and the divided edges of the peritoneum are then united immediately behind the pedicle by a silk suture which also includes a small fold of the serous membrane covering the posterior aspect of the cervix uteri *below* the level of the wire; by thus ensuring early adhesion between the serous surfaces referred to, the general peritoneal cavity is in great measure protected from infection through the strangulated tissues. All sponges are now removed from the abdomen with the exception of a flat one which serves to protect the cavity during the insertion of the sutures; after its removal, the incision is closed and the wire is finally tightened again.

Fig. 962.—Transfixing Pin for Uterine Stump.

The uterine stump, having been well dusted with iodoform powder, is then packed round with pledgets of dry absorbent gauze, and the abdomen is covered with a dry dressing of some antiseptic material, to be kept in place by strapping and a flannel binder. If all go well, this dressing need not be disturbed for a week, at the end of which time all dressings should be removed and the distal portion of the stump trimmed down to the level of the pin. One of two methods may now be adopted: the *serre-nœud* may be daily tightened up until the wire finally cuts its way through the constricted tissues; or the wire may at once be clipped through at its point of attachment, so as to allow of the withdrawal of the *serre-nœud*; the transfixing pin is cut out from the face of the stump, and the expanded wire loop is then readily removed, leaving a slough which gradually separates in the course of from three to four weeks, as the cavity heals by granulation.

In the class of cases above referred to, as characterized by the presence of multiple growths involving the lower segment of the uterus, and expanding one or both broad ligaments, the operative details are necessarily much more complicated:—The ovarian vessels (artery and venous plexus) in each broad ligament are first to be secured in their continuity by a ligature of which the ends are afterwards cut short. If the bladder be drawn up over the front of the tumour, its upper attachment should be freed by a horizontal incision through the serous coat of the uterus, in order that the viscus may be pulled downwards sufficiently to allow of the application of an elastic ligature around

the base of the tumour at as low a level as may be possible, for the purpose of controlling the uterine arteries. The ligature in question should twice encircle the uterus so as to ensure even and continuous compression, its free ends being secured by a pair of pressure forceps, which can readily be removed should the ligature require tightening. A circular incision through the outer layer of uterine tissue is now carried horizontally around the tumour dividing the ovarian vessels in either broad ligament above the level of their ligature. While this is being done, the mass of the tumour is held forcibly upwards by an assistant in order to facilitate the enucleation of its base, which process is rapidly carried out until the remaining portion of uterine tissue is sufficiently reduced in size to admit of the application of the serre-nœud wire immediately *above* the groove occupied by the elastic ligature. This latter is removed as soon as the wire has been properly secured and tightened. The transfixion pin is then passed, and the mass of the tumour is cut away, usually leaving a somewhat bulky stump which, together with the remains of the uterine capsule, will require to be freely trimmed down before it is reduced to a convenient size. The subsequent management of the case is identical with that already described.

The treatment of the uterine stump by means of the serre-nœud, known as the *extra-peritoneal* method, is on the whole the most generally applicable as well as the safest plan for adoption in dealing with fibro-myomatous tumours. It, however, involves a somewhat protracted stage of convalescence in bed, lasting usually five to six weeks; and further, the operation is liable occasionally to be followed by a ventral hernia at the lower end of the scar.

Another form of treatment, termed the *intra-peritoneal* method, although involving more immediate risk to life, avoids the disadvantages above alluded to, and may sometimes be adopted successfully in suitable cases. In this operation, the uterine appendages having first been tied off, the body of the uterus is constricted by an elastic ligature, and the tumour is cut away. An antero-posterior wedge-shaped piece is now excised from the uterine stump, and any portion of mucous membrane remaining on the inner surface of the two flaps of uterine tissue thus formed is carefully dissected off down to the level of the constricting ligature. The opening of the cervical canal, after being thoroughly cleansed by the use of a strong solution of carbolic acid (1 in 10), is then accurately closed by a few points of suture including mucous membrane alone; these are to be cut short. The trunk of each uterine artery is next secured by means of a ligature passed from behind forwards through the base of each uterine flap, and thence returned through the corresponding broad ligament to be tied at its original point of entry. The two flaps of uterine tissue, having been thoroughly cleansed, are then united face to face by successive rows of buried sutures until the stump is completely closed in, a final series of stitches being employed to accurately unite the divided edges of its peritoneal investment. The elastic ligature is now removed, and if no oozing be seen, the stump is dropped in, and the abdomen closed in the usual way.

The *submucous* variety of fibro-myoma, when occurring as a single growth of a more or less sessile character projecting into and dilating the uterine cavity, may occasionally necessitate surgical interference in consequence of alarming and persistent hæmorrhage which has proved totally unamenable to ordinary gynæcological treatment. Unless the cervix be expanded over the

protruding mass, preliminary dilatation of the cervical canal may advantageously be effected by the insertion of a sponge tent 12 hours previous to operation. This should remain *in situ* until the patient is placed on the operation table in the lithotomy position after having been anaesthetized. A free incision through the capsule of the presenting portion of the growth will then enable the operator to shell it out by a gradual process of enucleation, while firm suprapubic pressure is maintained by the hand of an assistant, in order to facilitate the extraction. This operation, often an extremely difficult and tedious one to perform if the growth is of large size, necessitating extraction piecemeal, is to be undertaken only for the relief of the most urgent symptoms in exceptional cases, since all submucous growths have a natural tendency to become polypoid in character, and thereby more easily removable.

The ordinary **fibroid polypus** is met with usually as an oval or pear-shaped growth attached to the posterior aspect or fundus of the uterine cavity by a more or less distinct pedicle. Such growths not uncommonly give rise to repeated and dangerous hæmorrhage, often altogether disproportionate to their size. The most efficient mode of treatment consists in removal by means of a wire écraseur, of which the loop is slipped over the polyp and then gradually tightened until division of the pedicle is effected. Unless the growth be protruding through the cervix, preliminary dilatation of this canal will be required in order to permit of the necessary manipulations.

Two other varieties of uterine polypi are met with, viz., the **glandular** and the **cellular polypus**. These grow from the cervix or its immediate neighbourhood, and their removal by simple torsion commonly offers no difficulty. It is an important rule, after all operations involving the cervical canal or the uterine cavity, to apply a strong solution of iodine freely to the interior of the womb, as the surest means of avoiding the risk of the subsequent development of any septic mischief.

**Malignant Disease** of the Uterus may develop in any one of the three following forms, viz., as Columnar Carcinoma; as Squamous Carcinoma; and much more rarely as Sarcoma.

**Columnar Carcinoma**, the most common form of malignant growth in this situation, is occasionally met with as a primary affection of the body of the uterus in women over fifty years of age. The disease, originating in the epithelium of the uterine glands, begins either as localized nodules in the substance of the uterine wall, or as a diffused fungating growth of the mucous membrane lining the cavity. The usual *symptoms* are pain, watery discharge, and hæmorrhage, the latter sign being most marked in cases of fungating disease. The uterine cavity is somewhat enlarged, and the os appears patulous on inspection; but the cervical tissues generally remain normal to sight and touch. The only radical *treatment* consists in vaginal extirpation of the entire uterus; but, in cases of fungating cancer in feeble women, removal of the intra-uterine growths with a curette will tend to prolong life by checking the hæmorrhage.

The more usual seat of origin of columnar carcinoma is in the *cervical* tissues where it may develop at any age between twenty and fifty-five. The disease commonly commences as a nodular growth in the wall of the cervix, thence tending to spread upwards into the body of the uterus, as well as both outwards and downwards, thus speedily involving the tissue of the

broad ligaments and the vesico-vaginal and recto-vaginal septa with consequent early impairment of the natural mobility of the uterus. In course of time the pelvic viscera become completely fixed and surrounded by the new growth, in which the occurrence of ulcerative changes gradually causes destruction of the cervix and other tissues implicated, occasionally leading to the formation of vesical or rectal fistulæ. Finally, general constitutional cachexia ensues, and the patient dies from exhaustion. The earliest *symptom* of cancer of the cervix, as in fact of any form of the disease in connexion with the uterus, is hæmorrhage, either exceeding the natural loss; or recurring irregularly. Pain is by no means a constant symptom, and is usually absent so long as the growth is limited to the cervix. In the advanced stages of the disease, pain may occasionally be very severe, necessitating the habitual use of anodynes. Profuse watery discharges accompanied by fœtor indicate ulcerative changes in the affected parts.

**Treatment** in advanced cases must necessarily be of a purely palliative nature; the chief indications being to control hæmorrhage, relieve pain, and to sustain the patient's strength.

In the earlier stages of the affection, attempts were formerly made to arrest its progress by excision or amputation of the cervix, followed by application of the cauter. Such methods can be of but little use in retarding the progress of the disease, although they may prove beneficial as a means of checking hæmorrhage and discharges in cases too advanced for the adoption of more radical measures. In suitable instances, *i.e.*, when the mobility of the uterus is still unimpaired, and no trace of deposit is to be detected in the adjoining tissues, recourse should be had without delay to one or other of the following operations, *viz.*, *supra-vaginal excision* of the cervix, or *complete extirpation* of the uterus.

The former of these consists in the removal not only of the entire cervix, but also of such portion of the uterine tissues above the level of the internal os as may be found implicated by the upward extension of the cervical disease. In this manner almost the entire organ may be excised, leaving merely a shell of the uterine wall with its serous covering intact. The earlier steps of the procedure are the same as those required in the operation for complete extirpation of the uterus; which may, therefore, be at once resorted to should such a course appear desirable. For a full description of the details of both these operations, the reader should consult the works of special writers on this subject, where statistics may be found, showing the relative mortality of the two procedures, and also the degree of protection against recurrence afforded by each one of them.

**Squamous Carcinoma** of the cervix differs essentially from the far more common *glandular* form of cancer above described, inasmuch as it begins as a *surface* growth and usually remains for a long time superficial without involving the deeper tissues. The disease originates in the stratified epithelium investing the *vaginal portion* of the cervix, or in the transitional cells immediately within the external os uteri; and tends to spread outwards and downwards on to the vaginal wall. When typically developed, it constitutes an irregular papillomatous growth—known as a *Cauliflower excrescence*—which bleeds readily on being touched. While still limited to the vaginal portion of the cervix, the disease may be eradicated by the operation above referred to as *supra-vaginal excision* of the neck of the womb; but if once the broad ligaments have been

invaded through extension of the growth to the vaginal vault, no radical interference can be undertaken, and the affection proves rapidly fatal.

**Sarcoma** is a comparatively rare disease of the *body* of the uterus. It is met with in middle-aged women, either as a diffused affection of the mucous lining of the cavity, or as circumscribed growths in the substance of the uterine wall—in either case tending to form compound polypoidal masses of greyish-white colour and pulpy consistence. The prognosis is always unfavourable, although the course of the disease is less rapid than that of true cancer. The removal of the intra-uterine growths after dilatation of the cervix, whether undertaken for diagnostic purposes or as a palliative method of treatment, should be followed by the application of strong iodine solution to the interior of the cavity. The only radical measure to be adopted in these cases is that of total extirpation of the uterus.

#### TUMOURS OF THE OVARY.

For clinical purposes, ovarian tumours may be broadly classed in two main groups. The first of these—including those growths in which cyst-development predominates—can be subdivided as follows: 1. Ordinary multilocular ovarian cysts, containing glairy fluid of a highly albuminous nature; 2. Multilocular cysts, with colloid (jelly-like) contents; 3. Dermoid cysts, containing sebaceous and fatty material, with hair growing from patches of true skin, bony plates, teeth, &c.; 4. Papillomatous cysts filled with thin, watery, non-albuminous fluid, and showing more or less extensive patches of warty growth (papilloma) on the inner surface of the cyst wall. The second group above referred to, consisting of the solid tumours, includes—1. Fibroma; 2. Sarcoma; 3. Carcinoma.

Of the growths here enumerated, those included in the first group constitute the large majority of ovarian tumours, the ordinary multilocular cyst being by far the most common form; the three next-named varieties occur much less frequently. The solid growths, named in the second group, are comparatively rare.

Tumours of the ovary may develop at almost any age, being occasionally met with in quite young children, and not very uncommonly in women who have long passed the menopause; but the largest proportion of cases occur between the ages of twenty and fifty. One or both ovaries may be affected.

If uninterfered with, the disease invariably proves fatal after a shorter or longer interval, usually within two or three years from the first development of an abdominal tumour, death occurring from gradual exhaustion due to interference with the functions of neighbouring viscera. But, in the great majority of instances, an earlier fatal termination is liable to result from some intercurrent complication or accident—such as rotation of the pedicle, inflammation of the cyst, rupture of its wall, &c., conditions which unless promptly dealt with, must inevitably hasten the patient's death.

**Diagnosis.**—The differential diagnosis of ovarian tumours from the numerous abdominal enlargements which may simulate them, is too extensive a subject to be treated of here. The following may, however, be enumerated as conditions possibly requiring elimination before a definite diagnosis of ovarian disease can be arrived at: 1. Obesity, oedema of the abdominal wall, tonic spasm of the recti muscles with hysterical tympanites (phantom tumour).

2. Stercoraceous accumulation, distended urinary bladder, retained menstrual fluid, distended gall-bladder. 3. Tumour of liver, spleen, or kidney, sarcoma of the abdominal glands. 4. Pelvic hæmatocele, abdominal or pelvic abscess. 5. Normal pregnancy, hydramnios, extra-uterine pregnancy, uterine fibromyoma, uterine fibro-cyst, hydro- or pyo-salpinx. 6. Hydro-nephrosis, hydatid cysts, pancreatic cysts, parovarian cysts. 7. Simple ascites, encysted dropsy of peritoneum, tuberculous disease, peritoneal cancer with ascitic fluid. The conditions enumerated in the last three of these groups are perhaps the most likely to mislead in forming an opinion.

In all cases of abdominal tumour, the patient should be examined undressed and lying upon her back with the shoulders somewhat raised and the knees drawn up. After carefully noting the salient points in the history of the case, such as the duration and rate of growth of the enlargement, its apparent seat of origin, the past and present condition of the menstrual function, &c., the Surgeon should proceed to determine the nature of the tumour by the systematic employment of the following means:—1. *Inspection*: Condition of the abdominal wall; amount of distension; shape and contour of the swelling, whether symmetrical or not, prominent anteriorly, or bulging laterally; extent of downward movement visible on deep inspiration. 2. *Percussion*: Position and extent of resonance, whether strictly limited or diffused, altered or not by change of position on the part of the patient; presence and nature of fluctuation, whether limited (encysted fluid), or general (free fluid). 3. *Palpation*: Size, outline, and consistence of the tumour; its relative mobility; solid or with fluid contents; presence of nodular outgrowths. 4. *Auscultation*: Presence of the foetal heart in case of suspected pregnancy; uterine souffle. 5. By *Vaginal* or *Rectal* examination combined with abdominal palpation it may be determined whether the tumour have a pelvic connexion or not; and if so, whether it be uterine, tubal, or ovarian.

Tapping or aspiration of a fluctuant abdominal tumour of doubtful origin is occasionally resorted to with a view to ascertain its nature by examination of the fluid withdrawn; and of late years an exploratory incision has been recommended in obscure cases as a more definite means of clearing up the diagnosis. This last procedure, although comparatively safe if performed with all due precautions, should by no means be rashly undertaken; but if practised, the operator must be prepared at once to proceed to the removal of the tumour, should such a step be found advisable.

**Treatment of Ovarian Tumour.**—1. *By Medical Means.* These cannot possibly exercise any curative influence, or in any way retard the progress of the disease. The utmost that can be done by medical treatment in advanced ovarian disease is to attend to the general health, by relieving constipation and promoting free action of the kidneys pending the removal of the tumour.

2. *Tapping* in ovarian dropsy was formerly recommended as a palliative mode of treatment; but experience has shown that after withdrawal of the fluid from a true ovarian cyst, re-accumulation invariably takes place, necessitating more and more frequent repetition of the tapping, if the treatment be persisted in, until the patient finally dies exhausted. The operation, therefore, not only holds out no prospect of cure; but as a matter of fact, its adoption is usually the precursor of a more rapidly fatal termination to the case than would otherwise occur. For, in addition to the more immediate

risks attendant upon the procedure—such as wound of a vessel in the abdominal wall, in the subjacent omentum, or in the cyst-wall itself ; puncture of adherent intestine or urinary bladder ; escape of irritating ovarian fluid into the peritoneal cavity, &c.—tapping entails also certain remote dangers which render its adoption of very questionable advantage to the patient, even when undertaken as a means of temporary relief. Foremost among these may be mentioned adhesive peritonitis, inflammation of the cyst-wall, suppuration of its contents—conditions which must very seriously complicate any future attempt to extirpate the tumour. Even though none of these untoward events should result, yet the operation, unless performed with the strictest antiseptic precautions, is always liable to induce septic contamination of the cyst-fluids, a state of things which, although not necessarily leading to any obvious trouble at the time, will surely tend to diminish the patient's chance of recovery from a subsequent ovariectomy by exposing her to the risk of septicaemia. Finally, the puncture in the cyst-wall may from some cause or other remain unsealed, thus allowing free escape of ovarian fluid into the peritoneal cavity with all its attendant dangers, among which not the least is that of malignant infection of the peritoneum from a protruding papillomatous growth.

The above enumeration of the dangers incurred through tapping ovarian cysts is in accordance with the experience of those Surgeons who have had the fullest opportunities of judging of the results of this operation ; and it is not too much to say that the procedure is one to which recourse should be had only when it is rendered justifiable by exceptional circumstances.

As a means of relieving urgent dyspnoea, tapping is clearly applicable only to unilocular cysts, or to those multilocular tumours in which one cyst cavity largely predominates in size over its neighbours. When imperatively called for with this view, the operation should invariably be performed with antiseptic precautions, in order to obviate the risks of septic infection of the cyst-contents. The puncture may be made through the linea alba, as in the case of ordinary ascites ; but not unfrequently the tumour presents more distinctly at some other part of the abdominal wall, and the point selected may be varied accordingly, care being taken always to choose a spot free from intestinal resonance, and sufficiently remote from the pubes to avoid any possibility of puncturing the bladder which may be drawn up in front of the tumour.

**Incision and Drainage** is a method of treatment occasionally applicable with advantage in exceptional cases of universally adherent suppurating cysts, when attempted extirpation of the tumour would entail extreme risk to life, owing to the probability of rupture of the cyst-wall during its removal—as accident most likely to prove fatal, as involving the escape of irritating septic matter into the peritoneal cavity. The operation in such instances involves a short incision in the usual situation, of sufficient extent to enable the Surgeon to judge of the closeness of the parietal adhesions, and by puncture of the cyst to determine the putrid nature of its contents. After thorough evacuation and sponging-out of the cyst cavity a drainage-tube should be inserted, and the incision closed around it by means of sutures connecting the cyst with the margins of the opening in the abdominal wall. The subsequent management of the case involves frequent withdrawal of fluid from the tube by means of a

suitable syringe, and the use of some efficient antiseptic to prevent putrefaction of the discharges. Under this treatment, the cyst-cavity rapidly contracts, and may finally close entirely.

**Other means** of dealing with ovarian cysts have from time to time been suggested, all aiming at the same object, viz. that of inducing gradual contraction of the cyst and cohesion of its walls. But of the procedures advocated, the above described is the only one to be at all recommended, and this only in the exceptional instances alluded to. No operation, however, short of complete extirpation can be looked upon as surely curative; since, even after incision and drainage, followed apparently by complete contraction, it not uncommonly happens that secondary cysts develop in the wall or base of the original tumour; and eventually a multilocular growth may be substituted for what was apparently in the first instance a unilocular cyst. These measures have consequently, wherever possible, given way to the safer and far more certain procedure of ovariectomy.

**Ovariectomy** is probably the greatest triumph of modern Operative Surgery. In its original conception, as in its ultimate perfection, this operation reflects the greatest lustre on the British School of Surgery.

Its history is curious. Its progress was slow, and was marked by those oscillations in the judgment and the favour of the Profession which frequently precede the final establishment of a great advance in practice. The operation was originally proposed, and its practicability discussed in 1762, by William Hunter. It was strongly advocated and its practicability taught by John Bell, at a later period. It is said to have been performed in France, by L'Annonier, in 1782, in a case of "scirrhus disease with abscess" of the ovary, the patient recovering. A pupil of John Bell—McDowell of Kentucky—first performed the operation in America in 1802; and in all operated thirteen times. In 1823, Lizars operated for the first time in this country. But the operation, though several times repeated, fell into discredit, in a great measure owing to the imperfection of the diagnosis of the cases in which it was done, and was not revived until 1836, when Jeaffreson of Framlingham practised it successfully through a small incision only an inch and a half long. From this operation we must date the revival of ovariectomy in Great Britain. This operation was followed by others performed by King of Saxmundham, Crisp of Harleston, and West of Tonbridge. The example of these provincial Surgeons was followed by their brethren in London, and the operation was practised by many, especially by Walne, F. Bird, and Baker Brown, but with very discouraging results; for of 162 cases collected by Robert Lee, in 60 the disease could not be removed, and of these 19 died; whilst of the remaining 102, 42 terminated fatally. Not only did these unfavourable results discourage the Profession, but a growing belief sprang up that this mortality, great as it was, did not by any means represent the whole extent of the fatal cases; and notwithstanding that C. Clay of Manchester continued to operate, ovariectomy was in great danger of falling into such disrepute as to be excluded from ordinary surgical practice. In 1857 appears for the first time in connexion with ovariectomy the name of a Surgeon, who was destined not only to revive ovariectomy, but to re-establish it firmly and definitively amongst the great operations in Surgery; for in December of that year Spencer Wells performed his first operation of this kind. This case, the first of a series of 1,000 cases completed by him in the year 1881,

led to a revival of the operation. In Spencer Wells's hands, ovariectomy assumed a new shape; its performance was guided by definite rules, the operative details were carefully worked out and systematized, and the after-treatment much improved. The results obtained showed a gradually increasing success, the proportion of recoveries rising from 66 to 89 per cent. in the cases operated on between 1857 and 1881. These results, admirable as they are, have been still further improved upon during late years by other well-known workers in this field of Surgery; and the procedure, formerly so fatal as to be pronounced unjustifiable, is now the most successful of all great surgical operations.

The wonderful improvement shown of late years in the death-rate of ovariectomy is in great measure to be explained by the very notable reduction in the number of deaths now recorded from septicæmia, a cause of mortality which formerly figured so largely in ovariectomy statistics.

The attainment of this result, apart from the employment of antiseptics which have so greatly influenced the progress of all surgical work during the past twenty years, is attributable to several causes, among which may be noted: 1. The gradual abandonment of the former practice of tapping ovarian cysts; 2. The general adoption of the intra-peritoneal method of dealing with the ovarian pedicle, in place of the extra-peritoneal treatment by means of the clamp, which was formerly used to a large extent; 3. The introduction of the plan of flushing out the abdominal cavity with warm sterilized water, as a substitute for the practice of cleansing the peritoneum by the use of sponges, followed or not by the employment of a drainage-tube.

In the days when the results of ovariectomy were much less good than they now are, the opinion generally held was in favour of postponing any surgical interference so long as the patient was tolerably free from pain and able to move about. Of late years, however, the increasing success of the operation, together with the fuller recognition of the serious risks entailed by delay in such cases, has led to the belief that an ovarian tumour should be removed as soon as its nature and connexions can be clearly ascertained, and its presence is beginning in any way to affect the patient's well-being.

**Preparation of the Patient.**—No special medical treatment is as a rule necessary, beyond attending to the state of the bowels. In the case, however, of a very large tumour of long standing, when the urine is scanty and highly concentrated, depositing quantities of mixed urates, benefit will be derived from the administration of full doses of citrate of potash or lithia during the forty-eight hours preceding operation, combined with the employment of a hot bath, should the skin be habitually dry and disinclined to act. Finally, a full dose of castor-oil or some equivalent aperient should be given the evening before, to be followed by an enema administered on the morning of the operation, to ensure thorough evacuation of the lower bowel.

The room selected for the operation and for subsequent occupation by the patient, must be thoroughly clean, airy, and well ventilated, if possible with an open fireplace. A trustworthy and competent nurse, accustomed to the use of the female catheter, and to the giving of nutrient enemata, should be chosen to take sole charge of the case; she, as well as all concerned in the operation, ought to be completely free from any taint of recent septic contamination.

All sponges and instruments, previously well cleansed, must be immersed in

a warm  $2\frac{1}{2}$  per cent. solution of carbolic acid, and placed within easy reach of the operator's hand. The silk employed for ligatures, sutures, &c., should be thoroughly purified by soaking in a 5 per cent. solution of the acid for an hour or two before being used. It is an important rule, for obvious reasons, carefully to count the sponges and artery-forceps in use immediately before commencing the operation, so as to prevent the possibility of any subsequent doubt as to their number.

After the bladder has been emptied by means of a catheter, the patient in her night-dress and wearing a flannel bed-jacket and warm stockings, is placed upon the operating-table with her head and shoulders comfortably

Fig. 963.—Scissors for use in Abdominal Operations.

supported by pillows. Anæsthesia having been induced, the lower limbs wrapped in a blanket are secured by a broad strap buckled across just above the knees, while her hands are fastened on either side of the table. A thin mackintosh sheet, large enough to cover the patient entirely from the shoulders downwards, and having an opening in the centre four inches by six, coated around with adhesive material, is next applied to the abdomen, of which the skin, previously well cleansed with soap and water, should be sponged over with carbolic lotion before commencing the operation. The Surgeon, standing

Fig. 964.—Ovariectomy Trochar.

on the right side of the patient, is faced by his assistant on the opposite side of the table.

**Operation.**—No definite rule can be laid down as to the length of the incision, beyond stating that while necessarily proportionate to the size and nature of the tumour, it should in all cases be as limited as possible. A small cut, two or three inches long, extending in the mid-line to within an inch of the pubes, will suffice for the removal of any simple cyst; and, if necessary, may readily be prolonged upwards. All hæmorrhage from bleeding points in the abdominal wall having been arrested by the application of Wells's pressure-forceps, the peritoneum must be divided, care being taken to open it fairly; for, if adherent, it may readily be mistaken for the cyst-wall, and so stripped off the under surface of the abdominal muscles.

On exposing the tumour, any soft parietal adhesions in the immediate neighbourhood of the incision may be separated by the Surgeon's finger. The

growth, if cystic, should then be tapped with Wells's trochar (Fig. 964), care being taken to prevent the escape of any fluid into the abdominal cavity by fixing the edges of the puncture with the trochar-clamps, which enable the operator to extract the gradually collapsing cyst. Should this prove impracticable owing to the multilocular nature of the growth, the trochar must be

Fig. 965. — Nélaton's Cyst-Forceps.

carefully withdrawn after applying Nélaton's forceps (Fig. 965), and the puncture in the cyst-wall sufficiently enlarged to permit of the Surgeon introducing his hand for the purpose of breaking down the contents of the tumour. If still unable to extract it, he must prolong his incision upwards, and care-

Fig. 966.

Fig. 967.

Figs. 966, 967, 968. — Various shaped Pressure-Forceps.

fully separate any parietal, omental, or intestinal adhesions which may be present, applying pressure-forceps (Figs. 966, 967, 968) as required to all bleeding points. Immediately after the extraction of the tumour, a dry sponge, squeezed thoroughly dry, should be introduced for the purpose of protecting the intestines and preventing their protrusion.

The pedicle is now examined and its connexion with the uterus clearly defined. As a rule it is most convenient to tie it before cutting away the tumour ; but, if desirable, it may be temporarily secured with strong pressure-forceps during division, and then dealt with subsequently. Either of the two methods here represented may be employed for this purpose. That shown in Fig. 969 is the one most generally adopted. A single thread is first passed at a point just internal to the large plexus of veins in the outer edge of the pedicle, and securely tied so as to include the plexus, together with the ovarian artery which lies along this border ; the pedicle is next transfixed centrally with a double ligature passed by means of the handled needle (Fig. 971), and is tied in equal halves, care being taken that the loops interlace at the seat of puncture. In the other method—shown in Fig. 970—the separate outer-edge ligature is usually dispensed with. The pedicle is transfixed as before, but with a needle carrying only a single thread, doubled upon itself ; after withdrawal of the needle, one end of the ligature is brought half round the pedicle, passed through the projecting loop on the side opposite to its own point of exit, and thence carried onward to unite with the remaining end of the ligature round the other half of the pedicle, which is thus secured by a continuous twisted loop. Pressure-forceps are then applied to either border on the distal side of the ligatures, and the tumour is cut away. Finally, a single loop of stout silk is tied firmly round the stump, either exactly in or immediately behind the groove formed by the previous ligatures. All the threads should be cut short, and the pedicle be returned, without, however, removing the

Fig. 969.—Ligature of the Ovarian Pedicle (double loop).

Fig. 970.—Ligature of the Ovarian Pedicle (twisted loop).

Fig. 971.—Curved Pedicle-needle.

pressure-forceps, which are left on in order to facilitate the final examination of the stump before closing.

The condition of the remaining ovary should next be ascertained ; and if diseased, it should be removed.

In dealing with tumours the base of which is implanted between the

expanded layers of the corresponding broad ligament—*intra-ligamentous* growths, so called in contradistinction to cysts connected with the uterus by a well-defined pedicle—resort must be had to the procedure known as *enucleation*. The tumour having been tapped and emptied, the investing layer of peritoneum is cautiously incised, and then gradually separated inch by inch from the base of the collapsed cyst until the main blood supply derived through the ovarian and uterine vessels is reached and clearly defined. These are now secured *en masse* by a double-loop transfixing ligature in the manner above described, and the cyst is cut away: any bleeding vessels on the inner surface of the remaining broad-ligament capsule are then tied, and its opposed surfaces are allowed to fall together at the bottom of the pelvis.

Parietal adhesions, unless of long standing, do not as a rule require ligature. temporary compression by forceps usually sufficing for the arrest of hæmorrhage. Should there, however, be general oozing from a somewhat extensive surface, the application of a sponge moistened with tincture of matico will serve readily to control it. Bands of pelvic adhesions must always be tied as near as possible to their seat of origin, and cut short. Omental and intestinal adhesions need careful management; the former should be dealt with either by transfixion and tying off in sections, or else by separate ligature of bleeding vessels; the latter, if extensive, may require to be laced by a fine continuous suture involving only the peritoneal coat of the intestine.

After all hæmorrhage has been controlled, a small soft sponge should be passed down to the bottom of the pelvis behind and also in front of the uterus for the purpose of removing any fluid or blood-clot that may remain in either one of these pouches. The pedicle is then finally examined to make certain that all is left secure; the forceps holding it are removed, and it is dropped in.

In cases of *ruptured cyst*, or where numerous and extensive vascular adhesions have been separated, the peritoneal sac may advantageously be flushed out with warm water, previously sterilized by boiling, introduced through a metal or stout glass tube directly to the more dependent portions of the abdominal cavity. This method of cleansing is far less irritating to the serous membrane than prolonged sponging; and, if thoroughly carried out, it effectually removes all blood-clot. The subsequent use of a drainage-tube is by no means essential, as any moderate amount of fluid left in the cavity is readily absorbed in the course of a few hours, and passed off through the kidneys.

The best material for suturing the abdominal incision is silk-worm gut, passed through the entire thickness of the parietes, including, of course, the divided edges of the peritoneum, at intervals of about half an inch. During the introduction of the stitches, the abdominal contents are to be protected by means of a small flat sponge.

Before closing the incision, all sponges and forceps are to be carefully counted, in order to make sure that none are missing.

Should drainage be deemed advisable, a glass tube of the required length is introduced to the bottom of Douglas's pouch from the lower end of the abdominal incision. The mouth of the tube is then covered with one or more well-carbolized sponges, enveloped in a rubber sheet with a perforation in its centre which fits closely around the everted lip of the tube (Fig. 972).

Finally, a dry antiseptic dressing is applied and kept in place by broad straps of adhesive plaster, over which a flannel binder is fastened securely round the patient's abdomen before placing her in bed.

*After-Treatment.*—Should sickness be troublesome, nothing need be given by the mouth for the first twenty-four or thirty-six hours beyond a little ice, plain soda-water, or brandy-and-water ; after which milk-and-water may be tried, to be succeeded, if retained, by plain bread-and-milk. In the meantime nutrient enemata of beef-tea with or without the addition of a tablespoonful of port wine, administered every three or four hours, will probably be of service ; the nurse being directed to introduce a rectal tube before each enema in order to facilitate the escape of flatus. The urine should be drawn off by the catheter four times daily for the first few days, or until the patient is able to pass it naturally. In a *drainage* case, renewal of the sponges, and withdrawal of fluid from the tube by means of a syringe with rubber tubing

Fig. 972.—Glass drainage-tube.

fitted to its nozzle, should be practised twice in each twenty-four hours until the tube is removed—usually at the end of the first forty-eight hours, when the opening left by it will readily close. If all be going well, ordinary light diet, such as milk-pudding, fish or chicken, may be allowed on the third or fourth day. Should there be much fever at any time, the application of an ice bladder to the head will soothe and tranquillize the patient, and promote reduction of the temperature. As a rule the bowels may be left undisturbed until they show some inclination to act, when they may be assisted by an enema. Finally, the stitches should be removed on the seventh or eighth day, and the patient may be allowed to leave her bed at the end of the second week, wearing a suitable abdominal belt.

After recovery from ovariectomy, the cure is usually complete.

The removal of one, or possibly of both, uterine appendages may, in exceptional instances of long-standing pelvic inflammatory troubles, justifiably be undertaken for the relief of persistent suffering associated with tangible disease of these organs. In such cases, the operation may prove to be of an exceedingly difficult and tedious nature, owing to the density and firmness of the adhesions in the pelvic cavity ; apart from this, however, the steps of the procedure required, and the details of the after-treatment, resemble in all essential features those above described in connexion with ovariectomy.

**Pelvic suppuration** may be broadly divided, according to its seat of origin, into *parametric* (subserous) and *perimetric* (intraperitoneal) formations of pus.

A **parametric** abscess usually originates in the substance of an inflammatory exudation developed between the folds of one or other broad ligament (pelvic cellulitis), or in a mass of hæmorrhagic effusion in the same situation (pelvic hæmatocele). If allowed to accumulate, the pus may find its way into the adjacent bowel or the urinary bladder ; or, extending downwards, it may effect its escape through the vaginal vault ; or, failing this, it may spread upwards towards the iliac fossa, ultimately pointing in the inguinal region or even over the iliac crest. Perforation of the abscess sac into the peritoneal cavity is an extremely rare accident. The proper *surgical treatment* of parametric suppura-

tion—as indicated by the occurrence of repeated chills combined with a characteristic temperature chart—depends upon the direction in which the abscess is pointing. If a distinct fluctuating swelling be detected in the *vaginal vault*, an exploratory puncture with a full-sized aspirator needle may be made in it after thorough cleansing and disinfection of the vagina; should the pus be readily reached, the abscess sac is to be opened with scissors or the cautery knife to an extent sufficient to allow of the introduction of a double self-retaining rubber tube, through which irrigation can subsequently be practised, in order to ensure efficient drainage of the cavity. A parametric abscess rising into the *groin* should be opened by an incision parallel to, and about half an inch above, Poupart's ligament, so as to avoid injury to the peritoneum; the cavity should be drained with antiseptic precautions.

A **perimetric** abscess is an encysted *intraperitoneal* collection of pus originating in connexion with suppurative (septic, or more rarely tuberculous) disease of one or both uterine appendages. The gradual formation of the abscess, due to repeated escape of small quantities of puriform matter from the imperfectly sealed ostium of an inflamed Fallopian tube (pyosalpinx), or to the presence of a small suppurating ovarian or tubo-ovarian cyst, accounts for the matting together of the pelvic viscera, which usually protects the general peritoneal cavity from infection. The proper *treatment* for such cases is *abdominal section*, in the performance of which great care must be taken at once to sponge away any purulent fluid which may be set free during the separation of pelvic adhesions. The diseased appendage should be cautiously enucleated from its pelvic attachments—if possible without being ruptured—until its uterine connexion can be defined, and ligatured previously to division. If the case be complicated by the existence of a rectal or vesical fistula, the subsequent use of a drainage-tube may be advisable for a few days.

Operations for the arrest of hæmorrhage in cases of **Ruptured Tubal Gestation**, by the removal of the damaged tube and ovary, usually present no special difficulty. After the broad ligament has been secured, the peritoneal cavity should be cleared of blood and clots by a thorough flushing out with a warm solution of common salt (1 drachm to the pint), and a drainage-tube be then inserted and retained for forty-eight hours.

**Hernia of the Ovary.**—It may happen that the ovary, on one or both sides, becomes displaced, and escapes from the pelvis through one of the openings which give passage to intestinal hernia. In three-fourths of the recorded cases (twenty-seven out of thirty-eight, according to English of Vienna) the displacement has been inguinal. In nearly one-half of the cases it was congenital; all these were instances of inguinal displacement; and all the instances of double ovarian hernia were inguinal and congenital.

The *Causes* of the displacement in the adult are not easily ascertained. In the congenital cases it would seem as if an abnormal descent of the ovary took place, analogous to the descent of the testis in the male.

*Symptoms.*—Congenital ovarian hernia is nearly always irreducible; while in most cases of acquired displacement of the ovary, it has been possible to return the tumour into the abdomen. The swelling is generally pyriform in the inguinal region, rounder in the femoral. There is no constant diagnostic symptom; but in several instances it has been noticed that the hernia became more tender on pressure, and larger during menstruation. At this time, also, inflammation of the ovary may take place; and, being attended with vomiting,

may lead the Surgeon to imagine that the case is one of strangulated hernia.

Strangulation of a hernia containing only the ovary is of rare occurrence. The condition has already been mentioned at page 838, where it was pointed out that the diagnosis may be difficult on account of the absence of the characteristic constitutional symptoms of strangulation. Thus, although there may be nausea, there is usually no actual vomiting, and although constipation is probably present, there is no real obstruction. Englisch showed that, of 20 cases in which symptoms of strangulation were present, a correct diagnosis was made in 7 only. Abscess or sloughing of the displaced ovary occasionally occurs.

In a case recently under the care of Bilton Pollard in University College Hospital, the end of the Fallopian tube was strangulated in a femoral hernia. The patient was thirty-seven years of age, and a swelling had been accidentally discovered in the left groin four days before her admission. On the following day the swelling became painful; the bowels continued to act; there was slight nausea, but no actual vomiting. The hernia was tense, rounded, and as large as a walnut. The sac contained clear fluid, and the swollen fimbriated extremity of the Fallopian tube, which was tightly nipped at the neck of the sac. The constriction was divided, and the tube returned into the abdomen.

*Treatment.*—So long as the hernia presents no special symptoms there is little or no occasion for interference, beyond the wearing of a properly fitted truss. If inflammation occur, the case must be treated on ordinary principles; and if the ovary suppurate, the abscess should be opened. When the ovary is very painful, or has become cystic, extirpation may be practised. If symptoms of acute strangulation occur, herniotomy must be performed, and as a rule removal of the ovary will be found necessary.
